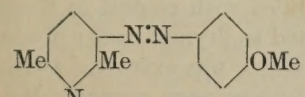
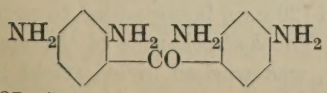
CC.—*Synthetical Experiments in the Naphthyridine Groups.*

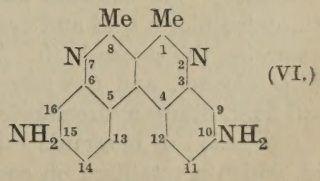
By JOHN MASSON GULLAND and ROBERT ROBINSON.



THE sodamide method of Tschitschibabin (*J. Russ. Phys. Chem. Soc.*, 1914, **46**, 1216; 1915, **47**, 835) has rendered many α- and γ-aminopyridine derivatives readily accessible, but it is still difficult to obtain β-aminopyridines in quantity. We have utilised the fact that 2 : 6-dimethylcinchomeronic acid is easily prepared (Mumm and Hüneke, *Ber.*, 1917, **50**, 1568) in devising a method of preparation of 3-amino-2 : 6-lutidine (III). 2 : 6-Dimethylcinchomeronimide (I), obtained from the acid by heating with carbamide (compare Herzog, *Z. angew. Chem.*, 1919, **32**, 301; Lawson, Perkin, and Robinson, J., 1924, **125**, 634), is converted by potassium hypobromite and potassium hydroxide into a salt of 3-amino-2 : 6-dimethyl*iso*nicotinic acid (II). This acid yields the aminolutidine on distillation with soda-lime. The product is quite different



(I.)



(II.)

(III.)

from 4-amino-2 : 6-lutidine (Marckwald, *Ber.*, 1894, **27**, 1325), and this fact establishes the constitution of the new base. We have made many fruitless attempts to convert this aminolutidine into 1 : 7-naphthyridine derivatives, for example, by condensation with acetylacetone and by application of the Doebner-Miller synthesis. The reactivity of the nucleus appears to be feeble. The diazonium salt derived normally from the base couples with phenol with formation of lutidineazophenol, the *O*-methyl ether (IV) of which was examined by the method of Jacobson for the semidine transformation on reduction. No evidence of this was obtained, and as regards the benzidine transformation, Friedl (*Monatsh.*, 1913, **34**, 765) has prepared 3-hydrazopyridine, but makes no mention of a molecular rearrangement of this substance. Intramolecular changes of these types are clearly not facile in the pyridine series.

(IV.) 

(V.) 

(VI.)

610263

The copyrine synthesis from derivatives of *oo*-diaminobenzophenone and 1 : 3-diketones described by Lawson, Perkin, and Robinson (*loc. cit.*) involves a very satisfactory reaction from the point of view of yield and convenience, but the number of available diaminobenzophenones is limited. We have now obtained 2 : 4 : 2′ : 4′-*tetra-aminobenzophenone* (V), and from it, by condensation with acetylacetone, a *diaminodimethyldibenzocopyrine* (VI).

Further brief indications of synthetical schemes will be found in the experimental section.

Experimental.

2 : 6-*Dimethylcinchomeronimide* (I).—In the preparation of 2 : 6-dimethylcinchomeronic acid (Mumm and Hüneke, *loc. cit.*) the isolation of the ester was found to be unnecessary. The product of the condensation of ethyl acetylpyruvate (83 g.) with ethyl β-aminocrotonate (69·3 g.) in ether (40 c.c.) was, after 15 hours, hydrolysed with potassium hydroxide (25 g.) dissolved in 70% alcohol (150 c.c.). Following steam distillation, the liquid was acidified with respect to Congo-red, and sodium acetate added to neutralise the mineral acid. The acid, m. p. 274° (pure 275°), crystallised from the solution in quantitative yield. The conversion into the *imide* by heating the ammonium salt at 230°, as described by Mumm and Hüneke, is troublesome, and the following process is far more convenient. The acid (10 g.) and carbamide (5 g.) were heated together with stirring at 225° until ammonia was no longer evolved (about 5 minutes), then at 230° for a few moments, and the mass was cooled and extracted with alcohol. The substance, m. p. 230° (Mumm and Hüneke give m. p. 230°), crystallises from the solution in yellow needles (yield 81%).

3-*Amino*-2 : 6-*dimethylisonicotinic Acid* (II). (Compare Gabriel and Colman, *Ber.*, 1902, **35**, 2832, for the preparation of 3-amino-*iso*nicotinic acid from cinchomeronimide).—Finely-powdered 2 : 6-dimethylcinchomeronimide (20 g.) dissolved when it was gradually added to a well-stirred, ice-cold solution of potassium hypobromite prepared from bromine (18·2 g.) and 10% aqueous potassium hydroxide (300 c.c.). After 2 hours, 10% potassium hydroxide (160 c.c.) was added and the mixture heated for 10 minutes on the steam-bath. The solution was acidified with respect to Congo-red with hydrochloric acid and evaporated to dryness under diminished pressure on the steam-bath. The residue was extracted twice with boiling alcohol, and the filtered solutions were concentrated to a small bulk, dilute hydrochloric acid (20 c.c.) being added to prevent the separation of inorganic salts. The *hydrochloride* of the amino-acid, which crystallised on cooling, was washed, dried (yield 16 g.

or 60%), and recrystallised from dilute hydrochloric acid, separating in slender, pale yellow needles, decomp. 248° (Found in material dried over sulphuric acid: Cl, 14·9; loss at 110°, 8·4; loss at 130°, 15·2. $C_8H_{11}O_2N_2Cl,2H_2O$ requires Cl, 14·9; $1H_2O$, 7·6; $2H_2O$, 15·1%). The long, yellow needles which separate from alcohol have m. p. 253—255° with previous slight darkening. This salt is readily soluble in water and sparingly soluble in dilute hydrochloric acid. The amino-group can be diazotised and coupling with β-naphthol produces a red azo-compound.

Sodium acetate was added to a concentrated aqueous solution of the hydrochloride, and the pale yellow, oblique-ended prisms of the *acid* which slowly separated were washed, and dried over sulphuric acid (Found: loss at 110°, 5·1; in material dried at 110°, C, 57·9; H, 6·1. $C_8H_{10}O_2N_2,0{\cdot}5H_2O$ requires H_2O, 4·9. $C_8H_{10}O_2N_2$ requires C, 57·8; H, 6·0%). The acid is sparingly soluble in neutral organic solvents, more readily soluble in water, and easily soluble in alcohol; it melts at 295° after darkening at 285°. The *copper* salt occurs in yellow, prismatic needles, moderately soluble in water, and the *lead* salt in colourless, quadrilateral or hexagonal prisms which do not melt at 315°.

3-*Amino*-2 : 6-*lutidine* (III).—A mixture of the hydrochloride of aminodimethyl*iso*nicotinic acid (15 g.) with powdered soda-lime (5 parts) was strongly heated in a combustion tube in a stream of hydrogen. The distillate, which solidified (6·4 g.), crystallised from benzene in colourless needles, m. p. 122°, and from water in needles which melted indistinctly between 70° and 75° and lost 14·4% on drying over potassium hydroxide in a vacuum; they then melted at 122° (Found: C, 68·7; H, 8·4; N, 22·9. $C_7H_{10}N_2$ requires C, 68·8; H, 8·2; N, 22·9% and $C_7H_{10}N_2,H_2O$ requires H_2O, 14·7%). This strong base has a characteristic odour and is readily soluble in most organic solvents, although somewhat sparingly soluble in ether. The *hydrochloride* is very readily soluble in water and separates from alcohol in flat needles, m. p. 235°.

3-p-*Hydroxybenzeneazo*-2 : 6-*lutidine* (corresponding with IV).—3-Aminolutidine (4·2 g.) was diazotised below 2° in hydrochloric acid (13·7 c.c.; *d* 1·16) and water (80 c.c.) with sodium nitrite (3·6 g.) in water (50 c.c.). The diazo-solution was slowly added to a cold, agitated solution of phenol (3·2 g.) and sodium hydroxide (6·9 g.) in water (100 c.c.), and, after 5 minutes, the dark red solution was saturated with carbon dioxide. The orange-brown precipitate, after being washed and dried (yield 6·7 g. or 86%), crystallised from toluene in flat, orange needles, m. p. 240° (decomp.) (Found in material dried at 110°: C, 68·9; H, 5·9; N, 18·6. $C_{13}H_{13}ON_3$ requires C, 68·7; H, 5·7; N, 18·9%). The substance is sparingly

soluble in ether, benzene, or chloroform, and is moderately readily soluble in alcohol, acetone, or ethyl acetate. The solutions in concentrated sulphuric and hydrochloric acids are bright red and the *hydrochloride* crystallises from dilute hydrochloric acid in orange-yellow needles, m. p. 239—240° (decomp.) (depressed by admixture with the base). In caustic alkalis, an orange-red solution is obtained, but the compound is less readily soluble in aqueous ammonia than benzeneazophenol.

The *methyl* ether (IV), which could not be obtained by the action of methyl sulphate on the phenol, since methylation of the tertiary nitrogen atom ensued, was prepared by Pyman's method (J., 1918, **113**, 227) for the *O*-methylation of phenolic bases; the conversion of benzeneazophenol into benzeneazoanisole by this process was found to be 75%. The lutidineazophenol (2 g.) and sodium methyl sulphate (3·6 g.; 3 mols.) were added to a solution of sodium *iso*amyloxide (from 0·2 g. of sodium) in *iso*amyl alcohol (20 c.c.), and the mixture was boiled under reflux for 2 hours, the colour changing from red to dark brown. Ether and dilute sodium hydroxide solution were added to the cold mixture, and the ethereal layer was washed with dilute alkali and water, filtered, and the solvent removed by distillation and steam distillation. The residue crystallised on cooling (yield 1·86 g. or 87·7%); 0·25 g. of unchanged phenol was recovered. *Lutidineazoanisole* is rather readily soluble in organic solvents and crystallises from light petroleum in elongated, diamond-shaped, red plates, often forming radiating clusters; it melts at 81—82° and solidifies to a yellow mass on cooling. When the bright red crystals were collected, they became yellow in places, but the change did not progress on keeping (Found: C, 69·6, 69·4; H, 6·2, 6·2. $C_{14}H_{15}ON_3$ requires C, 69·7; H, 6·2%). The *hydrochloride*, orange needles, sparingly soluble in dilute hydrochloric acid, melts to a paste at 112°, but, after drying at 100°, has m. p. 183—185° (decomp.). The semidine transformation was attempted by treatment of the ether both with acid reducing agents, such as alcoholic stannous chloride and hydrochloric acid, and with neutral reducing agents, such as aluminium–mercury and alcohol, and hydrogen in presence of palladium, followed by treatment with acids. The products gave no trace of triazole derivatives on treatment with nitrous acid. The failure of the semidine rearrangement also involved the breakdown of an otherwise feasible synthesis of harmine.

Derivatives of 3-*Amino*-2-*methylcinchoninic Acid*.—The object in view in making the experiments described below was the conversion of the accessible 3-amino-2-methylcinchoninic acid (Lawson, Perkin, and Robinson, *loc. cit.*) into a 1 : 7-naphthyridine derivative

by applying the Camps synthesis of 2 : 4-dihydroxyquinoline from anthranilic acid (*Arch. Pharm.*, 1899, **237**, 659). The attempt was abandoned on account of the difficulties encountered, and indicated in the sequel, but also because Seide (*Ber.*, 1924, **57**, 1806) failed to obtain a naphthyridine derivative in a similar manner from 2-aminonicotinic acid.

Methyl 3-*Amino*-2-*methylcinchoninate*.—The acid is not esterified when its solution in dry methyl alcohol (25 g. in 500 c.c.) is saturated with hydrogen chloride and heated under reflux for 3·5 hours. This phenomenon is not abnormal, since the conditions for the exercise of powerful steric hindrance are present, whilst, in addition, the basic character of the substance operates against the exhibition of oxonium character by the oxygen atoms of the carboxyl group.

A mixture of the acid (10 g.), sulphuric acid (10 c.c.), and methyl alcohol (100 c.c.) was boiled under reflux for 7 hours. Barely 1 g. of the *ester* was ultimately isolated as a viscous, yellow oil which soon solidified; it crystallised from light petroleum (b. p. 60—80°) in canary-yellow needles, m. p. 83—84° (Found : C, 66·4; H, 5·6. $C_{12}H_{12}O_2N_2$ requires C, 66·7; H, 5·6%). The substance exhibits brilliant blue fluorescence in ethereal solution, and is readily soluble in dilute hydrochloric acid and most organic solvents. The *acetyl* derivative was apparently not produced by the action of boiling acetic anhydride alone, but when the ester was boiled with an excess of acetic anhydride and fused sodium acetate for 10 minutes a substance was isolated in about 35% yield, which crystallised from benzene–light petroleum in pale yellow needles, m. p. 169°. This is doubtless *methyl* 3-*acetylamino*-2-*methylcinchoninate*, but the method of preparation is very unsatisfactory and attempts, unfortunately fruitless, were made to reverse the order of the operations. 3-*Acetylamino*-2-*methylcinchoninic acid*. A mixture of amino-methylcinchoninic acid (10 g.), fused sodium acetate (10 g.), and acetic anhydride (30 c.c.) was gently heated over a free flame until a vigorous reaction set in and the yellow colour disappeared. After being heated to incipient ebullition for a minute, the product was cooled, decomposed with water, and the precipitate collected and dried (10 g.). The material was a mixture, and an acidic fraction was separated from a neutral fraction (A) by means of dilute aqueous sodium carbonate. The acid precipitated from the filtered alkaline solution was at first gelatinous, but became crystalline when the mixture was heated on the steam-bath for about 10 minutes. The substance crystallises from much hot water in small, colourless needles which, after drying in a vacuum, lose 10·3% at 100° and then have m. p. 286° (Found in material dried at 100° : C, 64·2; H, 4·9. $C_{13}H_{12}O_3N_2,1{\cdot}5H_2O$ requires H_2O, 9·6% and $C_{13}H_{12}O_3N_2$

requires C, 63·9; H, 4·9%). This compound is sparingly soluble in most organic solvents, but dissolves in dilute hydrochloric acid at about 40° and separates again on cooling. The acetyl group was not removed when a solution of the substance in dilute aqueous sodium hydroxide was boiled for 4 hours; a sodium salt separated in silky needles from the cooled solution and by treatment with dilute acetic acid gave the unchanged acid, m. p. 286°.

A curious result followed an attempt to esterify the acid. A mixture of 3-acetylamino-2-methylcinchoninic acid (2 g.), sulphuric acid (3 c.c.), and methyl alcohol (20 c.c.) was boiled under reflux for 3·5 hours. After distillation of half the methyl alcohol, the mixture was added to water and ammonia and extracted with ether, which removed nothing. The ammoniacal solution was then acidified with hydrochloric acid and, on keeping, 1·9 g. of a yellow substance separated which crystallised from water in feathery, yellow needles, m. p. 217° (decomp.) [Found: loss at 100°, 14·3; in material dried at 100°, C, 64·8; H, 5·1. $C_{24}H_{22}O_5N_4(2C_{11}H_{10}O_2N_2 + C_2H_4O_2 - H_2O)$ requires C, 64·6; H, 4·9% and $C_{24}H_{22}O_5N_4,4H_2O$ requires H_2O, 13·9%). When the acetylamino-acid was boiled with concentrated hydrochloric acid it was quickly converted into an acid, devoid of basic properties, which, crystallised from dilute hydrochloric acid and then from alcohol, formed bright yellow needles, m. p. 234—235° (Found in material dried in a vacuum: loss at 100°, 5·6; in material dried at 100°, C, 63·1, 63·4; H, 5·5, 5·6; N, 12·8%). Both substances, m. p. 217° and m. p. 234—235°, are acids which are readily soluble in aqueous sodium carbonate, and the latter was shown to be unaffected by boiling dilute aqueous sodium carbonate in ½ hour. We have not reached any definite conclusion as to the nature of these substances.

Anhydro-3-acetylamino-2-methylcinchoninic Acid.—The material (A) obtained in the course of the acetylation of aminomethylcinchoninic acid crystallised from alcohol or benzene in colourless needles, m. p. 199—200° (Found: C, 69·1; H, 4·6; N, 12·2. $C_{13}H_{10}O_2N_2$ requires C, 69·0; H, 4·4; N, 12·4%). On boiling with water, the substance is slowly hydrated, but more rapidly in presence of sodium hydroxide, with the formation of 3-acetylamino-2-methylcinchoninic acid, m. p. 286°. The substance resembles acetylanthranil (compare Schroeter and Eisleb, *Annalen*, 1909, **367**, 124), and its constitution is probably analogous (O instead of NPh) to that of the pyrimidine derivative described below.

1-*Keto*-2-*phenyl*-3 : 5-*dimethyl*-1 : 2-*dihydro*-2 : 4 : 6-*naphtha*iso-*triazine*, $C_9H_4MeN<\begin{matrix}CO\cdot NPh\\ N=CMe\end{matrix}$.—A mixture of anhydro-3-acetylamino-2-methylcinchoninic acid (0·7 g.) and aniline (2 c.c.) was

boiled for 2 minutes and cooled, and the product was washed with alcohol and crystallised from much alcohol, separating in yellow needles, m. p. 235° (Found : C, 75·6; H, 5·3. $C_{19}H_{15}ON_3$ requires C, 75·7; H, 5·0%). This sparingly soluble substance is a weak base and is precipitated unchanged on addition of water to its solution in concentrated hydrochloric acid.

2 : 4 : 2′ : 4′-*Tetra-aminobenzophenone* (V).—Schöpff's method of tetra-nitration of diphenylmethane (*Ber.*, 1894, **27**, 2318) resulted in inferior yields, and the following method effected a considerable improvement. Molten diphenylmethane (53 g.) was added drop by drop to a stirred solution of potassium nitrate (128 g.) in sulphuric acid (360 g.) maintained below 25°. An equal quantity of potassium nitrate was then introduced and the mixture frequently shaken and heated on the steam-bath for 30 minutes. The isolation was by the method of Schöpff, and the yield 70%. The oxidation of tetranitrodiphenylmethane with chromic and acetic acids as described by Städel (*Annalen*, 1883, **218**, 341) proved a most unsatisfactory process and, after numerous trials, we finally adopted the following conditions. Tetranitrodiphenylmethane (10 g.) was dissolved in concentrated sulphuric acid (90 g.) and water (10 g.), and a concentrated aqueous solution of chromic acid (5·8 g.) added with vigorous agitation, the temperature being maintained below 40°. The mixture was finally heated for an hour on the steam-bath, added to water, and the precipitate collected and dried (7·5 g. or 72%). A specimen crystallised from acetic acid melted at 224—225° and for ordinary purposes the crude product can be satisfactorily purified by extraction with hot ethyl acetate. A good criterion of purity is the absence of the blue coloration with alcoholic potassium hydroxide which is so characteristic of tetranitrodiphenylmethane.

The tetranitrobenzophenone (10 g.) was suspended in a mechanically stirred mixture of acetic acid (100 c.c.) and concentrated hydrochloric acid (65 c.c.), and granulated tin (45 g.) gradually added. After about 20 hours, the liquid contained no solid nitrocompound in suspension and gave a clear solution with water. Sufficient water to dissolve the tin salt was added, and the filtered solution rendered strongly alkaline by the addition of sodium hydroxide. After a few hours, the black sludge and yellow needles were collected, dried, and extracted several times with hot alcohol. Dull, yellow prisms (3 g.) separated on cooling the concentrated extracts; the base, recrystallised from alcohol, had m. p. 202° (Found : C, 64·5; H, 6·0; N, 23·2. $C_{13}H_{14}ON_4$ requires C, 64·5; H, 5·8; N, 23·1%). Tetra-aminobenzophenone is readily soluble in acetone, ethyl acetate, or methyl alcohol, sparingly soluble in

benzene or chloroform, and very sparingly soluble in ether. Just above its m. p. the substance evolves ammonia; the residue dissolves in dilute hydrochloric acid, the yellow solution exhibiting bluish-green fluorescence. This behaviour indicates the formation of diaminoacridone. On treatment of an acid solution with sodium nitrite, a brown precipitate is thrown down and the solution contains a diazonium salt.

10 : 15-*Diamino*-1 : 8-*dimethyldibenzocopyrine* (VI). — Concentrated hydrochloric acid (5 c.c.) was added to a mixture of 2 : 4 : 2′ : 4′-tetra-aminobenzophenone (1 g.), acetylacetone (1 g.), and water (25 c.c.), and the whole gently heated. In about ½ minute orange crystals separated and the mixture was then boiled for a minute and cooled. The crystals were collected, washed with alcohol, and dried in a vacuum (Found : Cl, 26·6. $C_{18}H_{16}N_4$,3HCl requires Cl, 26·7%). This *hydrochloride* occurs in orange-red, rectangular plates, which decompose without melting at 310°. It crystallises in beautiful leaflets when hydrochloric acid is added to an aqueous solution. The yield in the preparation is almost quantitative if account be taken of the small amount of base recoverable from the original filtrate. In order to obtain the free base, the salt was dissolved in boiling dilute acetic acid and potassium hydroxide added until crystals began to separate. The heating was then discontinued and the remainder of the base precipitated by the further addition of potassium hydroxide. The substance was collected, washed, dried, and dissolved in a large volume of hot alcohol (charcoal). The filtered solution was concentrated by distillation and, at a certain stage, pale brown cubes were deposited from the hot solution (Found : C, 75·2; H, 5·6; N, 19·2. $C_{18}H_{16}N_4$ requires C, 75·0; H, 5·6; N, 19·4%). The substance is sparingly soluble in most organic solvents and its alcoholic solution exhibits a weak green fluorescence. It begins to decompose at about 305°, but does not melt at 340°. The base can be normally tetrazotised and coupled with β-naphthol to produce a crimson azo-compound.

An attempt to shorten the preparation was made, the product of reduction of tetranitrobenzophenone (1 mol.) being treated with zinc to eliminate tin and then with acetylacetone (3 mols.) on the steam-bath. After the red precipitate had been treated with successive quantities of cold alcohol, the residue consisted of the above-mentioned trihydrochloride. The alcoholic filtrates were evaporated to dryness; the residue crystallised from dilute hydrochloric acid in dark red needles which, air-dried, lost 19·6% at 130°, leaving a purplish-brown mass with a green reflex. This salt exhibits a most brilliant green fluorescence in solution and contains a diazo-

tisable amino-group. The amount of material at our disposal did not permit of further investigation.

Benzoylveratroylmethane, $PhCO{\cdot}CH_2{\cdot}CO{\cdot}C_6H_3(OMe)_2$. — Ethyl veratrate (10·5 g.) and acetophenone (7·5 g.) were condensed together by means of granulated sodium (2·3 g.) under dry ether (50 c.c.), and the diketone was isolated as the *copper* salt (5 g.) in the usual manner. This substance crystallised from benzene in pale green leaflets, m. p. 250° (Found: Cu, 10·1. $C_{34}H_{30}O_8Cu$ requires Cu, 10·1%). The *benzoylveratroylmethane* obtained by its decomposition with dilute sulphuric acid in presence of ether crystallised from methyl alcohol in pale yellow plates, m. p. 67°, and was readily soluble in most organic solvents (Found: C, 71·7; H, 5·6. $C_{17}H_{16}O_4$ requires C, 71·8; H, 5·6%). An alcoholic solution is coloured greenish-brown on the addition of ferric chloride.

Ethyl Benzoylveratroylacetate, $(MeO)_2C_6H_3{\cdot}CO{\cdot}CH(CO_2Et){\cdot}COPh$. —As the yield of benzoylveratroylmethane was rather poor in the direct process, this ester was prepared, but it could not be hydrolysed so as to yield the desired product.

Solutions of sodium ethoxide (from 8·7 g. of sodium) in alcohol (147 c.c.) and of veratroyl chloride (39·5 g.) in benzene (500 c.c.) were prepared. Half the sodium ethoxide solution was added to ethyl benzoylacetate (37·8 g.), and the mixture stirred and cooled to 0°. Half the veratroyl chloride solution was added during 15 minutes, and the mixture allowed to remain for 30 minutes. The cycle of operations was repeated several times, on each occasion one-half of the volume of the solution which remained being added. After 12 hours, the dense, yellow precipitate of crude sodium salt was collected, washed with benzene, dried in the air, and decomposed in aqueous solution with 2*N*-hydrochloric acid. The bulky, white precipitate of the ester was taken up with ether and the extract rapidly dried and concentrated, when, on standing, most of the product separated in colourless nodules. The substance was recrystallised by addition of light petroleum to a benzene solution (at about 50°), the long, slender needles obtained having m. p. 125—126° (Found: C, 68·9; H, 5·8. $C_{20}H_{20}O_6$ requires C, 68·9; H, 5·7%). Ferric chloride added to an alcoholic solution developed a red coloration. When the ester (15 g.) was boiled with aqueous ammonia (10·8 c.c.; *d* 0·880) in water (100 c.c.) for 5 minutes, the chief products were benzamide and ethyl veratroylacetate; veratramide, veratric acid, and acetophenone were also formed. Benzoic acid and acetoveratrone did not appear to be among the products of hydrolysis.

2 : 4-*Dinitro*-3′ : 4′-*methylenedioxystilbene*.*—We have prepared

* This work on some derivatives of stilbene was carried out in collaboration with William Stafford.

some stilbene derivatives in order to attempt to obtain 2 : 6-naphthyridine derivatives by the dehydration of *oo*-diacylaminostilbenes.

A molten mixture of piperonal (23 g.), 2 : 4-dinitrotoluene (27 g.), and piperidine (30 drops) was heated on the steam-bath for 3 hours, when the mass became solid. The very sparingly soluble product crystallised from acetic acid in bright salmon prisms, m. p. 180° (Found : C, 57·3; H, 3·2. $C_{15}H_{10}O_6N_2$ requires C, 57·3; H, 3·2%).

4-*Nitro*-2-*amino*-3′ : 4′-*methylenedioxystilbene*.—A cooled solution of dinitromethylenedioxystilbene (20 g.) in acetic acid (300 c.c.) was mixed with a solution of crystallised stannous chloride (40 g.) in acetic acid containing hydrogen chloride and stirred in the cold for 6 hours. The orange-yellow tin salt obtained was digested with water, and from the free, red amino-derivative produced the hydrochloride was prepared in alcoholic solution, and decomposed by water. The base crystallised from alcohol in dark red prisms, m. p. 213° (Found : C, 63·3; H, 4·4. $C_{15}H_{12}O_4N_2$ requires C, 63·4; H, 4·2%). Its constitution may be inferred from the results of Thiele and Escales (*Ber.*, 1901, **34**, 2842) relating to the semi-reduction of 2 : 4-dinitrostilbene combined with the fact that ammonia and hydrogen sulphide reduced dinitromethylenedioxystilbene to a quite different isomeric base.

2 : 4-*Dinitro*-2′ : 3′-*dimethoxystilbene* was prepared from 2 : 4-dinitrotoluene (18 g.), 2 : 3-dimethoxybenzaldehyde (17 g.), and piperidine (20 drops) as described above. It crystallised from acetic acid in bright yellow prisms, m. p. 165° (yield 31 g.; 94%) (Found : C, 57·9; H, 4·4. $C_{16}H_{14}O_6N_2$ requires C, 58·2; H, 4·3%).

2-*Nitro*-4-*amino*-2′ : 3′-*dimethoxystilbene*.—The conditions for the satisfactory preparation of 2-nitro-4-aminostilbene itself have been studied and the following method gives good results (compare Thiele and Escales, *loc. cit.*). Hydrogen sulphide was led for 3 hours through a gently refluxing mixture of dinitrostilbene (20 g.), alcohol (250 c.c.), and aqueous ammonia (30 c.c.; *d* 0·880). The cooled solution was filtered, and the hydrochloride precipitated with hydrogen chloride; the base obtained from the salt separated from alcohol in red crystals, m. p. 110°.

Nitrostilbenediazonium hydrogen sulphate is readily isolable in the crystalline condition and on decomposition with aqueous potassium iodide gives 4-*iodo*-2-*nitrostilbene*, bright yellow crystals, m. p. 105°. A similar reduction process was applied to dinitro-2′ : 3′-dimethoxystilbene and orange-red needles, m. p. 121—122°, were obtained (Found : C, 63·6; H, 5·2. $C_{16}H_{16}O_4N_2$ requires C, 64·0; H, 5·3%).

2 : 4-*Dinitro*-3′ : 4′-*dimethoxystilbene*, prepared from veratraldehyde and 2 : 4-dinitrotoluene, crystallises from acetic acid in

stout, maroon prisms, m. p. 143°, sparingly soluble in alcohol (Found : C, 58·0; H, 4·4. $C_{18}H_{14}O_6N_2$ requires C, 58·2; H, 4·3%). When triturated with acetic acid (35 c.c.) and nitric acid (25 c.c.; *d* 1·42), the substance (19 g.) became yellow; the product crystallised from acetic acid in short, yellow prisms, m. p. 192° (Found : N, 11·3. $C_{16}H_{13}O_8N_3$ requires N, 11·2%).

2 : 4 : 6′-*Trinitro*-3′ : 4′-*dimethoxystilbene* is readily soluble in acetone, but sparingly soluble in most other organic solvents.

2 : 4-*Dinitro*-2′-*hydroxystilbene* is obtained in poor yield from 2 : 4-dinitrotoluene and salicylaldehyde in presence of piperidine. It crystallises from ethyl alcohol in light brown, irregular granules, m. p. 179—181° (Found : C, 58·6; H, 3·6. $C_{14}H_{10}O_5N_2$ requires C, 58·7; H, 3·5%), is readily soluble in most organic solvents, develops no coloration with alcoholic ferric chloride, and dissolves in aqueous sodium hydroxide to a red solution.

2 : 4-*Dinitro*-3′-*methoxy*-4′-*hydroxystilbene*, produced (yield 67%) by condensation of 2 : 4-dinitrotoluene and vanillin in presence of piperidine, crystallises from acetic acid in stout, vermilion prisms, m. p. 193° (Found : C, 57·0; H, 3·8. $C_{15}H_{12}O_6N_2$ requires C, 56·7; H, 3·9%).

We desire to thank the Carnegie Trust for the Universities of Scotland for a Scholarship which enabled one of us (J. M. G.) to take part in this investigation.

[*Received, April 17th,* 1925.]

CCI.—*The Rotatory Dispersive Power of Organic Compounds. Part XVII. β- and π-Sulphonic Derivatives of Camphor.*

By EVAN MATTHEW RICHARDS and THOMAS MARTIN LOWRY.

1. *Purpose of the Observations.*

THE experiments now described were undertaken in order to extend our knowledge of the rotatory dispersion of the derivatives of camphor, more particularly by including in the scope of our investigations a number of water-soluble compounds, since it appeared likely that the influence of the solvent would be reduced to a minimum when the optically active molecule is in a medium for which (just as in the case of a soap) it has no affinity except through the influence of a single ionisable group. Recent work on the orientation of the β-derivatives of camphor (this vol., p. 279)

has, however, made it possible also to draw important conclusions in reference to the influence of substitution on the dissymmetry of the camphor molecule in relation to its optical activity.

2. *Summary of Experimental Results.*

(a) *Abnormality of the π-Derivatives of Camphor.*—The data now recorded confirm the conclusion, already arrived at in the preceding paper (Part XVI) from the study of the halogen compounds, that there is something mysterious about the optical rotatory power of the π-derivatives of camphor. Thus, whereas the molecular rotatory powers of the α- and α′-bromo-derivatives of camphor and of β-bromocamphor differ by 425° and 540°, respectively (this vol., p. 1261), the corresponding derivatives of π-bromocamphor differ so little that the order of magnitude of their rotatory powers actually depends on the solvent chosen, the corresponding figure to those cited above being −47°. The present investigation has disclosed the further remarkable fact that, whilst the optical rotation of camphor, and of all the derivatives that have yet been examined (except camphorquinone), contains a high-frequency term (corresponding with the general absorption of a saturated molecule) and a low-frequency term (corresponding with the selective absorption of the unsaturated ketonic group), the rotatory power of many of the π-derivatives can be expressed, within the limits of experimental error, by a "simple" formula containing only a single low-frequency term. Thus the rotatory power of *ammonium α-bromocamphor-π-sulphonate*, $C_{10}H_{14}BrO{\cdot}SO_2{\cdot}ONH_4$ (Table I) in water agrees rigidly, over the whole range of the visual and photographic observations, with the theoretical values calculated from the "simple" dispersion equation $\alpha = 22{\cdot}015/(\lambda^2 - 0{\cdot}09668)$. The dispersion constant of this equation, $\lambda_0{}^2 = 0{\cdot}09668$ ($\lambda = 3109$ Å.U.), has the low frequency which is characteristic of the ketonic group, the high-frequency term of the parent ketone being reduced to such a small magnitude that it cannot be detected in the range of wave-lengths covered by the observations. The same behaviour was observed in *ammonium α-chlorocamphor-π-sulphonate*, $C_{10}H_{14}ClO{\cdot}SO_2{\cdot}ONH_4$ (Table II), the rotatory dispersion of which is also simple, and can be expressed completely, throughout the range covered by the visual and photographic observations, by the equation $\alpha = 17{\cdot}677/(\lambda^2 - 0{\cdot}09946)$, from which we can deduce the value $\lambda_0 = 3154$ Å.U. The photographic observations were less regular than in the case of the bromo-compound, but only because the settings of the analyser did not happen to correspond with strong lines in the iron spectrum.

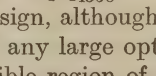
In addition to these two salts, *α-bromocamphor-π-sulphonethyl-*

chloroamide,* $C_{10}H_{14}BrO\cdot SO_2\cdot NCl\cdot C_2H_5$ (Table III), and *α-bromocamphor-π-sulphondichloroamide*,* $C_{10}H_{14}BrO\cdot SO_2\cdot NCl_2$ (Table IV), gave a simple dispersion throughout the visible region (although in this case the curve was not followed into the photographic region), the value of the dispersion constant being $\lambda_0^2 = 0{\cdot}09969$ ($\lambda = 3157$ Å.U.) for the former and $\lambda_0^2 = 0{\cdot}10719$ ($\lambda_0 = 3200$) for the latter compound. An isomorphous mixture of the stereoisomeric *αα′-bromochlorocamphor-π-sulphonamides*,*

$$C_{10}H_{13}ClBrO\cdot SO_2\cdot NH_2,$$

the data for which are not reproduced, gave, however, a dispersion curve which, although it deviated only moderately from the simple law in the red, green, and blue regions, swung aside sharply in the violet, the dispersion being therefore obviously complex.

The predominance of the low-frequency term which is such a striking property of the π-sulphonic derivatives of camphor is not a completely new feature, since it can already be seen in the simple bromo-derivatives. Thus, whereas the two partial rotations of camphor are comparable in magnitude, the rotation constants of the low- and high-frequency terms being + 29·4 and — 20·1, respectively, the corresponding constants of απ-dibromocamphor are + 25·2 and — 5·7 only.



(b) *Properties of the β-Derivatives.*—Whereas the π-derivatives of camphor have an exceptionally high rotatory power, substitution in the β-position generally causes a diminution of rotatory power. Thus the rotatory power of Reychler's well-known camphorsulphonic acid, $C_{10}H_{14}O\cdot SO_2\cdot OH$ (Table V), in water, $[\alpha]_{5461} = +30{\cdot}4°$, $[M]_{5461} = +70{\cdot}7°$, is actually lower than that of camphor in benzene, $[\alpha]_{5461} = +52{\cdot}34°$, $[M]_{5461} = +79{\cdot}7°$ (compare β-bromocamphor, this vol., p. 1261). The dispersion of the acid is, however, obviously complex, since a simple formula which agrees with the data for the red and blue lines Zn 6362 and Zn 4811 shows a deviation of + 1·5° in the green, — 21° in the violet, and — 196° in the ultraviolet at 3969 Å.U. In this respect, the sulphonic acid closely resembles camphor itself; and it was found that by using the same dispersion constants as in the case of camphor (this vol., p. 612) a two-term formula could be fitted to the curve for the sulphonic acid with fairly good results, the maximum deviation in the photographic readings being about 2° in each case. Whereas, however, the deviations in the case of camphor were distributed irregularly as regards sign and magnitude, and were clearly within the limits of the errors of observation, the deviations in the case of the sulphonic acid (on readings of smaller magnitude) were obviously systematic, since the errors were all positive in the visual

* Available through the kindness of Prof. Pope and Mr. F. G. Mann.

region and all negative in the photographic region. A revised formula was therefore deduced in which the systematic errors were reduced to a small fraction of their former magnitude.* It should be noted that this was probably the only attempt that we have made to deduce the constants of a dispersion equation from external data, and that it was a failure, mainly because we were fortunate enough to be working with a long column of a strong aqueous solution of a transparent substance, so that our observed rotations were nearly twice as great as the specific rotations deduced from them.

As might be expected, the α-derivatives of Reychler's camphor-β-sulphonic acid show higher rotations than the parent compound. Thus potassium α-chlorocamphor-β-sulphonate, $C_{10}H_{14}ClO{\cdot}SO_2{\cdot}OK$ (Table VI), and potassium α-bromocamphor-β-sulphonate, $C_{10}H_{14}BrO{\cdot}SO_2{\cdot}OK$ (Table VII), gave *higher* rotations than camphor, namely, $[\alpha]_{5461} = +77{\cdot}4°$, $[M]_{5461} = +236°$ and $[\alpha]_{5461} = +111{\cdot}3°$, $[M]_{5461} = +389°$, respectively. The dispersions of these salts are complex but normal, the two partial rotations being of similar sign in each case.

The *sulphonamide*, $C_{10}H_{15}O{\cdot}SO_2{\cdot}NH_2$, of Reychler's acid is remarkable in being almost inactive, $[\alpha]_{5461} = +0{\cdot}4°$ only. It was therefore of interest to find out whether this small rotatory power was due to the small asymmetry of the compound, or to an anomalous dispersion, the small readings being then due merely to the observations falling in a region near to the wave-length at which an inversion of sign takes place. Observations for two other lines gave $[\alpha]_{5780} = -0{\cdot}8°$, $[\alpha]_{4358} = +15{\cdot}16°$, showing that there is actually a reversal of sign, although the rotations are still small, and do not indicate that any large optical rotatory power would be developed in the accessible region of the spectrum.

The *anhydramide*,  , of Reychler's acid (Table VIII) has a rotatory power, $[\alpha]_{5461} = -35{\cdot}9°$, $[M]_{5461} = -76{\cdot}5°$, of about the same magnitude as the parent compound, *but opposite in sign*, since the anhydramide derived from *d*-camphor is lævorotatory. The dispersion of this compound conforms closely to

* We are indebted to Mr. G. Owen, M.Sc., for this recalculation, which extended over a period of several months, and involved the investigation of more than a score of formulæ, before a satisfactory agreement was reached. The ultimate alteration in the constants was, however, relatively small, showing that a full series of readings fixes these constants within fairly narrow limits, thus:

	k_1.	k_2.	λ_1^2.	λ_2^2.
Old formula	21·523	−17·586	0·0872	0·0528
New formula	22·17	−18·32	0·085815	0·04945

Biot's law of inverse squares, but, on account of its small dispersion ratio, must be formulated as complex, just as in the analogous cases of sodium tartrate (Lowry and Austin, *Phil. Trans.*, 1922, *A*, **222**, 278) and octyl oxalate (Lowry and Richards, J., 1924, **125**, 1593). This observation is, however, of considerable interest in that, as a result of eliminating the ketonic double bond of camphor and replacing it by an imido-link in a closed ring, the *low-frequency term* in the dispersion equation has been reduced to a proportion which is almost negligible, whereas in the π-derivatives it is the *high-frequency term* which disappears from the equation.

3. *Relation between Rotatory Dispersion and Absorption.*

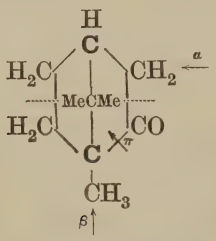
As in the case of Parts XV and XVI, publication of the dispersion data in the present paper has been delayed for more than a year in order to correlate them with measurements of absorption. A detailed comparison of the dispersion constants with the wave-lengths, λ_a, of the absorption bands now gives the results shown in the following table.

Dispersion Constants of Sulphonic Derivatives of Camphor.

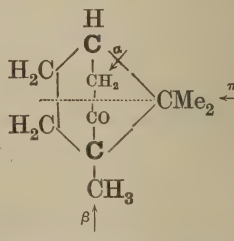
	k_1.	k_2.	λ_1^2.	λ_2^2	λ_1.	λ_a.	$\lambda_1 - \lambda_a$.
Ammonium α-chlorocamphor-π-sulphonate	+17·677	—	0·09946	—	3150	3030	+120
Ammonium α-bromocamphor-π-sulphonate	+22·015	—	0·09668	—	3110	Am′ 3020 K′ 3040	+ 90
α-Bromocamphor-π-sulphonethylchloroamide	+25·889	—	0·09969	—	3160	—	—
α-Bromocamphor-π-sulphondichloroamide	+23·897	—	0·10719	—	3275	—	—
Camphor-β-sulphonic acid	+22·17	−18·32	0·08515	0·04945	2920	2850	+ 70
Camphor-β-sulphonanhydramide	—	−10·696	—	0*	—	—	—
Potassium α-chlorocamphor-β-sulphonate	+12·060	+ 5·1354	0·09768	—	3125	3000	+125
Potassium α-bromocamphor-β-sulphonate	+18·78	+ 5·569	0·09517	—	3085	3030	+ 55

* This compound conforms closely to Biot's law of rotatory dispersion.

In general, these constants follow one another fairly closely; thus Reychler's acid, which gives an abnormally small value for λ_1^2, is also seen to give an exceptionally small value for λ_a. As in all the cases hitherto examined, however, there is a steady discrepancy between the characteristic wave-lengths, λ_1 and λ_a,



as deduced from the optical rotations and from the absorption spectra respectively. Since this discrepancy is in the same direction as in every previous case, and is, moreover, of the same order of magnitude, namely, 90 Å.U. as an average of five individual cases, it may now be regarded as a perfectly normal phenomenon. It therefore calls for no further comment, except to add that the " simple " one-term equations now worked out for some of the π-derivatives show just the same degree of concordance, and therefore rest on just as secure a foundation, as the " complex " two-term equations of the preceding paper of this series. In those cases, it was assumed in advance that the total rotation contains two partial rotations of unequal frequency; if a similar assumption were made in the present case, it would merely result in the development of equations in which $k_2 = 0$.



Attention may also be directed to the fact that camphor-β-sulphonanhydramide (in which the low-frequency partial rotation has disappeared from the equation as a sequel to eliminating the ketonic oxygen) is exceptionally transparent in the ultra-violet, and exhibits only a general absorption of light, without even a " step-out " to mark the presence of an incipient selective absorption (Lowry and Desch, J., 1909, **95**, 1343).

4. *Discussion of Experimental Results.*

In view of the proof that has recently been given (Wedekind, Schenk, and Stüsser, *Ber.*, 1923, **56**, 663; compare Lowry and Burgess, this vol., p. 279) that the β-derivatives, like the π-derivatives, are formed as a result of substitution in a methyl group, the three positions in which substitution can take place in the camphor molecule can be shown in two alternative aspects as in I and II :

(I.)

(II.)

Both methods of formulation bring out the fact that the molecule is almost symmetrical above and below the dotted horizontal line, and would indeed become completely symmetrical if (i) the >CO group were reduced to $>CH_2$, and (ii) the terminal methyl were replaced by hydrogen, or conversely. A still closer approach to symmetry can be seen in formula I, where the only element of

dissymmetry about a vertical plane perpendicular to that of the paper would again disappear if the CO group of camphor were reduced to CH_2.

(a) *Simple Dispersion of π-Derivatives.*—In summarising the experimental results it was stated that the rotatory dispersion of several of the π-derivatives can be expressed by means of a single term of Drude's equation, governed by a low-frequency dispersion constant only. In cases such as these, one may always suspect that the apparent simplicity of the low-frequency dispersion may mask the presence of a high-frequency term instead of eliminating it completely; but this does not excuse us from the necessity of inquiring why the high-frequency term has become impotent, or why this impotence should appear abruptly on passing from one group of compounds to another. The phenomenon to be accounted for is indeed very similar, whether the dispersion is fundamentally " simple " or only simple within the limits of experimental observation. In the analogous case of camphorquinone (J., 1924, **125**, 2511), the disappearance of the high-frequency term from the equation can be accounted for by noticing that (i) the low-frequency partial rotation of the unsaturated quinonoid group has a characteristic period in the visible spectrum, and therefore dominates completely the rotatory power of the molecule in the restricted region within which the compound is transparent, whilst (ii) the high-frequency partial rotation (which we attribute to the direct influence of the two asymmetric carbon atoms) is almost cancelled out by the growing symmetry of the molecule, since each asymmetric carbon atom is now adjacent to a CO group, and the only element of dissymmetry which remains is due to a contrast between hydrogen and methyl, so that *apo*camphorquinone (unlike *apo*camphor) would be optically inactive. In the case of the π-sulphonic derivatives these two asymmetric carbon atoms, which are already partly compensated in camphor itself, have been still more closely compensated by the introduction of symmetrically-placed sulphonic groups in the median plane between them, and therefore contribute only a negligible partial rotation to the total rotatory power of the molecule. In both cases, then, the disappearance of the high-frequency term can be associated with the approximate symmetry of the molecule about the median plane, just as in the case of camphoric anhydride, $C_8H_{14}\begin{matrix}<\mathrm{CO}\\ \mathrm{CO}>\end{matrix}O$, the specific rotatory power of which is less than 1° (Lowry, J., 1903, **83**, 968).

(b) *Induced Asymmetry in the π-Derivatives of Camphor.*—The increased magnitude of the low-frequency partial rotations, which is such a striking property of the π-derivatives, can be accounted

for by noticing the increased difference between the groups on either side of the vertical plane in formula II, since it is this difference alone which makes it possible to attribute an "induced asymmetry" to the ketonic group. A much more striking anomaly is, however, to be found in the fact that the reversal of sign of the >CHBr group in the α- and α′-derivatives, which has an enormous effect on the rotatory power of camphor, produces an almost negligible change in the rotatory power of the π-derivatives. A clue to the explanation of this curious fact may be found in the suggestion, put forward more than 20 years ago, in order to explain the reactivity of the methyl group in π-sulphonation, namely, the possible "formation of a direct linkage between the ketonic carbon and a median methyl" (Armstrong and Lowry, J., 1902, **81**, 1473). A

† Deviation from simple formula $[\alpha] = 23{\cdot}891/(\lambda^2 - 0{\cdot}08379)$, obs. − calc. = + 9·1°.

Note.—The dispersion formulæ for these two compounds, which have been calculated by Mr. G. Owen, M.Sc., contain two partial rotations of similar sign, and therefore provide two more examples of the type of complex rotatory dispersion which has been described as "impossible to detect in practice" (compare footnote, this vol., p. 1262). The deviations from the simple formulæ (calculated to fit the red and blue zinc lines) are, however, already substantial even in the intermediate green region of the spectrum, and increase to about 2° in the case of the mercury violet line, and to about 10° at the extreme end of the visible spectrum; they are therefore far too obvious to be overlooked. This type of rotatory dispersion, although quite easy to detect in this series of compounds, is not common, since the induced asymmetry of the ketonic group is always opposite in sign to the fixed asymmetry of the camphor nucleus, except when the sign of the latter has been reversed by the creation of a new positive partial rotation as a result of introducing a substituent in the α-position.

formula was then given which shows the formation of a new ring by the transference of a hydrogen atom from the π-methyl group to the ketonic oxygen; but it would be more in accord with our present views to postulate only a co-ordination of the reactive π-hydrogen atom with the ketonic oxygen. This co-ordination would have the advantage of enabling us to attribute the induced asymmetry of the ketonic group to a more concrete influence than that of a mere unsymmetrical field of force. It would, moreover, permit of a very simple explanation of the fact that the partial rotation of the ketonic group is always positive in sign, and is not even altered substantially in magnitude when the specific rotation of the molecule is shifted through several hundred degrees by reversing the sign of the >CHBr radical which is immediately adjacent to the ketonic group. In the π-derivatives this particular type of co-ordination is prevented by the elimination of the π-hydrogen atom; the two adjacent groups are therefore free to adjust themselves in such a way that a reversal of the fixed asymmetry of the saturated >CHBr group at once produces a compensating change in the induced asymmetry of the unsaturated >C=O group, whereby the balance of the molecule as expressed by its optical rotatory power is preserved almost unchanged.

5. *Summary.*

(*a*) The rotatory dispersion and absorption spectra of a series of β- and π-sulphonic derivatives of camphor have been determined. As in previous cases, there is a discrepancy of nearly 100 Å.U. between the characteristic frequencies deduced from the two series of observations.

(*b*) The rotatory dispersion of several of the π-derivatives can be expressed by one term of Drude's equation, the high-frequency

partial rotation being negligible in comparison with the magnitude of the low-frequency term, just as in the case of camphorquinone.

(*c*) The β-derivatives all exhibit complex dispersion, but the anhydramide nearly obeys Biot's law, since the low-frequency partial rotation and the band of selective absorption both disappear as a sequel to the elimination of the ketonic oxygen.

We are indebted to the Department of Scientific and Industrial Research for a maintenance grant to one of us (E. M. R.) during the period in which this research was carried out. We are also indebted to Prof. Pope and Mr. F. G. Mann for the loan of some of the compounds examined.

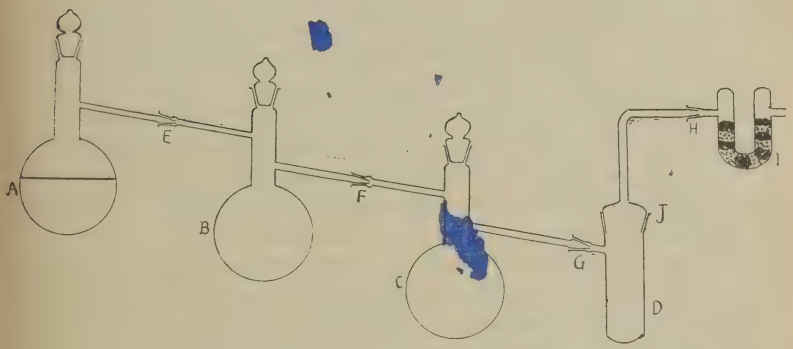
CCII.—*Sulphur Sesquioxide.*



By ISRAEL VOGEL and JAMES RIDDICK PARTINGTON.

FROM the reaction between sulphur and sulphur trioxide Vogel (*J. Chem. Phys.*, 1812, **4**, 121) isolated a deep blue liquid, a bluish-green solid, and a brown liquid, all of which were considered to be definite compounds of sulphuric anhydride and sulphur. Similar results were obtained by Schweigger (*ibid.*, 1815, **13**, 484). Wach (*ibid.*, 1827, **50**, 1) endeavoured to determine the composition of the blue, green, and brown substances and found that the amount of sulphur combined with a definite quantity of sulphur trioxide increased in the order named. Fischer (*Ann. Phys. Chem.*, 1829, **16**, 119) and Rose (*ibid.*, 1834, **32**, 98) considered that the blue liquid contained a definite compound, whilst Berzelius ("Traité de Chimie," 1845, Tome I, p. 459) maintained that no new oxide of sulphur was present, and Stein (*J. pr. Chem.*, 1873, **6**, 172) ascribed the colour of the solution to the presence of finely divided sulphur. Weber (*Ann. Phys. Chem.*, 1875, **156**, 531) found the sulphur content of the bluish-green solid to correspond with S_2O_3. No further work appears to have been done, and the current view seems to be that the supposed sulphur sesquioxide is a "colloidal solution" (compare Hofmann, "Anorganische Chemie," 1920, p. 166; Ephraim, "Anorganische Chemie," 1922, p. 437). The present research was accordingly undertaken with the object of definitely deciding between these two theories and of studying the properties of the substance if it were proved to be a chemical compound.

The starting materials of previous investigators were far from pure, and this was probably the cause of the different results obtained.

Purification of Sulphur.—The purest commercial precipitated sulphur was distilled in a Pyrex retort in a current of pure carbon dioxide, the distillate being collected and allowed to solidify in a Jena glass flask; the first and last fractions were neglected. The distillate was melted and the liquid poured on to watch-glasses of Jena glass, the melting and cooling being conducted in an atmosphere of dry carbon dioxide. When the sulphur had almost completely resolidified, it was cut up into small pieces and the above process repeated three times, considerable head and tail fractions being discarded in each distillation. After the first distillation, the sulphur did not darken appreciably but melted to a clear and mobile liquid which, with rise of temperature, exhibited all the usual phenomena, but did not darken appreciably. The purified sulphur

FIG. 1.

was finely powdered and preserved in a vacuum desiccator over phosphorus pentoxide until required.

Preparation of Pure Sulphur Trioxide.—Although many types of apparatus have been devised and employed for the preparation of pure sulphur trioxide (compare Weber, *Ann. Phys. Chem.*, 1876, **159**, 313; Divers and Shimosé, *Ber.*, 1883, **16**, 1009; Schenk, *Annalen*, 1901, **316**, 1; Lichty, *J. Amer. Chem. Soc.*, 1908, **30**, 1834; Beckmann, *Z. anorg. Chem.*, 1912, **77**, 90), none of these permit of the preparation of large quantities of the anhydride in a comparatively short time, nor do they allow of the convenient handling of the pure product. The apparatus shown in Fig. 1 was constructed for the preparation of pure sulphuric anhydride from oleum. The apparatus was entirely of Durosil resistance glass. The three distilling flasks, A, B and C, and a reaction vessel D were connected by interchangeable ground joints. Stoppers were ground to fit the mouths of the flasks and reaction vessel and also both parts of the joints E, F and G so that any flask or flasks could be

removed from the remainder of the apparatus without access of moisture. A phosphorus pentoxide drying tube, I, was attached to the reaction vessel by means of the joint H.

Kahlbaum's pure 65% oleum (about 200 c.c.) was placed in A, B was immersed in a bath of ice-cold water, C surrounded by a freezing mixture of finely-ground ice, and the bath of concentrated sulphuric acid surrounding A was very carefully warmed. Sulphur trioxide distilled over and condensed in B, only a very small quantity finding its way to C. The sulphuric anhydride which passed over on gentle heating was the only portion collected. After distillation and some cooling, the flask A was detached at E and immediately replaced by a ground glass stopper. B was then placed in the sulphuric acid bath, C surrounded by cold water, D immersed in a freezing mixture of ice and salt, and the bath surrounding B very gently warmed. Sulphur trioxide distilled into C, the distillation being stopped when about three-quarters of the contents of B had passed over : flask B was then removed and replaced by a ground glass stopper. Flasks B and A after cleaning and drying were then attached to the apparatus and the distillation was repeated in the manner described. In this way, pure sulphur trioxide was obtained, two to three distillations usually being sufficient. It melted completely at about 15° to a colourless liquid and crystallised on cooling in beautiful needles.

To transfer the anhydride to the reaction vessel, the solid was melted and the flasks were rotated about the ground glass joints.

Preparation and Analysis of Sulphur Sesquioxide.—A mode of procedure similar to that described by Weber (*Ann. Chem. Phys.*, 1875, **156**, 531) was first employed. About 20 c.c. of liquid sulphuric anhydride were placed in the reaction vessel and the latter was closed by a ground glass stopper at G. Sulphur was then added in small quantities by momentarily detaching the ground glass joint J, a fresh portion being added only after the previous quantity had entered into combination. The sulphur on coming in contact with the anhydride formed blue drops, most of which sank, but some became attached to the sides of the vessel near the surface of the sulphur trioxide. In order to avoid formation of a cake of solid at the surface, the vessel must be shaken during the preparation, when most of the substance sinks as soon as formed. If the sulphur be added too rapidly, the temperature of the sulphuric anhydride rises and the solid near the surface decomposes with the evolution of sulphur dioxide. If, however, the vessel be shaken during the addition and care be taken that the temperature does not rise above 15°, very little decomposition occurs. After about 1 or 2 g. of sulphur had been added, the excess of liquid sulphur trioxide,

which should be colourless, was poured off and any still remaining removed by warming in a vacuum at 30—40°, two towers, containing concentrated sulphuric acid on pumice and borax on glass wool respectively, being interposed before the pump. All the sulphuric anhydride could not be easily removed in this manner and it was necessary first to powder the bluish-green substance in an atmosphere of dry carbon dioxide and then to heat in a vacuum as described. Weber's compound probably contained small quantities of occluded sulphur trioxide, since he attempted to remove the latter merely by warming to " blood " temperature.

The substance thus obtained was a bluish-green solid, which soon decomposed at the ordinary temperature with the evolution of sulphur dioxide, sulphur remaining. Decomposition was accelerated by warming. The compound was very hygroscopic; if left exposed to the air, decomposition occurred and moist sulphur remained. If all the sulphuric anhydride had been removed, the substance was stable for several minutes at about 15°. In carrying out the analyses the weighings were performed as rapidly as possible.

Weber's method of analysis (*loc. cit.*) was first repeated and confirmed. Some of the substance was weighed out into a small glass-stoppered tube and, after removing the stopper, the tube was allowed to slide down the side of another but larger glass-stoppered vessel containing a mixture of concentrated and fuming nitric acids, great care being taken that the acid did not reach the contents of the small tube. The larger tube was then stoppered and completely wrapped in a cloth, since explosions sometimes resulted. The vessel was inclined so that the acid came in contact with the substance; a violent reaction ensued, and the stopper was held down. The whole was allowed to stand over-night. The contents of the tube were then diluted and the precipitated sulphur was collected on a weighed Gooch crucible. The sulphur in the filtrate was estimated, after the nitric acid had been boiled off, with barium chloride solution in the usual manner. The results are given in Table I.

In another method of analysis the sulphur of the compound was oxidised to sulphuric acid in one operation by a mixture of fuming nitric acid and bromine, the operation being carried out in the manner described. Of some twenty-five analyses carried out by this method, four exploded. A few typical results are

recorded in Table II : all the successful analyses were between the limits of 56·96 and 57·81% sulphur.

The results are in agreement with those found by the first method and with the value required by S_2O_3. It appears, therefore, that the substance has a constant chemical composition.

The method of preparation of the compound given above is somewhat laborious and cannot be used for the preparation of comparatively large quantities. It was found that instead of adding the sulphur to the liquid sulphuric anhydride, one might add the latter to the former and obtain a similar result. About 1 g. of finely-powdered sulphur was placed in the reaction vessel and about 15 c.c. of liquid sulphur trioxide were added. No reaction appeared to take place at first, although the whole assumed a deep blue colour and became somewhat viscid. After approximately 30 seconds, a violent reaction set in, so that it was found advisable to detach the phosphorus pentoxide tube from the reaction vessel, clouds of white fumes being evolved. After about 2 minutes the reaction subsided, the supernatant liquid sulphuric anhydride, which was coloured very pale blue, was poured off, and the residual sulphur trioxide removed from the resultant bluish-green solid in the manner already described. The bluish-green solid * thus obtained dissolved in oleum with the production of a deep blue solution, decomposed on exposure to air and on keeping with the evolution of sulphur dioxide, absorbed moisture from the air, and appeared to be identical with the substance prepared by the first method. The analysis by the fuming nitric acid and bromine method yielded the following results :

TABLE III.

G. of substance.	G. of $BaSO_4$.	G. of S.	Total percentage of S.
0·1994	0·8296	0·1140	57·16
0·2316	0·9660	0·1327	57·30
0·1778	0·7406	0·1017	57·22
		Calculated for S_2O_3	57·19

This method of preparation is simpler and more convenient than the first one, and the residual sulphuric anhydride from one preparation

* On some occasions the solid was green.

may be employed again for the conversion of another quantity of sulphur into the sesquioxide.

Owing to the great instability of the compound a number of experiments were performed with a view to render it more stable. It was found that the solid could be kept unchanged for several hours in a completely dry oxygen-free atmosphere at low pressures (less than 1 mm. of mercury). Cooling to liquid air temperatures had no appreciable effect.

The empirical formula of the compound has been shown to be $(S_2O_3)_x$, which for the sake of simplicity was taken as S_2O_3. From this it would seem that the substance might be the anhydride of hyposulphurous acid, but it may be said at once that all attempts to convert it into either the acid or its simple derivatives failed, owing to the simultaneous side and consecutive reactions and the production of mixtures of complicated sulphuroxy-acids, the reactions and identification of which are described below.

It was thought that the formula of the compound might be established by processes similar to those employed by Bernsthen (*Annalen*, 1881, **208**, 142) for sodium hyposulphite, but it was found that substances are formed in solution which complicate the reactions and that no evidence as to the constitution of the substance can be obtained from these results.

The molecular weight of the substance was not determined, since no solvent could be found with which the compound did not react. Purified phosphorus oxychloride, the only pure solvent for sulphuric anhydride at present known (compare Lichty, *J. Amer. Chem. Soc.*, 1912, **34**, 1441), caused complete decomposition of the sulphur sesquioxide.

Owing to the extremely reactive and unstable nature of the substance, all attempts to deduce its constitution by methods usually applicable to acid anhydrides were unsuccessful. Nevertheless, the results obtained could be completely reconciled with the formula S_2O_3 for the original compound.

Properties of Sulphur Sesquioxide.—Sulphur sesquioxide dissolves in oleum with the formation of a deep blue solution identical with that produced by the addition of sulphur. A solution of indigo in concentrated sulphuric acid or of indigo-carmine in water is partially decolorised; in no case could complete decoloration be effected even by the addition of comparatively large quantities of the substance. A similar reaction takes place with strongly ammoniacal copper sulphate solution, the decoloration being only partial.

With anhydrous ether a violent reaction takes place, the compound decomposing with the separation of sulphur and the production of a yellow solution; on decanting the clear, evil-smelling

liquid and distilling off the ether, a very small quantity of a yellow oil remained. The amount, however, was too small for analysis and qualitative tests pointed to the presence of sulphur.

A similar reaction takes place with absolute (100%) ethyl alcohol. Here a very small quantity of a pale yellow liquid was obtained after removal of the separated sulphur by filtration and the alcohol by distillation. The amount was too small for analysis, but qualitative tests indicated the presence of sulphur.

Sulphur sesquioxide when allowed to come into contact with water decomposes, a pale yellow solution (compare hyposulphurous acid) being momentarily formed, the decomposition being accompanied by a loud hissing noise and the simultaneous formation of a milky solution due to the separation of sulphur. If a relatively large quantity of the sesquioxide be employed, yellow sulphur separates, which when freshly formed is somewhat plastic, but soon becomes brittle. The filtered solution contained sulphuric acid and trithionic acid, together with small quantities of penta- and possibly tetra-thionic acids, as detected by the reactions with mercurous nitrate, cupric sulphate, mercuric chloride, and ammoniacal silver nitrate solutions, respectively (compare Takamatsu and Smith, J., 1880, **37**, 592; Debus, J., 1888, **53**, 278; Riesenfeld and Feld, *Z. anorg. Chem.*, 1921, **119**, 225; Forster and Hornig, *ibid.*, 1922, **125**, 86), whilst the presence of sulphurous acid was indicated by the coloration with ferric chloride solution. The yellow coloration with ferric chloride solution is not, however, exclusive to sulphurous acid (compare Debus, *loc. cit.*), but is also produced by sulphoxylic acid and its salts (*vide infra*), hence both these substances may have been present. That the yellow coloration is due to a substance other than sulphurous acid is probable, since after removing the latter by the passage of a current of air through the solution for several hours, the residual liquid gave a yellow coloration with ferric chloride. The complete removal of sulphur dioxide was detected by inserting two flasks, the first containing a known volume of standard iodine solution and the second a known volume of standard thiosulphate solution, before the pump, and titrating : the total quantity of iodine remained unaltered when the process was complete. The quantities of tetra- and pentathionic acids increased with time, as was shown by the yellow opalescence produced on the addition of the first few drops of mercurous nitrate solution. No qualitative tests are at present known by which small quantities of tetrathionic acid or its salts may be detected in the presence of pentathionic acid or its salts, hence the conclusion as to the presence of tetrathionic acid in the solution is somewhat doubtful.

The initial reaction with water may consist in the decomposition of the sulphur sesquioxide into monoxide and dioxide :

$$S_2O_3 = SO + SO_2.$$

Some of the monoxide polymerises, the polymeride in the presence of water forming pentathionic acid :

$$5SO + H_2O = H_2S_5O_6$$

(compare Debus, *loc. cit.*; Riesenfeld and Feld, *loc. cit.*), whilst another portion reacts with water to produce sulphoxylic acid :

$$SO + H_2O = H_2SO_2.$$

The chief reaction, however, consists in the formation of trithionic acid; two modes of interaction are possible, the first being between water, sulphur sesquioxide and sulphur dioxide :

$$S_2O_3 + SO_2 + H_2O = H_2S_3O_6,$$

and the second between sulphur monoxide, sulphur dioxide and water :

$$SO + 2SO_2 + H_2O = H_2S_3O_6.$$

The latter reaction probably take place to the greater extent. If the solution be kept for some time, the trithionic acid gradually combines with *nascent* sulphur with the production of tetra- and penta-thionic acids :

$$H_2S_3O_6 + S = H_2S_4O_6;$$
$$H_2S_4O_6 + S = H_2S_5O_6;$$
$$H_2S_3O_6 + 2S = H_2S_5O_6.$$

The last reaction to be studied was that with an anhydrous alcoholic solution of sodium ethoxide, prepared by adding sodium to absolute ethyl alcohol in a Jena flask fitted with a reflux condenser and phosphorus pentoxide drying tube. On addition of sulphur sesquioxide, an extremely vigorous reaction took place, small quantities of a yellow, crystalline solid separating out and the whole liquid assuming a yellowish-brown colour. The product of the reaction had a very strong and unpleasant odour somewhat resembling that of garlic and affecting the voice if the vapour was inhaled for any length of time. On adding sulphuric acid immediately after the reaction a white solid was precipitated, which was separated by adding absolute alcohol, filtering, and drying over phosphorus pentoxide. The solid was fairly soluble in water, neither the solution nor the solid decolorising indigo or ammoniacal cupric sulphate solutions. Qualitative tests indicated the presence of sulphur and sodium. The sodium was determined as sulphate,

whilst the sulphur was estimated by fusion with a mixture of sodium peroxide and sodium carbonate (Treadwell-Hall, "Quantitative Analysis," 1919, p. 849) and in a second process by oxidation with a mixture of fuming nitric acid and bromine, as detailed above. The latter method is much more convenient than the first. The results of the analyses agreed fairly well with those required by *sodium ethyl sulphoxylate* (Found : Na, 20·10, 20·06; S, 27·80, 27·85. $NaEtSO_2$ requires Na, 19·81; S, 27·61%).

Unless extreme precautions are taken to prevent the access of moisture, and unless the substance is isolated immediately after the reaction, the resulting solid consists of a mixture of sodium ethyl sulphoxylate and its hydrolysis product. The completely hydrolysed product was isolated from the solution by allowing it to stand over-night and then gradually acidifying with dilute sulphuric acid; a yellow precipitate separated which became white as soon as the whole solution was acid. The precipitate was immediately filtered with the aid of the pump, washed with absolute alcohol, and dried over phosphorus pentoxide for a week. A perfectly white, crystalline solid was obtained which remained unchanged when heated at 110° for 2 hours. The sulphur content was determined by the fuming nitric acid and bromine method; in the estimation of sodium the substance was first decomposed with a boiling mixture of fuming nitric acid and bromine, evaporated to small bulk, diluted with water, and transferred to a weighed platinum dish, the estimation for sodium as sulphate being continued in the usual manner (Found : Na,40·24, 41·08, 41·04; S, 29·16, 29·20, 29·14. Na_2SO_2 requires Na, 41·80; S, 29·13%).

Sodium sulphoxylate is moderately soluble in cold and more soluble in hot water and sparingly soluble in alcohol. It is practically unattacked by boiling concentrated hydrochloric and sulphuric acids, but is attacked by a hot mixture of fuming nitric acid and bromine. The aqueous solution gives a yellow coloration with ferric chloride solution. On exposure to air, the white solid assumes a yellowish-brown colour.

The filtrate from the preparation of sodium sulphoxylate, which still possessed a strong unpleasant odour, was found to contain salts of trithionic, sulphoxylic, and sulphuric acids, and also small quantities of penta- and possibly tetra-thionic acids. The product of the reaction between sulphur sesquioxide and sodium ethoxide has a strongly alkaline reaction and under these conditions it would be expected that any tetra- and penta-thionates formed would decompose with the formation of sulphites and thiosulphates, but the absence of the latter clearly proved that very little, if any, of these substances had been produced in the initial reaction.

The reactions which take place may be represented as follows :

(1) $S_2O_3 = SO + SO_2$.
(2) $SO + NaOEt = NaEtSO_2$.
(3) $NaEtSO_2 + NaOH = Na_2SO_2 + EtOH$.

Some of the sulphur monoxide or sesquioxide may react thus :

(4) $SO + 2SO_2 + NaOEt = NaEtS_3O_6$ or
(4a) $S_2O_3 + SO_2 + NaOEt = NaEtS_3O_6$.
(5) $NaEtS_3O_6 + NaOH = Na_2S_5O_6 + EtOH$.

The very small quantity of pentathionate present may be formed by the polymerisation of the sulphur monoxide :

(6) $5SO + NaOEt = NaEtS_5O_6$.
(7) $NaEtS_5O_6 + NaOH = Na_2S_5O_6 + EtOH$

or more probably by the decomposition of the trithionate :

(6a) $5Na_2S_3O_6 = Na_2S_5O_6 + Na_2S_4O_6 + 3Na_2SO_4 + 3SO_2$

(compare Debus, *loc. cit.*). The unpleasant odour of the solution may be due to the sodium ethyl salts present.

Attempt to isolate Sulphur Monoxide, SO.—Divers and Shimosé (*Ber.*, 1883, **16**, 1009) showed that the analogous tellurium compound, tellurium sulphoxide, $STeO_3$, decomposes when gradually heated in a vacuum to 235° with the production of tellurium monoxide; $STeO_3 = TeO + SO_2$, as confirmed by J. J. Doolan and one of us (J., 1924, **125**, 1403). It was possible that a similar reaction might take place with sulphur sesquioxide, although it was expected that the resulting sulphur monoxide would, if formed, be very much less stable. Sulphur sesquioxide was placed in a small Jena flask, and the latter exhausted to a pressure below 1 mm. of mercury. The flask was then gradually heated in a metal bath. As the temperature rose, the bluish-green solid slowly changed colour and signs of appreciable decomposition were apparent at about 70° : decomposition was complete at 95°. On further heating, the residue melted to an amber-coloured liquid which exhibited all the properties of sulphur.

It is possible that by employing a slower rate of heating in a very high vacuum from which all traces of moisture and oxygen have been excluded, sulphur monoxide might be isolated.

The "Colloidal Solution" Theory.—Although in the light of the experiments described in this paper there is little doubt that the bluish-green solid obtained by the interaction of sulphur and liquid sulphur trioxide is a definite chemical compound and not a "colloidal solution," it was considered advisable to obtain further evidence

against the latter view. Stress must be laid on the fact that pure sulphur is *insoluble* in pure sulphuric anhydride, although combination occurs with the formation of sulphur sesquioxide, which is also practically insoluble. It is only in the presence of small quantities of water that the substance dissolves to a blue solution.

Liquid sulphuric anhydride was added to sulphur contained in a glass tube, no precautions being taken to exclude moisture. After the violent reaction was over, the blue solution was poured off. An intense beam of light from a lantern was passed through the solution, but no Tyndall cone was visible.

If concentrated sulphuric acid be added gradually to the blue solution, and the latter examined after each addition for a Tyndall cone, it will be found that at a certain point corresponding to the green and brown solutions a marked Tyndall cone is visible, indicating that a substance (sulphur) of ultramicroscopic dimensions has separated. Further addition of sulphuric acid results in the separation of sulphur in a form visible to the naked eye.

Some of the blue liquid was carefully poured into water, and the resultant solution filtered from the precipitated sulphur. The filtrate contained trithionic acid (the main constituent), penta- and possibly tetra-thionic acids, sulphurous, sulphoxylic and sulphuric acids. If the deep blue solution be poured into a concentrated solution of potassium acetate, large quantities of potassium trithionate and little, if any, potassium tetra- and penta-thionates are present in the solution. It appears, therefore, that the tetra- and penta-thionates are produced from trithionates and nascent sulphur. Similar results are obtained with the green and brown solutions. One can accordingly conclude that the blue liquid is a *molecular* solution of sulphur sesquioxide in oleum, whilst the other coloured liquids produced by the dissolution of sulphur in fuming sulphuric acid of certain strengths are mixtures of colloidal solutions of sulphur and molecular solutions of sulphur sesquioxide.

In conclusion, the authors express their indebtedness to the Chemical Society for a grant which has partly defrayed the expenses incurred in the research.

CCIII.—*The Parachor and Chemical Constitution. Part I. Polar and Non-polar Valencies in Unsaturated Compounds.*

By Samuel Sugden, John Brent Reed, and Henry Wilkins.

(1) *Double Bonds and the Parachor.*

A new method of comparing molecular volumes by the use of a constant termed the "parachor" has been suggested by one of us (Sugden, J., 1924, **125**, 1177), who showed that this quantity is an additive function of certain atomic and structural constants by means of which the experimental values for a large number of organic compounds can be predicted with considerable accuracy.

Amongst the structural constants there evaluated is the effect of a double bond, which was found to add 23·2 units to the molecular parachor. Some of the data for this type of linking are given in Table I. The values of $[P]$ obs. given in the fourth column are calculated from observations by the investigators indicated by initials in the third column; full references are tabulated on p. 1535. The fifth column, headed $\Sigma[P]$, gives the sum of the atomic constants, and by subtracting this from the observed parachor the constant for the double bond in the last column is obtained.

Table I.

Parachor of non-polar double bonds.

Substance.	Formula.	Observer.	$[P]$ obs.	$\Sigma[P]$.	Double bond.
Ethylene	C_2H_4	M. & W.	99·5	78·0	21·5

Methyl hexyl ketone	$C_8H_{16}O$	M. & O.	355·7	332·0	23·7

This type of double linking has been found in a large number of organic compounds and gives an average increase of 23·2 units in the molecular parachor. The same value is found for double bonds between carbon and carbon, carbon and oxygen, carbon and sulphur, and nitrogen and oxygen atoms.

We have recently investigated a number of compounds of nitrogen, phosphorus, and sulphur, and have found several anomalous cases in which the presence of a double bond appears to have little or no effect on the parachor. The nitrogen compounds will be discussed

later; data for nine compounds of phosphorus and sulphur which show this anomaly are collected in Table II.

The atomic parachors for phosphorus and sulphur used in this table are $P = 37{\cdot}7$, and $S = 48{\cdot}2$; data on which they are based are presented on p. 1533. These values are consistent with those found for neighbouring elements in the periodic table

C.	N.	O.	F.	Si.	P.	S.	Cl.
4·8	12·5	20·0	25·7	12·0	37·7	48·2	54·3

and indicate a periodic variation of atomic parachors with increasing atomic number similar to the well-known property of atomic volume.*

The data presented in Tables I and II provide definite experimental evidence of the existence of two kinds of double bond, one, common in carbon compounds, but found also in compounds of other elements, which causes an increase in the parachor of 23·2 units, and another, present in derivatives of the oxyacids of sulphur and phosphorus, which lowers the molecular parachor by 1·6 units.

* The variation of the parachor with atomic number will be discussed more fully in a subsequent paper.

(2) *Electron Valency Theories.*

The compounds discussed in Table II belong without exception to the class in which the octet valency theories of Lewis (*J. Amer. Chem. Soc.*, 1916, **38**, 762) and Langmuir (*ibid.*, 1919, **41**, 868, 1543; 1920, **42**, 274) lead to a modification of the usual structural formulæ. The electronic formulæ for phosphoric, sulphurous, and sulphuric acids are indicated in formulæ II; if a valency bond is written for each pair of shared electrons, then formulæ III are obtained which

(I.) (II.) (III.) (IV.) (V.)

do not exhibit the double bonds found in the usual formulæ I. It has been pointed out by Lowry (*Trans. Faraday Soc.*, 1923, **18**, 285) that in formulæ II the oxygen atom sharing two valency electrons and holding six others will be negatively charged and that, therefore, a double bond is present but consists of one covalency and one electrovalency. Lowry suggests two methods (IV and V) of formulating this type of linking; we have in most cases used the first of these methods in which a barb on the valency bond indicates the direction in which an electron has been transferred. This choice was largely determined by the consideration that formulæ of type V are apt to be confused with other formulæ in current use in which + and − signs are attached to atoms without removing a valency bond and so do not indicate an electrovalency.

Lowry has proposed the terms "mixed" or "ionised" double bonds for the linking present in formulæ IV and V. The second of these has been criticised by Porter, and by Rankine (*Trans. Faraday Soc.*, 1923, **18**, 296) on the grounds that no free ions are present, and the term "mixed" is somewhat indefinite. The nomenclature of Lewis (*loc. cit.*) for the two kinds of single bond, namely, polar valencies and covalencies, is now in common use, and in conformity with this we propose to term the double bond

consisting of one covalency and one electrovalency a semipolar double bond. The linking commonly found in carbon compounds which consists of two covalencies will be termed a non-polar double bond.

That two kinds of double bond do exist is shown clearly by the experimental evidence summarised in Tables I and II. Further, from the fact that all the substances in Table II must, on the octet theory, contain semipolar double bonds it is evident that a parachor of — 1·6 must be assigned to this linking. The double bond with a parachor of 23·2 which is common in carbon compounds must therefore be identified as the non-polar double bond. The effect of these two types of linking on the parachor is readily understood when it is remembered that this constant is a measure of the molecular volume.

When any additive relation is analysed and reduced to a series of atomic and structural constants it is well known that the effect of a single bond cannot be separately evaluated and the assumption is usually made that the constant for this linking is zero. In the first paper on the parachor, this practice was followed and the atomic parachors there obtained include the effect, if any, of a single bond. The semipolar double bond consists of a covalency with a superimposed electrovalency; its effect should therefore be that of a single bond, which is taken as zero, plus the effect of the electrostatic attraction between the two charged atoms, which should cause a contraction in volume. This contraction would not be large, since it appears improbable that considerable distortion of the outer shells of electrons could occur. It is significant that with one exception all the substances in Table II give a negative value for the parachor of a semipolar double bond. The mean value, — 1·6, is of the same order of magnitude as the deviations of individual values from this mean, but the balance of evidence seems to be in favour of a real but small negative value for the contribution of this linking to the parachor.

For the non-polar double bond there is the large expansion in volume of 23·2 units. The original cubical atom of Lewis (*loc. cit.*) would give a smaller volume for two cubes placed face to face than for two cubes edge to edge. The statical theory of atomic structure is, however, quite incapable of accounting for all the modern work on spectra and atomic structure and in particular the successful application of relativity considerations to the explanation of the fine structure of spectral lines seems to provide conclusive evidence in favour of the dynamical theory. On this view, the large expansion in volume caused by a non-polar double bond indicates that when four shared electrons move in orbits around or between the

two atoms which share them the mutual interactions of the electrons thus crowded together lead to a looser structure of the molecule as a whole.

It should be emphasised here that, with this exception, none of the results of the Lewis-Langmuir theory discussed in the present paper is concerned with the assumption of a cubical atom or of a statical theory of atomic structure. All the deductions with regard to valency follow from two postulates: (*a*) that a covalency consists of two shared electrons, and (*b*) that the maximum number of electrons in the outer shell of any atom is eight. The latter assumption is limited to the first two periods of the periodic table by Langmuir, who, for elements of higher atomic number, postulates the existence of a greater number of electrons in the outer shell. This view has been modified by Bury (*J. Amer. Chem. Soc.*, 1921, **43**, 1602), who retains the outer shell of eight for all the inert gases, whilst Bohr's theory of atomic structure ("The Theory of Spectra and Atomic Structure," Cambridge University Press, 1922) retains eight electrons of greatest total quantum number, which may be regarded as valency electrons.

In this connexion the recent measurements of von Wartenberg (*Annalen*, 1924, **440**, 97) of the surface tension and density of osmium tetroxide are of considerable interest, as they provide an experimental test of the truth of the octet theory for an element of high atomic number. From these data, the parachor for osmium tetroxide is 154·0. On the assumption that the oxygens are held by four semipolar double bonds giving an outer shell of eight electrons, the parachor for osmium is 80·4; if the osmium atom in this compound has an outer shell of sixteen electrons, and four non-polar double bonds are present, then the parachor for osmium becomes — 18·8. Although there are no further data on osmium compounds available from which an independent value of the parachor can be obtained, it will be seen from the rough values for neighbouring elements given below that the value $Os = 80$ falls into place in the series which exhibits a minimum at gold. Hence it appears probable that osmium tetroxide has the structure $Os(=O)_4$ and that the octet rule may hold for elements of high atomic number as well as for the first two periods of the table.

Element	Os	Ir	Pt	Au	Hg	Tl	Pb	Bi
Atomic number	76	77	78	79	80	81	82	83
Parachor	80	—	68	54	70	—	90	92
Observer	—	—	Q.	Hey.	H.	—	H.	H.

In most of his formulæ Langmuir assumes wherever possible the formation of complete octets; in later theories (Latimer and Rodebush, *J. Amer. Chem. Soc.*, 1920, **42**, 1419), the existence of

sextets is postulated in certain cases. In particular, Lowry (J., 1923, **123**, 822) has suggested that most double bonds are semi-polar and states that " a double bond in organic chemistry usually reacts as if it contained one covalency and one electrovalency." This view has been criticised on stereochemical grounds (Sugden, *ibid.*, p. 1861; Farmer, *ibid.*, p. 2531) and, so far as the normal state of the molecule is concerned, it seems necessary to retain the conception of the non-polar double bond to account for the existence of geometrical isomerides. We have now, in the parachor, a method of determining experimentally what type of linking is present in a particular molecule, and the remainder of the present paper will be devoted to the discussion of the constitution of a number of unsaturated compounds of carbon, nitrogen, phosphorus, and sulphur for which experimental values of this constant are available.

(3) *Carbon Compounds.*

The non-polar double bond contributing 23·2 units to the molecular parachor appears, so far, to be the only type of double linking in which the carbon atom takes part. It has been found in more than one hundred carbon compounds including hydrocarbons, aldehydes, ketones, and esters. In particular, it may be mentioned that five pairs of geometrical isomerides recently examined in this laboratory have all been found to possess this type of linking.*

The case of the carbonates is of special interest. Langmuir gives the usual formula $(RO)_2C{=}O$ and points out that carbonates are not isomorphous with sulphites, which, on Lowry's method of formulation, have the structure $(RO)_2S{\rightleftharpoons}O$. On the other hand, Lowry suggests that the stability of oxyacids depends upon the presence of a positively charged nuclear atom and writes the carbonate ion $\overset{-}{O}{-}\overset{+}{C}\begin{matrix}\overset{-}{O}\\ \\ O\end{matrix}$. We have therefore measured the surface tension and density of two esters of carbonic acid with the following results :

		[*P*] calc.	
	[*P*] obs.	Non-polar.	Semipolar.
Diethyl carbonate	277·4	278·2	253·4
Diphenyl carbonate	467·4	468·0	443·2

It is evident that these compounds contain a non-polar double bond.

(4) *Nitrogen Compounds.*

The structure of nitrous acid presents the same ambiguity as that of carbonic acid. Langmuir gives the formula $RON{=}O$, whilst

* The data for these substances will be presented in a later paper.

Lowry assumes that a semipolar double bond is present and writes the nitrite ion $\bar{O}—\overset{+}{N}—\bar{O}$. We have therefore examined two esters of nitrous acid; it will be seen from the values found for the parachor that Langmuir's formula is correct and that the esters of nitrous acid, like those of carbonic acid, do not contain a positively charged nuclear atom.

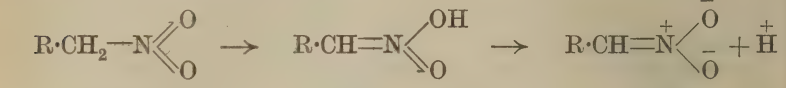
		[*P*] calc.	
	[*P*] obs.	Non-polar.	Semipolar.
n-Butyl nitrite	251·8	248·8	224·0
*iso*Amyl nitrite	287·4	287·8	263·0

The existence of two types of double bond gives no fewer than four possible formulæ for the nitro-group. These formulæ together with the corresponding values of the parachor for the group NO_2 are given below. Formula (VI) is of course excluded by the octet

98·9
(VI.)

74·1
(VII.)

49·3
(VIII.)



69·5
(IX.)

theory, and Langmuir adopted (VII) for this group, whilst Latimer and Rodebush and Lowry give the symmetrical formula (VIII). In the first paper on the parachor, it was pointed out that the experimental figures for this group were much smaller than would be expected for (VI) and it was assumed that the nitro-group possessed the alternative cyclic structure (IX). If this view is accepted, then from the experimental figures for nitro-compounds the constant for a three-membered ring is 21·5. An investigation of derivatives of *cyclo*propane and of ethylene oxide is now in progress, and the results so far obtained indicate that this value is too high and that the constant for a three-membered ring is approximately 17 units; this figure has been used in calculating the parachor given under (IX). The experimental data for nitro-compounds are tabulated below; the mean value of 74·2 is very close to the figure calculated for (VII), and (VI) and (VIII) are certainly excluded. The difference between (VII) and (IX) is not very large; the balance of evidence

Substance.	Formula.	Observer.	[*P*] obs.	Σ[*P*].	NO_2
Nitrogen peroxide	$NO_2 \cdot NO_2$	R. & S.	144·4	0	72·2
Nitromethane	$CH_3 \cdot NO_2$	M. & S.	132·0	56·1	75·9
		H. C. & R.	132·1	,,	76·0
Ethyl nitrate	$C_2H_5 \cdot O \cdot NO_2$	M. & S.	189·6	115·1	74·5
Nitrobenzene	$C_6H_5 \cdot NO_2$	S.	264·5	190·0	74·5
p-Nitrotoluene	$C_7H_7 \cdot NO_2$	,,	302·8	229·0	73·8

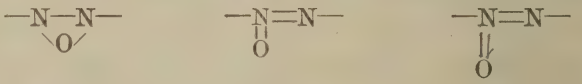
					Mean 74·2

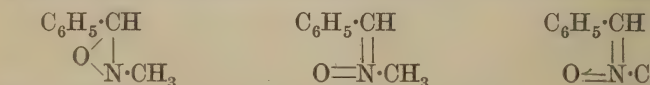


is in favour of (VII), although (IX) cannot be entirely excluded until the constant for a three-membered ring has been investigated more

fully. On chemical grounds, the Langmuir formula (VII) is to be preferred to the cyclic formula, as it suggests an explanation of the production of an *aci*-form from primary and secondary nitroparaffins as indicated in formulæ (X), (XI), and (XII). On this view the ion of the ψ-acid has the symmetrical formula (XII) suggested by Lowry, whilst the original nitro-compound contains only one semipolar double bond.

(X.) (XI.) (XII.)

Azoxy-compounds were at one time supposed to have the structure shown in (XIII). The existence of pairs of isomerides of a number of unsymmetrical azoxy-compounds (Angeli, *Ahrens Vort.*, 1913, **19**, 447) has led to the adoption of formula (XIV), which is, however, impossible on the octet theory, since the nitrogen atom is quinquecovalent. One of the double bonds must be semipolar and from electrochemical considerations and from the fact that azoxy-compounds are readily formed by the oxidation of azo-compounds it appears probable that this is the linking between nitrogen and



62·0 91·2 66·7
(XIII.) (XIV.) (XV.)

oxygen as shown in (XV). We have examined azoxybenzene and *o*-azoxytoluene with the following results :

	[*P*] obs.	Σ[*P*].	N_2O.
Azoxybenzene	444·7	380·0	64·7
o-Azoxytoluene	528·6	458·0	70·6

If Angeli's evidence for excluding formula (XIII) is accepted, these results give a satisfactory confirmation of (XV).

We are indebted to Dr. O. L. Brady for the loan of specimens of the *N*- and *O*-methyl ethers of benz*anti*aldoxime, the measurement of which has given the following results : *O*-Methyl ether, [*P*] obs. = 324·2 ; *N*-methyl ether, [*P*] obs. = 325·9. The *O*-ether must have the structure $C_6H_5{\cdot}CH{:}N{\cdot}O{\cdot}CH_3$, for which [*P*] calc. = 323·7, in good agreement with the observed value. For the *N*-ether the structures indicated in formulæ (XVI), (XVII), and (XVIII) are

317·5 346·9 321·2
(XVI.) (XVII.) (XVIII.)

possible. Here, again, the parachor confirms the octet theory in excluding formulæ such as (XVII) in which nitrogen is quinquecovalent. The observed figure, whilst rather high, is in favour of the modified nitrone structure (XVIII) with a semipolar double bond between nitrogen and oxygen.

The investigation of other types of quinquevalent nitrogen compounds will obviously be of considerable interest, and we hope to extend our work in this direction in the near future. For the three types so far examined, namely, nitro-compounds, azoxy-compounds, and *N*-oximino-ethers, the parachor confirms completely Langmuir's contention that the maximum covalency of nitrogen is four, the fifth valency, as pointed out by Lowry, being always an electrovalency.

(5) *Phosphorus Compounds.*

The following table contains the data from which the parachor for phosphorus has been deduced and does not call for further comment :

Substance.	Formula.	Observer.	$[P]$ obs.	$\Sigma[P]$.	Phosphorus
Phosphorus trichloride	PCl_3	M. & D.	199·0	162·9	36·1
		R. & S.	201·1	,,	38·2
Phosphorus tribromide...	PBr_3	S. R. & W.	242·9	204·0	38·9
Triphenylphosphine	$P(C_6H_5)_3$	W. & S.	607·7	570·0	37·7
					Mean 37·7

Data for phosphorus oxychloride and for two esters of phosphoric acid are contained in Table II. In accordance with the octet theory the double bond in these compounds is of the semipolar type.

(6) *Sulphur Compounds.*

The following table contains the data from which the parachor for sulphur has been calculated :

Substance.	Formula.	Observer.	$[P]$ obs.	$\Sigma[P]$.	Sulphur
Sulphur monochloride ...	S—Cl | S—Cl	R. & S.	205·1	108·6	48·2
Carbon disulphide	S=C=S	,,	144·7	51·2	46·8
		M. & T. M. & D.	143·6	,,	46·2
		H. C. & R.	142·9	,,	45·9
Ethyl mercaptan	C_2H_5·SH	M. & C.	162·9	112·2	50·7
Phenyl mercaptan.....	C_6H_5·SH	W. & S.	257·5	207·1	50·4
		M. & C.	256·4	,,	49·3
					Mean 48·2

The data for the acid chlorides and esters of sulphurous and sulphuric acids are contained in Table II; in accordance with the requirements of the octet theory these compounds all contain semipolar double bonds.

Data for a few thiocyanates and thiocarbimides are available and

present some points of interest. The table below shows that the double and triple bonds in these compounds are all of the non-polar type, since the values of $[P]$ calc. obtained on this assumption are in good agreement with the observed figures. The double bonds in carbon disulphide also are non-polar, hence the absence of such bonds in sulphites and sulphates cannot be ascribed to an intrinsic property of the sulphur atom which prevents the formation of normal linkings.

Substance.	Formula.	Observer.	$[P]$ obs.	$[P]$ calc.
Methyl thiocyanate	$CH_3{\cdot}S{\cdot}C{:}N$	Sch.	168·6	168·2
Ethyl thiocyanate	$C_2H_5{\cdot}S{\cdot}C{:}N$	R. & S.	210·7	207·2
		M. & C.	209·1	,,
Ethylthiocarbimide	$C_2H_5{\cdot}N{:}C{:}S$	,,	211·7	207·0
Allylthiocarbimide	$C_3H_5{\cdot}N{:}C{:}S$	,,	232·4	235·0
Phenylthiocarbimide	$C_6H_5{\cdot}N{:}C{:}S$	,,	304·1	301·9

Ethyl thiocyanate and ethylthiocarbimide have almost exactly the same parachor. This is further evidence for the value 46·6 for the triple bond (deduced from nitriles and acetylene derivatives), which is almost exactly twice the constant for a non-polar double bond (23·2). This suggests that each covalency in a multiple bond adds 23·2 units except the first one, which has no effect on the parachor.

In conclusion, it should be stated that in the present paper we are considering only the structure of the molecule in the " resting " state, whilst some of the formulæ discussed above (particularly those of Lowry) are intended to refer to the " reactive " condition. The arrangement of the atoms in the molecule in the " resting " state expressed in the structural formula is fundamental, not only for stereochemistry and for the discussion of physical properties, but as a basis for the consideration of the structure of the molecule in the " reactive " state. The structure of the activated molecule, if it differs perceptibly from that of the inactive molecule, must be simply related to it. We have shown in the present paper that whilst semipolar double bonds do occur in certain compounds they are not found in the non-activated molecules of carbon compounds generally. Lowry's hypothesis concerning carbon compounds may therefore be taken to mean that the activation of such compounds consists in the transference of an electron whereby a non-polar double bond is converted into one of the semipolar type. This view does give a simple connexion between the structures in the activated and non-activated states; it is beyond the scope of the present paper to discuss whether this hypothesis gives a satisfactory picture of the nature of the change involved in the process of activation. So far as the non-activated molecules are concerned, one general rule holds. Semipolar double bonds are only formed when each

atom except hydrogen has attained a complete octet and when the formation of a non-polar double bond would cause one or other of the atoms concerned to be associated with more than eight electrons, or, in other words, to have a covalency greater than four.

Summary.

(1) By means of the parachor the existence of two types of double bond has been demonstrated experimentally.

(2) These are identified as the non-polar and semipolar double bonds predicted by the octet theory as developed by Lewis, Langmuir, and Lowry.

(3) The nature of the double linking in a number of compounds of carbon, nitrogen, phosphorus, and sulphur has been investigated. In all the cases so far examined, semipolar double bonds are formed only when each atom, except hydrogen, has attained a complete octet. The octet is never exceeded and semipolar bonds are not found when their existence would necessitate the presence of a sextet around one or other of the atoms concerned. Sextets must be present in a few cases, as in the ion of triphenylmethyl chloride, but such structures are apparently rare.

(4) There is some evidence that the octet rule is not restricted to elements of the first two periods of the periodic table, but that it may hold for elements of higher atomic number.

Experimental.

New measurements have been made of the surface tension and density of sixteen substances, the former by the method of maximum bubble pressure (Sugden, J., 1922, **121**, 858; 1924, **125**, 27) and densities by means of the U-shaped pyknometer described in

the second of these papers. Three bubblers were used, the constants for which are given below:

App.	8b.	8c.	4d.
r_2	0·206	0·206	0·139 cm.
A	0·003730	0·005622	0·007767

In the tables below, the first column gives the apparatus used and the second column the temperature. The thermometers used were compared with a reference standard calibrated at the National Physical Laboratory and the observations are corrected for exposed stem. The difference of the pressures (expressed in dynes/cm.^{2}) required to liberate bubbles from the two tubes of the bubbler is given under P, D is the density of the liquid in g./c.c., and ϕ a correction factor calculated by the formula $\phi = 1 + 0{\cdot}69r_2gD/P$, where r_2 is the radius of the wide tube in cm. and $g = 981$ cm./sec.^{2}. γ is the surface tension in dynes/cm. calculated by the equation $\gamma = AP\phi$, where A is the apparatus constant determined by experiments with benzene. The parachor in the last column is then obtained by the expression $[P] = \gamma^{1/4}M/(D - d)$, where M is the molecular weight and d the density of the vapour in g./c.c. In most cases d is very small compared with D and can be neglected except at temperatures approaching the boiling point. A method of calculating approximate values of the vapour density is given as an appendix to this paper, and has been used in those cases in which $D - d$ has been placed at the head of column 4 in the tables below.

Ethyl carbonate was twice fractionally distilled; the portion used boiled at 125·2—125·8° (corr.)/756 mm. Densities determined: $D_{4°}^{13°}$ 0·974, $D_{4°}^{26°}$ 0·959, $D_{4°}^{42°}$ 0·941, $D_{4°}^{56·5°}$ 0·925; whence $D_{4°}^{t°} = 0{\cdot}988—0{\cdot}00113t$. Molecular weight 118·1.

Appendix.

Calculation of Vapour Density in the Neighbourhood of the Boiling Point.—The expression for the parachor involves the quantity $D - d$ and whilst the vapour density, d, is small compared with D in most cases, it becomes sufficiently large to affect the value of the parachor at temperatures approaching the boiling point. The value of d can, however, be calculated in the following manner with sufficient accuracy, since it only enters into the expression for the parachor as a small correction term.

If it is assumed that the gas laws hold for the vapour at the boiling point, then $d_b = 0·0122M/T_b$, where d_b is the vapour density at the boiling point T_b on the absolute scale at 760 mm., whilst M is the molecular weight. For lower temperatures, the variation of the vapour density is expressed with sufficient accuracy by the expression $\log_{10}d/d_b = 5(T/T_b - 1)$, where d is the vapour density at an absolute temperature, T. The accuracy with which this empirical expression can be used to calculate the vapour density is shown by the examples below. The values of d obs. are those given by Young (*Proc. Roy. Soc. Dublin*, 1910, **12**, 374).

CCIV.—*The System Chromium Trioxide–Boric Acid–Water.*

By Lionel Felix Gilbert.

This investigation was undertaken in continuation of previous work on the interaction of chromic acid with other acids (Gilbert, Buckley, and Masson, J., 1922, **121**, 1935; Mumford and Gilbert, J., 1923, **123**, 471).

The general experimental method was similar to that previously described (*loc. cit.*). The reaction tubes were partly filled with chromic acid solutions of different concentrations and with approximately known amounts of (ortho-) boric acid. The temperatures were again 25° and 45°.

Chromic acid was estimated iodometrically; total acidity was determined by titration of another sample with barium hydroxide, mannitol being added when the end-point, indicated by phenolphthalein, was near. As the commercial mannitol used had a slightly acid reaction, it was found convenient to make up a saturated stock solution in water and to neutralise from time to time with barium hydroxide. A few c.c. of the saturated solution were sufficient for each titration. Baryta was run into each suitably diluted mixture till a definite pink colour persisted for 3 minutes (compare Kolthoff, *Chem. Weekblad*, 1922, **19**, 449). This end-point is, however, sometimes difficult to determine accurately.

The results obtained are shown in Tables I and II, boric acid

being calculated as B_2O_3; the data of Table I are also shown graphically in the figure, in which the value shown for the solubility of boron trioxide in water at 25° (3·1% B_2O_3) has been calculated from Seidell's tables. It will be observed that the productions of the tie-lines connecting liquids with corresponding wet solids pass very closely to the point representing the composition of boric

acid (56·3% B_2O_3, marked by an arrow on the diagram). The same occurs when the data for 45° are plotted. Apparent irregularities at 45° in the boron trioxide content of solutions containing much chromium trioxide may be ascribed to analytical errors, especially as the end-point in the total acidity determination is not sharp, and the small amounts of boron trioxide are determined by

The solubility of boric acid in aqueous solutions of chromic acid at 25°.

difference. For these reasons no great accuracy is claimed for the boron trioxide determinations, but from the behaviour of the tie-lines there seems no doubt that the solid phase is always boric acid. The shape of the curve appears to indicate that the depression of solubility of boric acid as the concentration of chromic acid is raised is due chiefly to common ion (hydrogen) action.

CCV.—*The Dissociation Constants of Selenious Acid.*

By James Stuart Willcox and Edmund Brydges Rudhall Prideaux.

The first dissociation constant of selenious acid as determined by Ostwald ("Allgemeine Chemie," 1893) is $1{\cdot}59 \times 10^{-3}$ (conductivity method). The first and second constants as determined by Blanc (*J. Chim. phys.*, 1920, **18**, 39) are $2{\cdot}7 \times 10^{-3}$ and $5{\cdot}1 \times 10^{-8}$. Blanc, who stated his results with considerable reserve, appears to have used the following method. 0·595*N*-Sodium hydroxide was added, 0·1 c.c. at a time, to 0·0108*N*-selenious acid, and from the results obtained a conductivity–neutralisation curve was plotted, the rectilinear branches of which were produced in the usual manner to give the points of intersection corresponding to $NaHSeO_3$ and Na_2SeO_3. Solutions of the two salts prepared in accordance with these results were then treated with congo-red, phenolphthalein, or α-naphtholbenzoïn and matched against buffer solutions of acetate and phosphate. These indicators were admittedly unsatisfactory; at the second point, $p_H = 9{\cdot}7$, phenolphthalein was at the limit of its change, and the colour change of naphtholbenzoïn was not a pronounced one. Owing to the shape of the curve at these points, however, the accuracy in the determination of p_H was probably sufficient. We consider that a more serious source of error is the difficulty of finding the p_H points of inflection on the neutralisation–conductivity curve and of reproducing the correct stoicheiometrical proportions of acid and alkali with sufficient accuracy. For example, whilst 0·1 c.c. of alkali of the concentration employed by Blanc neutralises 6% of the acid, a change of 1% in the amount neutralised corresponds, from our curve, with a change of 1·0 in p_H value. We have therefore redetermined the constants with the aid of several indicators, including some of the modern ones, and at those stages of neutralisation at which the solutions are well buffered, and therefore not unduly sensitive to small errors in the addition of alkali.

Experimental.

A solution of selenium dioxide (prepared according to the usual method) in alcohol was filtered, and evaporated to dryness on the water-bath; the residue was recrystallised several times from hot water. To 20 c.c. of a 0·05*M*-solution of this selenious acid (factor 0·97, found by analysis, the acid being converted into and weighed as selenium) were added measured volumes of 0·189*N*-sodium hydroxide, free from carbonate, in the presence of suitable indicators. The colours were matched, in Nessler glasses, against

those of solutions obtained by the addition of the same alkali to 20 c.c. of the British Drug Houses universal indicator (J., 1924, **125**, 427) containing the same number of drops of indicator, and hence the hydrion concentrations corresponding to each 3% of acid neutralised were obtained.

Calculation of K_1 *and* K_2.—In the following tables x is the number of c.c. of alkali added to 20 c.c. of the selenious acid solution. The percentage of acid neutralised is calculated from the value of x, and the total concentration, c, of the acid is $0{\cdot}97/(20 + x)$. The concentration of the sodium salt, [NaHA], and of the anion derived from this, is $0{\cdot}189x/(20 + x)$. Individual values of h + [NaHA] and $c - (h + [\mathrm{NaHA}])$ introduced into the equation

$$K_1 = h(h + [\mathrm{NaHA}])/\{c - (h + [\mathrm{NaHA}])\} \quad . \quad . \quad (a)$$

give the values of K_1 up to $p_{\mathrm{H}} = 3{\cdot}9$; the results marked * in the tables have been used. For values of p_{H} a little greater than 3 up to 4, equation (1) (J., 1924, **125**, 427), which does not take account of the total concentration, may be used, terms containing K_2 being omitted; *i.e.*,

$$K_1 = Rh/(1 - R) \quad . \quad . \quad . \quad . \quad . \quad . \quad (1)$$

where R = equivalents of alkali added to 1 mol. of acid = % acid neutralised — 50. For values of p_{H} from 6·0 upwards, K_2 is calculated from the equation

$$K_2 = h(R - 1)/(2 - R) \quad . \quad . \quad . \quad . \quad (2)$$

The figures marked † in the tables have been introduced into equation (1), those marked ‡ into equation (2).

FIG. 1.

The neutralisation of selenious acid.

⊙ *Experimental.* + *Calculated from present constants.* × *Calculated from Blanc's constants.*

The mean values of $10^3 \times K_1$ calculated from equations (*a*) and (1) above are: Thymol-blue, 4·18*; bromphenol-blue, 3·3*, 3·22†; congo-red, 4·32*; B.D.H. indicator, 4·37*†. Allowance being made for the number of observations, the general mean is: $K_1 = 4{\cdot}0 \times 10^{-3}$.

The mean values of $10^8 \times K_2$ are: B.D.H. indicator, 0·62;

litmus, 1·15; phenol-red, 0·72; thymol-blue, 1·04. The general mean is : $K_2 = 0{\cdot}87 \times 10^{-8}$.

A few values of p_H calculated from these constants are represented by + on the graph, *i.e.* :

% acid neut.	0	50	50·5	54·0	74·4	95·25	100
p_H ..... =	1·86	5·23	6	7	8	9	10·35

The experimental results are represented by circles, and the values calculated from Blanc's constants, at a molarity of 0·05, by ×.

% acid neut. =	0	0·7	12·5	35·5	41·5	47·7	50·05	50·4
p_H ..... =	1·99	2	2·3	3·0	3·3	4·0	5	5·3
% acid neut. =	52·4	54·6	66·5	75·25	91·5	95·5	99·05	
p_H ..... =	6·0	6·3	7·0	7·3	8·0	8·3	9·0	

The first branch of Blanc's curve lies distinctly above ours. The second branch of our curve has a very different position from Blanc's, the alkalinities throughout being greater.

The end-points in the titration of 0·05*N*-acid are :

	$NaHSeO_3$.	Na_2SeO_3.
Blanc	4·93	9·70
W. & P.	5·23	10·35

The choice of *p*-nitrophenol for the first titration is justified, and cochineal, lacmoid, and resazurin also should be suitable.

The second end-point does not of course give so accurate a titration, but we have obtained fair results with thymolphthalein (to a full blue). Tropæolin O is not so good.

UNIVERSITY COLLEGE, NOTTINGHAM. [*Received, April 27th,* 1925.]

CCVI.—*The Interaction of Carbon Dioxide and Hydrogen on the Surface of Tungsten.*

By CYRIL NORMAN HINSHELWOOD and CHARLES ROSS PRICHARD.

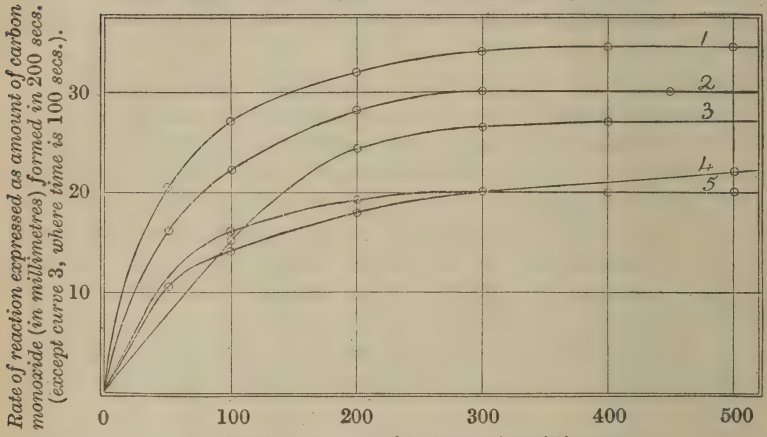
ACCORDING to Taylor (*Proc. Roy. Soc.*, 1925, *A*, **108**, 105), only a small fraction of a catalytic surface is necessarily active and this fraction is a function, not merely of the surface itself, but also of the reaction catalysed. This theory, which is based upon evidence of different kinds, was very helpful in interpreting the results of our investigation of the interaction of carbon dioxide and hydrogen on the surface of platinum, and other experiments (this vol., p. 806), where complete lack of correlation was sometimes found between total adsorption and that part of the adsorption which determines the kinetics of heterogeneous reactions. These all lend support to Taylor's view that catalysis may be confined to certain active centres.

In continuation, the interaction of carbon dioxide and hydrogen on the surface of tungsten has been investigated. Kinetically, the reaction is somewhat different from the reaction on the surface of platinum, but there is equally good evidence that it is determined by the adsorption of carbon dioxide and hydrogen on active centres. From measurements of the velocity of reaction, it must be inferred that saturation of the active surface with respect to each of the gases is reached without any appreciable displacement of the other. Saturation may be reached simultaneously and independently with respect to each. This seems to show that those centres which adsorb the carbon dioxide are not the same as those which adsorb the hydrogen, and that interaction requires the adsorption of molecules of each on adjacent centres of the appropriate kind.

The experimental method was essentially the same as that used in the previous investigation except that the reaction vessel was now a tungsten filament Osram lamp (30 volt, half-watt) to which were sealed capillaries leading to gas-holders, manometer and Gaede pump. The temperature of the filament was calculated from its resistance with the aid of Langmuir's data for the variation of the resistance of tungsten with temperature (*Physical Rev.*, 1916, **7**, 159).

The reaction was rendered irreversible by the absorption of the water formed in concentrated sulphuric acid in the bottom of the reaction vessel.

It was shown by analysis that under the conditions of the experiments the only reaction taking place to an appreciable extent was the simple change $H_2 + CO_2 = H_2O + CO$.



Pure carbon monoxide rapidly attacks a heated tungsten wire with formation of carbonyl, and the resistance of the wire increases very rapidly. Under the conditions of our experiments, however, the carbon monoxide produced in the reaction had no effect on the wire. Whether this was because the pressure was not great enough or because the other gases had a protecting action on the wire was not investigated, but it was ascertained with the greatest care that the resistance of the wire remained constant and, an even more delicate test, its catalytic activity remained remarkably steady. Control experiments under standard conditions were repeatedly made to ensure that the results were not being vitiated by any change in the wire.

Influence of the Pressure of the Hydrogen on the Rate of the Reaction.—Experiments were made with a constant pressure of carbon dioxide and varying hydrogen pressures. The rate of reaction first increases with the pressure of hydrogen and then remains constant, showing that the active part of the surface becomes saturated with hydrogen.

This is illustrated in Fig. 1. The curves were obtained with four different wires, the saturation capacities of which were naturally slightly different. The reaction–time curves are almost linear over a considerable range, so that the amount of carbon monoxide formed in 100 or 200 seconds is a quite legitimate and convenient measure of the initial rate of reaction. The following figures were obtained with one of the four wires used.

FIG. 1.

Relation between rate of reaction and hydrogen pressure.

(1) *Wire* 1, 50 *mm.* CO_2, 1182°; (2) *Wire* 3, 50 *mm.* CO_2, 1135°; (3) *Wire* 1, 100 *mm.* CO_2, 1182°; (4) *Wire* 5, 50 *mm.* CO_2, 1027°; (5) *Wire* 2, 50 *mm.* CO_2, 1215°.

TABLE I.

Influence of Hydrogen Pressure.

Pressure of carbon dioxide = 50 mm. in each case. Temperature = 1182°.

Press. of H_2 (mm.) $[H_2]$.	% CO_2 changed to CO in 100 sec.	200 sec.	300 sec.	Press. of H_2 (mm.) $[H_2]$.	% CO_2 changed to CO in 100 sec.	200 sec.	300 sec.
50	22	41	56	300	40	68	85
100	30	54	74	400	41	70	86
200	36	63	82	500	41	66	84

If σ is the fraction of the active surface covered with hydrogen, then the simplest type of adsorption equilibrium is expressed by $k_1(1 - \sigma)[H_2] = k_2\sigma$, whence $\sigma = [H_2]/(k_2/k_1 + [H_2])$.

Taking the readings at 100 seconds as proportional to initial velocities, a procedure justified by the almost linear form of the curves, and calling x the limiting rate at infinite hydrogen pressure,

we have for $[H_2] = 50$, $\sigma = 22/x$ and for $[H_2] = 100$, $\sigma = 30/x$; whence we find $x = 47$ and $\sigma = [H_2]/(57 + [H_2])$.

The following table gives the values of σ calculated from this equation, and also calculated on the supposition that the fraction of the active surface covered with hydrogen is given by the ratio of the actual velocity to the limiting velocity. This is referred to as $\sigma_{obs.}$

$[H_2]$	(50)	(100)	200	300
$\sigma_{obs.}$	(0·47)	(0·64)	0·77	0·85
$\sigma_{calc.}$	(0·47)	(0·64)	0·78	0·84

At 400 and 500 mm. $\sigma_{obs.}$ falls below the calculated value, that is to say, the rate of reaction does not increase quite as rapidly as it should. Indeed the calculated limiting rate is 47% of carbon dioxide transformed in 100 seconds, whilst the observed limiting rate is 41%. The hydrogen therefore has a certain displacing action on the carbon dioxide at higher pressures, but, as the table shows, this is negligible up to 300 mm. and even above this the displacing action is not wholesale as it would be if both gases competed for the same portions of the surface. Other wires gave similar results as the diagram shows, but detailed figures need not be given.

Influence of the Pressure of the Carbon Dioxide on the Rate of Reaction.—This is similar to that of the hydrogen pressure, but saturation is reached at lower pressures and a slight diminution in the rate of reaction occurs at the highest pressures. This indicates that the carbon dioxide can displace hydrogen to some slight extent, but the effect is almost negligible compared with that found when a platinum wire is used.

Table II.

Influence of Carbon Dioxide Pressure.

Pressure of hydrogen = 50 mm. in each case. Temperature = 1182°.

Taking the saturation value as 25 and ignoring the slight displacement effect at 400 and 500 mm., $\sigma_{CO_2} = [CO_2]/(5 + [CO_2])$ is found to represent the fraction of the active surface covered with carbon dioxide at various pressures.

Typical curves obtained with various wires are shown in Fig. 2.

The Kinetics of the Reaction.—We have seen that the surface can apparently become saturated with hydrogen and carbon dioxide independently. Thus, for example, the experiments in which the pressure of the carbon dioxide is varied show that the surface is nearly saturated with respect to this gas at 50 mm. pressure. Yet with 50 mm. of carbon dioxide the hydrogen pressure can be increased from 200 to 500 mm. with little change in the reaction rate. If hydrogen displaced carbon dioxide, the rate would pass through a pronounced maximum, as it does in the experiments where carbon dioxide displaces hydrogen from certain active points on platinum surfaces.

FIG. 2.

Relation between rate of reaction and carbon dioxide pressure.

(1) *Wire* 1, 100 *mm.* H_2, 1182°; (2) *Wire* 1, 50 *mm.* H_2, 1182°; (3) *Wire* 2, 100 *mm.* H_2, 1215°; (4) *Wire* 3, 50 *mm.* H_2, 1135°; (5) *Wire* 5, 50 *mm.* H_2, 1027°.

If we have nearly independent adsorptions in this way, the simplest assumption to make is that the rate of reaction is proportional to $\sigma_{H_2}\sigma_{CO_2}$.

From the results of the previous section we should therefore have

$$\text{Rate of reaction} = k \cdot \frac{[H_2]}{(57 + [H_2])} \cdot \frac{[CO_2]}{(5 + [CO_2])}.$$

The factors $[H_2]/(57 + [H_2])$ and $[CO_2]/(5 + [CO_2])$ were found from experiments with pressures of 50 mm. of carbon dioxide and hydrogen respectively. Using them, we may test the constancy of k at other pressures. The following are some typical experiments, all carried out at 1182°.

	Amount of carbon monoxide (mm.) formed in time t.			
t (seconds).	50 mm. H_2 \ 50 mm. CO_2 /	100 mm. H_2 \ 100 mm. CO_2 /	200 mm. H_2 \ 200 mm. CO_2 /	300 mm. H_2 \ 300 mm. CO_2 /
100	11·5	18·5	23	29
200	20	34	46	58
300	27	46	64	87
400	32	56	87	116
500	36·5	—	105	—
	$k = 27$	$k = 30$	$k = 30$	$k = 35$

The following table gives values of k for a number of similar experiments. In every case the rate of reaction from which k is obtained is expressed as the amount of carbon monoxide produced in 100 seconds. All the figures refer to wire 1.

Press. of CO_2 (mm.).	Press. of H_2 (mm.).	k.	Press. of CO_2 (mm.).	Press. of H_2 (mm.).	k.
50	100	26	100	50	25·5
100	100	25	100	100	25
150	100	27·5	100	150	27
200	100	27·5	100	200	31·5
300	100	27	100	300	31
500	100	27			

The idea of independent adsorption of the two reacting substances thus seems to be substantiated.

The Influence of Temperature.—The temperature coefficient of the reaction rate was measured with one only of the wires. Experiments were made with a standard mixture of hydrogen (100 mm.) and carbon dioxide (100 mm.) at each temperature.

CO (pressure in mm.) formed in	Temperature.

300 „	7	16	33	52	—

The value of the apparent heat of activation calculated from these by means of the Arrhenius formula is 30,000 calories.

Summary.

The rate of the reaction $H_2 + CO_2 = H_2O + CO$ on the surface of a tungsten filament heated to temperatures between 1000° and 1300° is proportional to $\sigma_{H_2} \cdot \sigma_{CO_2}$, where σ_{H_2} and σ_{CO_2} are the fractions of certain active parts of the surface which are covered with adsorbed hydrogen and carbon dioxide respectively.

The adsorption of each gas on the active centres is almost independent of the pressure of the other. This shows that the whole surface is not active, but that only certain parts are able to adsorb hydrogen and carbon dioxide and cause them to react. The parts which adsorb hydrogen in this way are different from those which

adsorb and render reactive the carbon dioxide. Interaction apparently takes place when molecules of the two gases are adsorbed on adjacent centres of the appropriate kind.

We are indebted to the Royal Society and to the Chemical Society for grants with which some of the apparatus used was purchased.

CCVII.—*The Relation of Homogeneous to Catalysed Reactions. The Catalytic Decomposition of Hydrogen Iodide on the Surface of Gold.*

By CYRIL NORMAN HINSHELWOOD and CHARLES ROSS PRICHARD.

A HETEROGENEOUS catalyst may influence a reaction in two ways. It may modify the mechanism of the chemical change by allowing it to proceed along another path. It may also facilitate the transformation by lowering the energy of activation, *i.e.* the energy which must be imparted to the reacting molecules before they can be transformed chemically. There is very good evidence that in homogeneous chemical changes this energy of activation is the quantity which plays the decisive part in determining the rate at which the reaction can take place at a given temperature. It must therefore be expected to have considerable significance in catalytic reactions also.

The modification of reaction mechanisms is exemplified by the thermal decomposition of nitrous oxide. The homogeneous reaction is bimolecular (*Proc. Roy. Soc.*, 1924, *A*, **106**, 284). On the surface of platinum or gold the change becomes unimolecular (*Proc. Roy. Soc.*, 1925, *A*, **108**, 211; this vol., p. 327). It is resolved into the stages $N_2O = N_2 + O$ and $O + O = O_2$. The affinity of the metals for atomic oxygen renders possible the first stage, which could only take place homogeneously if a very large amount of energy were communicated to the nitrous oxide molecule, for the production of free oxygen atoms is a highly endothermic process. The metal acts as a resting place for the oxygen atoms until they meet others of their kind. It appears also that on the surface of platinum ammonia decomposes unimolecularly (this vol., p. 1105), whilst, although the homogeneous reaction has not been actually observed, it is almost certain from analogy with known examples that it would be bimolecular.

The question of the influence of the second factor, the lowering of the energy of activation, has not received a conclusive answer. The nitrous oxide decomposition is the only example hitherto investigated in which a homogeneous reaction has been quantitatively compared with the corresponding heterogeneous change on one or more surfaces. The homogeneous transformation requires the collision of two molecules possessing a combined energy of 58,500 calories. This quantity can be obtained from the temperature coefficient of the reaction velocity. The corresponding heats of activation obtained in the same way from the temperature coefficients of the surface reactions on gold and platinum are 29,000 and 32,500 calories, respectively. But it is not quite justifiable to compare these various values directly. In the case of bimolecular homogeneous reactions, there is ample evidence that the heat of activation is a real measure of the energy that the colliding molecules must possess in order that they may be transformed (compare J., 1924, **125**, 1841). In heterogeneous reactions, however, the temperature coefficient of the reaction velocity depends partly on the variation with temperature of the amount of reactant actually adsorbed on the surface, and therefore the value of E obtained from the formula $d \log k/dT = E/RT^2$ requires correction before it represents the energy which the adsorbed molecules must acquire in order to undergo chemical change (compare J., 1923, **123**, 1014). There exists a real temperature coefficient of the rate of reaction of the molecules actually adsorbed. This would furnish a true value for the heat of activation having direct physical meaning, but since the relative numbers of molecules of reactant adsorbed at different temperatures are not known, the correction which would make the observed reaction velocities at various temperatures directly comparable with one another cannot be applied. The adsorption of the reacting gas diminishes with temperature. This acts in opposition to the normal increase of the true reaction rate with temperature and thus the observed temperature coefficient is less than the true value. Thus $E_{obs.}$ is too small. It is likely that the necessary correction is quite small compared with 30,000 calories, so that we are probably safe in concluding that the total activation required in each of the surface reactions of the nitrous oxide is much less than in the homogeneous reaction. It is true that the 58,500 calories refers to 2 gram-molecules, whilst the values 29,000 and 32,500 refer to 1 molecule only, the catalytic reactions being unimolecular. But the fact remains that the total activation necessary in the surface reaction is very much less, since in the homogeneous reaction one molecule is not activated without the other.

These conclusions are interesting, but not free from a little uncertainty, arising from the lack of knowledge about the exact correction that should be applied to the experimentally found heats of activation in the surface reactions. The object of this paper is to present results which are free from any such uncertainty.

The difficulty to be overcome is the unknown variation in the degree of adsorption of the reacting substance at different temperatures. The difficulty vanishes in one special case, namely, when the surface is saturated at all temperatures so that the number of molecules present is always the same. This state of affairs is recognised by the fact that the absolute rate of reaction becomes independent of the pressure of the reacting gas, or, in other words, the reaction is of zero order.

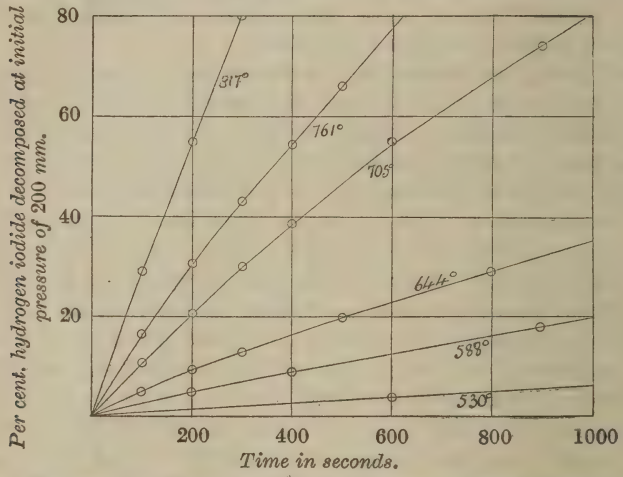
The heterogeneous decomposition of ammonia on the surface of tungsten was recently found to be approximately of zero order (this vol., p. 1105) and results are described in the present paper to show that the decomposition of hydrogen iodide on the surface of gold is also of this type. The observed heats of activation in these reactions are therefore equal to the true values and may be compared directly with the values for the corresponding homogeneous reactions.

The value found for the decomposition of hydrogen iodide on the surface of gold is 25,000 calories. Since the reaction is of zero order, it is impossible to tell whether one or two molecules of hydrogen iodide are involved in it; to decide this point is only possible with sparsely covered surfaces—when the surface is saturated, it makes no difference to the actual kinetics of the reaction whether one molecule decomposes spontaneously or two adjacent ones interact. From analogy with the case of nitrous oxide, it seems probable that only one is involved. However this may be, the total heat of activation is again very much lower than that of the homogeneous reaction, which amounts to 44,000 calories.

With regard to ammonia the homogeneous reaction has not been observed, but its velocity has been shown to be negligible up to 1050° (this vol., p. 1105). From analogy with the decompositions of ozone, chlorine monoxide, hydrogen iodide, and nitrous oxide, it seems certain that it would be found to be bimolecular, and from the table given by Hinshelwood and Hughes (J., 1924, **125**, 1841), showing the relation between the heat of activation of bimolecular reactions and the temperatures at which they attain a given rate, it is obvious that the heat of activation in the homogeneous ammonia decomposition cannot be less than about 80,000 calories. The heat of activation of the reaction on the surface of tungsten was found to be 38,700 calories.

The following table gives a summary of the various relationships :

Reaction. Thermal decomposition of	Total activation required for the homogeneous change (bimolecular).	Total activation required for the heterogeneous change (probably or certainly unimolecular).
Hydrogen iodide	44,000	25,000 (gold)
Nitrous oxide	58,500	29,000 * (gold)
		32,500 * (platinum)
Ammonia	probably >80,000	39,000 (tungsten)



* + small correction ?

(The decomposition of ammonia on platinum cannot be brought into this table because it is retarded by the hydrogen formed in such a manner as to make the temperature coefficient mainly a function of the hydrogen adsorption.)

It will be observed that the values for the surface reactions are in each case approximately half the corresponding values for the homogeneous reactions. There is perhaps some temptation to suppose that the numerical ratio of 2 : 1 would be exact if perfectly accurate data could be obtained, and to interpret this in terms of activation by one and two quanta. This, however, is not admissible. Activation doubtless takes place in accordance with quantum dynamics, but the characteristic quanta involved in reactions taking place under physical conditions so different as to lead to completely different reaction rates cannot be expected to bear any simple numerical relation to one another. When the stability of a molecule is profoundly modified, it can only be as the result of a rearrangement of the internal forces which will also lead to a fundamental change in the size of the quanta. We must at present content ourselves with observing the greatly decreased heat of activation in the surface reactions and the probable change from bimolecular to unimolecular processes.

The Catalytic Decomposition of Hydrogen Iodide on Gold.—The experimental procedure for measuring the rate of decomposition of hydrogen iodide on the surface of a heated gold wire was exactly as described in previous papers (this vol., p. 327; *Proc. Roy. Soc.*, 1925, *A*, **108**, 211). The iodine liberated in the reaction was condensed on the walls of the vessel, which was kept at 0°. The vapour pressure of iodine at 0° is negligible. The reaction $2HI = H_2 + I_2$ is therefore accompanied by a decrease in pressure which allows its rate to be measured. There existed the possibility that the gold wire might be attacked by the iodine. Gold iodide is, however, decomposed at 200°, and the lowest temperature of the wire in the experiments was 530°. Iodine, therefore, under the experimental conditions never had the opportunity of reaching

the wire except at a temperature several hundred degrees above that at which gold iodide ceases to be capable of existence. It should be mentioned that gold iodide is apparently endothermic, although F. Meyer finds that the interaction of gold and iodine diminishes with temperature and almost ceases above 190°. This leaves it just possible that there might be slight interaction again at higher temperatures. But it is in the highest degree unlikely that the dissociation pressure of gold iodide would at 800° have fallen below the minute iodine pressure prevailing in these experiments, and the special experiments made to test for interaction showed that it was in fact inappreciable. The change in pressure observed when the decomposition was complete coincided with the

Catalytic decomposition of hydrogen iodide with surface of gold. Initial pressure 200 mm.

theoretical value. The resistance of the wire at 0° was measured from time to time and found not to vary as it would if the gold were being attacked, and the catalytic activity remained constant. The action of the gold may therefore be regarded as purely catalytic in the usual sense of the term.

The hydrogen iodide was prepared by dropping syrupy phosphoric acid on a mixture of finely divided potassium iodide and phosphorus pentoxide in an apparatus made entirely of glass. The gas was dried by passage over phosphorus pentoxide and condensed in a bulb surrounded by liquid air. While the hydrogen iodide was kept solid, any non-condensible impurities such as hydrogen were pumped away. About one-third of the liquid was then allowed to distil into an evacuated blackened glass bulb, provided with a tap. This bulb was then sealed to the decomposition apparatus.

Since hydrogen iodide attacks mercury, special precautions have to be taken in measuring the reaction velocity with the aid of a mercury manometer. Fortunately, it was found that hydrogen has no influence on the velocity of decomposition and it was therefore convenient to allow the reaction always to proceed in the presence of a certain amount of hydrogen, which was let into the apparatus first and thus acted as a buffer in the capillary manometer, protecting the mercury completely from any attack by the hydrogen iodide.

The following figures show that hydrogen has no effect on the reaction velocity.

Temp. 705°. HI alone (200 mm.). Amt. decomposed in 200 secs. = 32 mm. HI (200 mm.), H_2 (100 mm.). Amt. decomposed in 200 secs. = 34 mm.

Temperature 705°.	Amount of hydrogen iodide decomposed (mm.).		
Time (sec.).	50 mm. H_2 \ 100 mm. HI /	100 mm. H_2 \ 100 mm. HI /	200 mm. H_2 \ 100 mm. HI /
100	19	18	18
200	35	36	34
300	49	50	47
400	61	62	59
500	72	72	68

The absolute amount of hydrogen iodide decomposed in unit time is nearly independent of its pressure. This may be seen by an inspection of the following results. It will also be observed that the curves shown in the figure are not far from linear.

Temperature 705°. 100 Mm. of hydrogen present in each expt.

Time (sec.).	Amount of hydrogen iodide decomposed. 100 mm. HI.		200 mm. HI.	400 mm. HI.	Time (sec.).	Amount of hydrogen iodide decomposed. 100 mm. HI.		200 mm. HI.	400 mm. HI.
100	18	18	22	26	800	88	90	—	—
200	34	36	42	46	900	—	—	148	174
300	48	50	60	—	1200	—	—	—	224
400	60	62	76	76	1500	—	—	—	266
500	69	72	—	—	1800	—	—	—	308
600	77	79	110	118	2100	—	—	—	334
700	—	—	—	—	2400	—	—	—	352

Temperature 588°.

Time (secs.).	Amount of hydrogen iodide decomposed. 200 mm. HI.	400 mm. HI.
200	10	11
400	18	—
500	—	26
900	36	44
1600	54	—

Temperature 817°.

Time (secs.).	Amount of hydrogen iodide decomposed. 100 mm. HI.	200 mm. HI.	400 mm. HI.
100	58	58	76
200	84	111	144
300	92	162	196
400	—	—	252
500	—	—	298
600	—	—	334
700	—	—	354

The reaction is thus nearly of zero order, a fourfold increase in pressure increasing the absolute reaction rate only in the ratio 1 : 1·45 at 705° and 1 : 1·46 at 817° instead of in the ratio 1 : 4·0, as would happen if the change were according to the unimolecular law.

The nearness of this ratio to unity shows that saturation of the surface is nearly reached at both temperatures and the equality of the ratio at the two temperatures shows that the deviation from saturation at a given pressure cannot differ appreciably in the two cases. The temperature coefficient should therefore be independent of the variation of adsorption with temperature.

The influence of temperature on the velocity of reaction was measured from 530° to 817°. From the slope of the line obtained by plotting the reciprocal of the absolute temperature against log t, where t is the time taken for 50 mm. out of an initial 200 mm. of hydrogen iodide to decompose, a value of 25,000 calories is found for the heat of activation. The same value is found from the times required for 20 mm. out of the initial 200 mm. to react.

Absolute temperature.....	803°	861°	917°	978°	1034°	1090°
t (seconds)	6000	1450	650	242	157	85

A discussion of these results has been given in the earlier part of the paper.

Summary and General Conclusions.

It is shown that the thermal decomposition of hydrogen iodide on the surface of a heated gold wire is a catalytic reaction the rate of which is almost independent of the pressure of the gas and uninfluenced by the presence of hydrogen.

It is pointed out that such " zero-order " reactions are of special importance because their temperature coefficients are not influenced by the changing degree of adsorption of the reactant. The " heat of activation " may therefore be expected to have, without correction, the direct physical significance that it possesses in the case of homogeneous reactions.

On the basis of the results described in this and previous papers it is now possible to make a comparison between the mechanism of homogeneous reactions and that of the corresponding reactions catalysed by surfaces.

The reactions considered are the homogeneous thermal decomposition of nitrous oxide, hydrogen iodide, and ammonia, and the heterogeneous decomposition of nitrous oxide on platinum and gold, of hydrogen iodide on gold, and of ammonia on tungsten.

It is shown that the surface reactions have heats of activation only about half as great as those of the bimolecular homogeneous changes. But the surface reactions have been shown in some cases

to involve only one molecule, and this is probably the general rule. Thus the function of the surfaces in the reactions considered is to permit the occurrence of a unimolecular process instead of a bimolecular process requiring an energy of activation about twice as great.

[*Received, May 26th,* 1925.]

CCVIII.—*The Adsorption of Water from the Gas Phase on Plane Surfaces of Glass and Platinum.*

By IVAN ROY MCHAFFIE and SAM LENHER.

THE results of numerous investigators (Ihmori, *Ann. Phys. Chem.*, 1887, **31**, 1006; Briggs, *J. Physical Chem.*, 1905, **9**, 617; Trouton, *Proc. Roy. Soc.*, 1907, *A*, **79**, 383; Katz, *Proc. K. Akad. Wetensch. Amsterdam*, 1912, **15**, 445; Parks, *Phil. Mag.*, 1903, **6**, 517) would indicate that the film of water adsorbed on a glass surface at the ordinary temperature from the gas phase may be of more than monomolecular thickness when the pressure of water vapour is not far removed from the saturation value at the corresponding temperature. Langmuir (*Proc. Faraday Soc.*, 1922, 607; *Physical Rev.*, 1915, **6**, 79), in stating his important theory of adsorption, says, "Only when we have saturated vapours should we ever get films of gas molecules of more than monomolecular thickness." The present research is a study of the films of water adsorbed from the gas phase on plane glass and platinum surfaces when the pressure of the water vapour is near the saturation value.

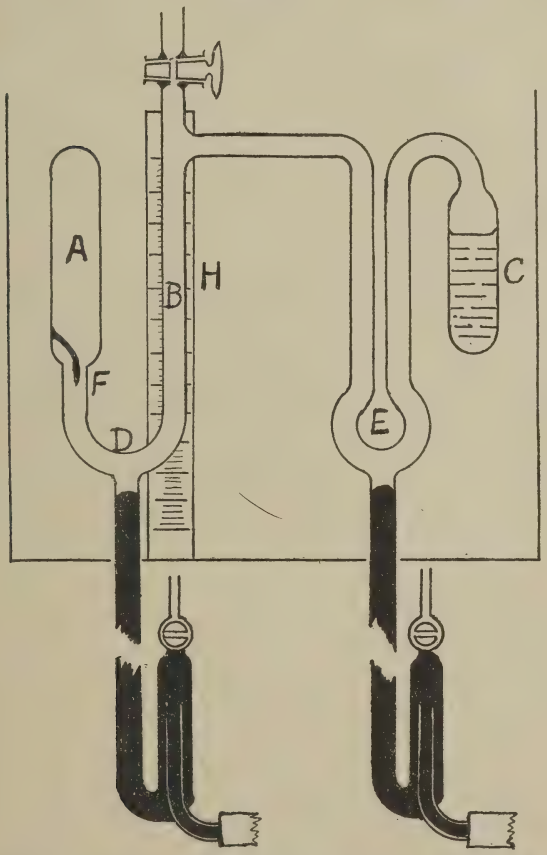
The method employed is such that a direct measurement of the number of molecules adsorbed from a saturated vapour on a known area of a plane surface can be made. The phenomenon on which this study of adsorption is based was observed by one of us in another research and may be briefly stated as follows. Consider a closed, evacuated system into which a limited mass of water is introduced. This mass must be such that at some higher temperature the entire amount will be in the state of vapour, but at the initial temperature part of the water exists in the liquid phase, the remainder being in the gas phase. The pressure in the system due to water vapour should be equal to the vapour pressure of water at the initial tem-

perature, and the pressure at successively increasing temperatures should be equal to the vapour pressure of water at the corresponding temperatures until all of the water present has passed into the gaseous phase.

The increases of pressure above this value due to increasing temperatures should be proportional to the absolute temperature. If the temperatures be plotted as abscissæ and the corresponding pressures as ordinates, the curve obtained from these theoretical considerations would be *aob* (Fig. 2). The portion *ao* is the vapour-pressure curve for water and *ob* is the curve showing the effect of temperature on the pressure of a gas at constant volume. The values of pressure in the system as a function of temperature, determined experimentally, do not agree with these theoretical considerations. The experimental curve for such a system is *acb* (Fig. 2). At temperatures below the point *a* the experimental curve coincides with the vapour-pressure curve for water (*ao*), and at the temperatures above the point *b* the experimental curve coincides with the theoretical curve *ob*. The measurements of pressure at temperatures between *a* and *b* are in every case less than those expected from the simple theory given above. The greatest deviation of the experimental curve from the theoretical curve is at the temperature given graphically by the point *o*. At this temperature all the water in the system should be in the gaseous phase, if adsorption did not occur, and the pressure due to water vapour should be equal to the vapour pressure of water at this temperature. If the temperature and the pressure of the system are those of the point *b*, then all of the water present exists in the gaseous phase. The pressures determined experimentally at successively decreasing temperatures between *b* and *o* should be those represented by the line *bo*, if adsorption did not occur, but the values of pressure determined lie along the curve *bc*; continued pressure measurements at temperatures between *c* and *a* give the curve *ca*, the experimental curve from *a* to *b* being a smooth continuous curve.

The pressure measured at any temperature between *a* and *b* is less than the expected value. This decrease of pressure must be due to adsorption of water from the gas phase. That equilibrium is established along the curve is evident from the fact that at any one temperature the value of the pressure measured is the same whether the system be heated to that temperature or cooled down from a higher one.

It is not possible to state definitely from the findings of this research whether the adsorption measured takes place directly on the solid surface of the glass or platinum, or on the surface of a stable adsorbed layer of water which is on the surface throughout



all of the experiments. The procedure adopted is such that this question cannot be settled here.*

The method of experimentation was as follows.

The Adsorption of Water on a Glass Surface.

The Apparatus.—A diagram of the apparatus employed to measure the pressures in a constant-volume system is shown in Fig. 1.

FIG. 1.

A is a hollow cylindrical tube of soft Duroglass closed at the top end; the lower end is sealed to a glass tube of smaller diameter

* The adsorbing surfaces in the case of glass or platinum (the materials employed in this investigation) are not of course ideally plane as assumed in this paper, and so the amount of substance adsorbed per unit of area of adsorbing surface may be smaller than as calculated. A discussion of this question is reserved for a subsequent paper.

which is bent into a U, D. At the bottom of the U a glass tube 78 cm. long is sealed; a mercury air-trap is sealed to the bottom end of this tube, which is in turn attached to a mercury reservoir by means of rubber tubing. The internal dimensions of A were carefully measured before the tube was constructed; tubing of uniform bore and as free as possible from imperfections was chosen. The tube was annealed for 4 hours at 500°. The internal surface of the tube A was cleaned by first washing with organic solvents. The tube was then filled with freshly prepared chromic acid cleaning solution and allowed to stand for 24 hours. The cleaning was completed with fuming nitric acid and repeated washings with distilled water. The volume of the tube to the pointer F was calibrated to 0·005 c.c. The open end of the U, D, is connected to mercury diffusion pumps and a McLeod gauge. A tap is placed in the tube B. A few cm. below the tap a side tube is sealed making connexion with a second U tube, E, the other end of the U is sealed to a bulb, C, containing distilled water.

To the bottom of the U, E, a tube similar to that at the bottom end of D is sealed and is connected as before to a mercury reservoir. In making the final position seals in the clean apparatus the glass blowing was done through a phosphorus pentoxide tube. All the mercury used in the apparatus was thoroughly purified and dried by the usual methods. The whole was mounted vertically in a water thermostat, the temperature of which was maintained and controlled electrically, the thermoregulator permitting of an adjustment over a long range of temperature. The tubes from D and E passed through stuffing boxes in the bottom of the thermostat. A scale, H, calibrated to 0·01 mm., was mounted behind the tube B. Plate glass windows were set in the sides of the thermostat so that the differences in level between the mercury in F and B might be read by means of a cathetometer provided with a micrometer screw adjustment. Evacuation was carried out by means of a diffusion pump backed by a Töpler pump. Pressure readings at high vacuum were made by the McLeod gauge. Before the apparatus was used for any determinations the air was entirely removed from the apparatus and from the water in C.

Experimental Procedure.—The mercury in D and E is lowered and the pressure of the air reduced by means of the water pump to such a value that the water in C just begins to boil. Excessive boiling must be avoided, otherwise water will be carried over from C into the U, E. The mercury is then raised in E, and the evacuation continued by the diffusion pump until the pressure remaining in the apparatus cannot be read on the McLeod gauge. The tap B is then closed and the mercury lowered in E.

When sufficient time has elapsed for the pressure to come to equilibrium with the vapour pressure of the water in C, the mercury in E is again raised and evacuation continued. This process is carried out a sufficient number of times so that the last remaining traces of air in C are removed. The position of the pointer F is now determined relative to the scale H.

When the vacuum is as high as possible, the mercury in D is raised until the tip of the pointer just touches its reflected image in the mercury meniscus. The position of the meniscus in B is then read off to 0·01 mm. on the scale H. This determination of the "zero" position of the pointer was carried out a number of times and in every case concordant results were obtained. The tap B is then closed and the mercury lowered in D and E. The temperature of the thermostat is adjusted so that the value of the pressure in A due to water vapour, and hence the mass of water in A, is that desired for a particular measurement. During the filling process the mercury in D and E is lowered just below the bottom of the U's so that any condensation of water on the mercury surfaces is avoided. The mercury is then raised in D and E, B is opened, and the apparatus completely evacuated to the mercury surfaces. The pressure in A is then determined by raising the mercury in D until the tip of the pointer just touches its reflected image, and reading off with the cathetometer the position of the meniscus in B on the scale H. The difference between this value and that of the "zero" position of the pointer is the pressure in mm. of mercury at the temperature of the thermostat exerted by the water vapour in A. From this reading it is possible to decide whether or not the desired amount of water has been admitted to A. If it is not sufficient, the temperature of the thermostat is increased, and the filling operation again performed. If too much water has been admitted, B is closed, the mercury is lowered in D, permitting some of the water vapour to escape into B, the mercury is then raised in D, the tap B is opened, and the portion of the apparatus above the mercury surfaces is further evacuated. This procedure is continued until the amount of water in A is that desired. It is not essential at this stage to know exactly the mass of water which has been admitted to A, since the mass may be determined from later measurements. Readings of the pressure in A are made both at successively increasing and decreasing temperatures, and in both instances readings obtained at any one temperature agree to 0·01 mm. The temperature is increased until the water vapour is behaving as a gas whose pressure at constant volume is increasing linearly with increasing temperature. The readings are continued at successively lower temperatures until the pressures measured agree as nearly

as possible with the vapour pressures of water at the corresponding temperatures.

Results.—The readings obtained in a series of measurements are given in Table I. T is the absolute temperature, and p the pressure read at the corresponding temperature in mm. of mercury at 0·0° C. The volume of the tube A was 13·307 c.c. and the area of the internal surface was 55·10 sq. cm.

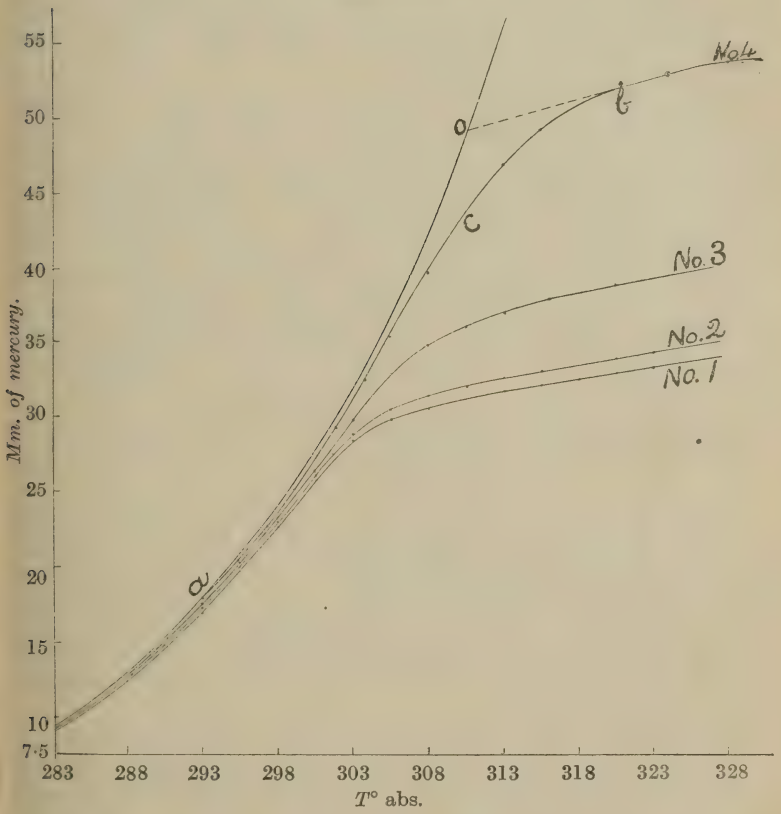
In Fig. 2 the values of T given in Table I are plotted as abscissæ and the corresponding values of p as ordinates. The vapour-pressure curve for water is also given, plotted from the data of Scheel and Heuse (*Ann. Phys.*, 1910, **31**, 715).



At the higher temperatures the values of p are increasing linearly with increasing temperature. The mean value of the rate of increase per degree is 0·0037. This is sufficiently near the temperature coefficient of a perfect gas that water vapour at these concentrations may be considered to behave as such. Hence the mass of water present in the system may be calculated from the equation $pv = nRT$, where p is the pressure at some point on the linear portion of the experimental curve at the temperature $T°$; v is the volume of the system; n is the number of moles present; and R is the gas constant, which, if p is measured in mm., is equal to 6·244 $\times$

10^4 c.c.-mm. per degree. If any other point be chosen on the experimental curve, then the temperature and pressure will be T_1 and p_1. The number of moles of water in the gaseous phase can be calculated at the new temperature and pressure and is given by $n_1 = p_1 v/RT_1$.

The number of moles adsorbed on the glass surface will be $n - n_1$, where $n - n_1 = pv/RT - p_1 v/RT_1$.

FIG. 2.

Glass–water.

The Avogadro number is $6{\cdot}06 \times 10^{23}$. The actual number of molecules adsorbed on the glass surface is $(n - n_1) \times 6{\cdot}06 \times 10^{23}$, or, if this number be denoted by N, then

$$N = \frac{v}{R}\left(\frac{p}{T} - \frac{p_1}{T_1}\right) \times 6{\cdot}06 \times 10^{23}.$$

Since v, the volume of the apparatus, and R are constant,

$$N = (p/T - p_1/T_1) \times 1{\cdot}292 \times 10^{20}.$$

The area of the inside surface of the glass tube can be calculated to 0·05 sq. cm. In this calculation, the area of the glass pointer must be included. The value obtained was 55·10 sq. cm. The number of molecules adsorbed per sq. cm. (N/cm.^{2}) is given by,

$$N/\text{cm.}^2 = (p/T - p_1/T_1) \times 2{\cdot}344 \times 10^{18}.$$

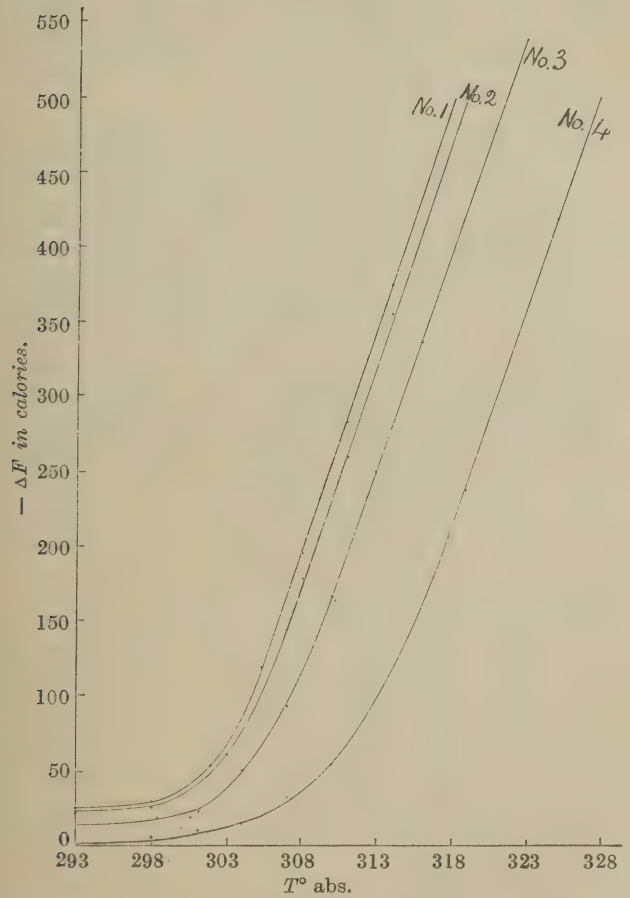
The degree of accuracy of this calculation is fairly high. The temperature was read to 0·05°; the pressure to 0·01 mm.; the volume was calibrated to 0·005 c.c., and the area calculated to 0·05 sq. cm. If the equation giving N/cm.^{2} be differentiated and these values be substituted for the corresponding differentials, the probable error in the calculation is 0·50%.

If the diameter of the water molecule be taken as $2{\cdot}9 \times 10^{-8}$ cm. (compare Jeans, "Dynamical Theory of Gases"), the number of molecular layers in the adsorbed layer may be calculated. The only assumption made, other than that made in the determination of the diameter, is that each molecule in a monomolecular layer occupies a square area each side of which is equal in length to the molecular diameter. No assumption is necessary concerning the packing of one layer on another. The surface of the glass may be considered as a plane surface. The number of molecules in a single layer covering an area of 1 sq. cm. is $1/d^2$, where d is the diameter of the molecule.

The number of layers in an adsorbed film will be $N/\text{cm.}^2 \div 1/d^2$. If this value be denoted by θ, then

$$\theta = (p/T - p_1/T_1) \times 1972.$$

Table I, column 3, gives the total number of molecules adsorbed per sq. cm. (N/cm.^{2}) at the temperatures $T°$ for each curve in Fig. 2; Table I, column 4, gives the thickness, θ, of the film in molecular layers. In Table I, No. 4, the initial reading at 298° abs. is that of a film the equilibrium pressure of which is equal to that of water in bulk. Such a film is produced when 2188×10^{14} molecules are adsorbed per sq. cm.



The experimentally measured pressure on any curve in Fig. 2 at any temperature is the equilibrium pressure between the film of water adsorbed on the glass surface and the water in the gaseous phase in the system. Taking as a standard state that of saturated water vapour at each temperature, it is possible to calculate from the experimental data the decrease of free energy, $-\Delta F$, corresponding to the adsorbed film. These values of $-\Delta F$ are calculated from the well-known thermodynamic equation, $-\Delta F = RT \log (p/p_1)$, where p is the vapour pressure of water at $T°$, p_1 is the equilibrium pressure of the adsorbed film at the same temperature, and R is the gas constant in calories per degree. The values of

$-\Delta F$ in calories per mol. of water adsorbed are given, together with the corresponding temperatures and thicknesses of film, in Table I.

The changes of free energy are shown graphically as a function of temperature in Fig. 3. It is evident from these curves that the

FIG. 3.

Glass–water.

free energy change accompanying the adsorption of water on glass is increasingly less for each new layer adsorbed.

Further discussion of these results will be more fruitful after the results for the adsorption of water on platinum have been given.

The Adsorption of Water on a Platinum Surface.

By a modification of the apparatus, as shown in Fig. 1, the adsorption of water from the gas phase on the surface of platinum was studied. The tube A, Fig. 1, is cut from the apparatus and a platinum tube, constructed to given internal dimensions, is sealed in its place. The volume is accurately determined before the tube is mounted in the apparatus. The inner surface of the platinum was polished, and thoroughly cleaned with concentrated nitric acid. The cleaning was completed by repeated washing with distilled water. The pointer F cannot be used in this experiment as the zero position at constant volume.

By the following method constant volume and constant adsorption surface of platinum were maintained. One terminal of an accumulator is connected to a voltmeter which is in turn in electrical connexion with the platinum tube, the other terminal of the accumulator is in electrical connexion with the mercury in the reservoir attached to D. When the mercury is lowered in D, the voltmeter does not register, but as soon as the mercury is raised until it touches the bottom end of the platinum tube the electrical circuit is completed and the voltmeter registers. By careful adjustment it is possible by this means to maintain a constant volume within the system.

The method of admitting water vapour to the system is identical with that already described. During each increase of temperature in a series of measurements, the mercury in F is raised a short distance into the platinum tube so that the water vapour does not adsorb on the glass surface of the tube F. When equilibrium has been established at the higher temperature, the mercury is carefully adjusted to the zero position and the pressure read as before. The methods of measuring the amounts of water adsorbed from the gas phase, and the calculations from the pressures measured, are in every case similar to those already described and need not be set out in detail here. The equation giving the free energy change is that already employed. The dimensions of the platinum tube are different from those of the glass tube, the volume being 5·317 c.c. and the area of the internal surface 15·36 sq. cm. The introduction of these values into the other equations alters the value of the constants as given below.

The measurements of pressure and the values of $N/\text{cm.}^2$, θ, and $-\Delta F$ at the corresponding temperatures are given in columns 2, 3, 4, and 5 respectively in Table II.

$N/\text{cm.}^2 = (p/T - p_1/T_1) \times 3{\cdot}359 \times 10^{18}$. $\theta = (p/T - p_1/T_1) \times 2824$.

The adsorbed film of water on a platinum surface the equilibrium pressure of which is equal to the vapour pressure of water is produced

according to varying temperatures when from 265·3 to 325·8 $\times$ 10^{14} molecules are adsorbed per sq. cm. The curves in Fig. 4 show the change in the equilibrium pressure of the film with varying thickness at constant temperature. The limiting pressure value of adsorption measurements at any one temperature is the normal vapour pressure of water at that temperature. Hence the highest pressure on each isotherm is the vapour pressure of water at that temperature. It is evident from the shape of these isothermal curves that they will all cut the ordinate axis at a finite pressure. It follows that below

these pressures measurable adsorption of the type studied here does not occur. These pressures where the adsorption first begins cannot be measured directly, but the extrapolation of these curves

FIG. 4.

Platinum–water.

would give this pressure. The value so obtained from the 298°-isotherm is 20·50 mm. The isotherms above 298° abs. will cut the pressure axis above this point. The extrapolation of the other curves is unwarranted. It is possible that a stable film of adsorbed water is present on the platinum surface whose equilibrium pressure

is too small to be measured by this means. If this is actually the case, the true value of the molecular thickness would be $\theta + n$, where n is the number of molecular layers in the stable film. However, allowing for the possible existence of a stable film on the surface, we may still say that adsorption of the type studied here begins at a finite pressure.

The adsorption on glass is much greater than on platinum. The free energy change accompanying adsorption on a glass surface is much greater than that on a platinum surface.

The results given here are in good agreement with those of other investigators working at similar pressures and temperatures and with similar surfaces but by different methods.

The best of these are probably those of Ihmori (*loc. cit.*), who studied the adsorption of water on a plane Jena glass surface. He states the thickness of the adsorbed film on a glass surface to be from 0·3 to $4{\cdot}0 \times 10^{-6}$ cm. Our results show the film to be from 0·0 to $5{\cdot}3 \times 10^{-6}$ cm. thick. His value for platinum is from 0·0 to $1{\cdot}2 \times 10^{-6}$ cm., whilst ours is 0·0 to $1{\cdot}13 \times 10^{-6}$ cm. Other investigators, working with powdered substances or with glass wool, have obtained consistently higher values than these. These large adsorption values are due to the difficulties involved in calculating the surface of a finely-powdered substance and to capillary and sorption effects. As the adsorption measured here is a reversible equilibrium, it cannot be due to solid solution or chemical combination.

This work is being extended by one of us to other surfaces and vapours.

Summary.

(1) A new method has been devised for measuring the adsorption of vapours on solid surfaces.

(2) The adsorption of water vapour on a glass and a platinum surface has been studied.

(3) The number of molecules adsorbed per sq. cm. has been accurately determined and this value for an adsorbed film, the equilibrium pressure of which is equal to that of the vapour pressure of water, has been determined for glass and platinum surfaces.

(4) The change in free energy accompanying adsorption of water from the gaseous phase on glass and platinum surfaces at various temperatures and different numbers of molecules per sq. cm. adsorbed has been calculated.

(5) The magnitudes of the adsorption of water from the gaseous phase on glass and on platinum surfaces have been compared qualitatively.

(6) Experimental results show, in the case of water vapour on a platinum surface, that this type of adsorption begins at a finite pressure.

The authors wish to express to Prof. F. G. Donnan their appreciation of the interest he has taken in this research.

THE SIR WILLIAM RAMSAY LABORATORIES OF PHYSICAL AND INORGANIC CHEMISTRY,
UNIVERSITY COLLEGE, LONDON. [*Received, May 1st*, 1925.]

CCIX.—*A New Method of Diagnosing Potential Optical Activity. Part I. The Optical Activity of Chlorobromomethanesulphonic Acid.*

By JOHN READ and ANN MORTIMER MCMATH.

THE difficulty of obtaining satisfactory experimental evidence of the actual or potential existence of optically active forms, corresponding with enantiomorphous modifications, of substances possessing fewer than three carbon atoms in the molecule is well known. Despite repeated attempts on the part of numerous investigators, the accounts of which have doubtlessly remained to a large extent unpublished, it was not until forty years after the promulgation of Le Bel and van 't Hoff's theory of the spatial molecular configuration of carbon compounds that incontrovertible proof was forthcoming of the capacity of substances of such simple molecular constitution to exist in optically active enantiomorphous modifications. Even yet, chloroiodomethanesulphonic acid, $CHClI{\cdot}SO_3H$, resolved into optically active components by Pope and Read in 1914 (J., **105**, 811), provides the sole example of the existence of a one carbon-atom molecule in optically active modifications. Since failure to resolve such simple asymmetrically constituted substances had been hitherto ascribed to their ready racemisation, the extraordinarily pronounced optical stability of the active forms of chloroiodomethanesulphonic acid (*loc. cit.*, p. 819) provided a striking and unexpected contrast to Swarts' description of the presumed immediate racemisation of fluorochlorobromoacetic acid when liberated from combination with strychnine (*Bull. Acad. roy. Belg.*, 1896, **31**, 28; "Mémoires couronnés," 1896, 54), and Porcher's account of the fleeting activity of chlorosulphoacetic acid (*Bull. Soc. chim.*, 1903, **27**, 438).

Many seeming anomalies remained after the optical resolution of chloroiodomethanesulphonic acid, one of the most striking being

the lack of success to resolve chlorobromomethanesulphonic acid (compare Pope and Read, J., 1908, **93**, 797). This substance bears the closest conceivable constitutional relationship to chloroiodomethanesulphonic acid, and also, as described below, forms a brucine salt distinguished by an almost identical sparing solubility. Nevertheless, repeated attempts to prepare optically active specimens of the bromo-acid or its salts by fractional precipitation with brucine, according to the method applied successfully to the iodo-acid, resulted in failure. In seeking a reason for this apparent anomaly, it appeared very improbable, in the light of the observations recorded for the iodo-acid, that any explanation could be based upon extreme facility of racemisation; but before exploring other lines of inquiry it was felt advisable to submit this possibility to more stringent tests than have been as yet applied in investigations of the kind. In further experiments with brucine and strychnine, the possible racemising action of heat and alkaline reagents was avoided as far as possible by producing the alkaloidal salts from aqueous solutions at the ordinary temperature and decomposing the various fractions with the minimum amount of cold dilute ammonia; no resolution, however, could be established in this way.*

In view of the possible catalytic racemising action of water upon a presumed highly mobile asymmetric system, attempts were next made to carry out the processes as completely as possible in organic solvents. The very sparing solubility of the brucine salt appeared unfavourable for such a purpose, and eventually hydroxyhydrindamine was selected as a base likely to yield a salt capable of ready fractional crystallisation from a suitable series of organic solvents (Pope and Read, J., 1912, **101**, 760). Preliminary experiments showed that no resolution could be accomplished by using this base in aqueous solution. The salt prepared by mixing equivalent amounts of the free acid and *l*-hydroxyhydrindamine in presence of acetone containing traces of water crystallised without difficulty, and exhibited two widely distinct kinds of crystals at the first recrystallisation from this solvent: a preliminary separation of compact, glistening plates was succeeded in the supernatant mother-liquor by a radiating mass of long, silky needles; and upon carrying out a lengthy fractional crystallisation these two forms recurred,

* These experiments, carried out at intervals over a long period but hitherto unpublished owing to the inconclusive results, were completed prior to the publication of the recent paper by Backer and Burgers (this vol., p. 233) describing the successful adoption of very similar precautions in the apparently partial optical resolution of chlorosulphoacetic acid. The chlorobromomethanesulphonic acid used in the preliminary work was kindly made available several years ago by Sir William Pope.

any particular fraction consisting as a rule of one type only. The plates, when carefully recrystallised from acetone, separated in magnificent and highly lustrous crystals of tabular habit; whilst the needles maintained their characteristics when recrystallised from glacial acetic acid: the description below indicates their widely different morphological characteristics. Further examination disclosed the remarkable fact that the needles when recrystallised from acetone of ordinary purity separated mainly in the tabular form, whilst the plates when recrystallised from glacial acetic acid yielded nothing but needles; moreover, both kinds of crystals decomposed at practically the same temperature (187°), although the tabular form exhibited a preliminary change in appearance well below this point (160°). The relationship would therefore be ascribed in the ordinary way to the occurrence of dimorphism; and, indeed, the general appearance of the two kinds of crystals in the original separation was strongly reminiscent of the dimorphic forms of *p*-bromoacetanilide, as pictured by Chattaway and Lambert (J., 1915, **107**, 1766). Upon fuller examination, however, the plates and needles, although both giving a molecular rotatory power in dilute aqueous solution equivalent to that of the basic ion, were found to display widely different rotatory powers in organic solvents. Further, the plates, which gave the higher numerical values, exhibited marked downward mutarotation * in these solvents, the final value being in each case practically identical with the value observed for the needles in the same solvent. No mutarotation was evident in aqueous solution. Of all the organic solvents available, the plates gave the highest numerical values in pure dry acetone; moreover, the needles, which otherwise displayed little tendency towards mutarotation, showed a rapid upward change in this solvent until the attainment of the final value given by the plates in the same solvent. In all instances, the crystalline residues obtained by ordinary evaporation of the above solutions on the water-bath gave the rotatory powers characteristic of the needles, when redissolved in the various solvents indicated.

After further investigations, described below, these results were interpreted by assuming that the plates and needles represent salts of *l*-hydroxyhydrindamine with *l*- and *dl*-chlorobromomethanesulphonic acid, respectively. The main measurements of molecular rotatory power may now be summarised in the following

* For the sake of brevity the term "mutarotation" is used throughout this paper to denote the observed progressive changes in rotatory power, although possibly it would be preferable to use a distinctive word for changes of the special nature here concerned.

Methyl alcohol (absolute)	−180°	−71°	−71°	−71°	−109°	+38°
Ethyl alcohol (99·5%)	−180	−90	−75	−83	−105	+30
Acetone (pure anhydrous) ...	−256	−187	−71	−187	−185	+114
Glacial acetic acid	−184	−66	−59	−59	−125	+ 66
Water	−60	−60	−60	−60	—	—

The values in water are practically coincident with the value ±60·5° recorded for the basic ion in dilute aqueous solution (J., 1912, **101**, 770).

It has been observed that the active hydroxyhydrindamines, more particularly in combination with weak acids, exhibit mutarotation in certain organic solvents (*loc. cit.*, p. 759); but the slight changes recorded below for *l*-hydroxyhydrindamine benzenesulphonate and *d*-hydroxyhydrindamine acetate disclose no similarity to the very sharply defined changes now under discussion. Further, the quantitative relationships explained below and the fact that marked differences persist in new salts prepared from the two *l*-hydroxyhydrindamine salts by displacement of the base do not permit of the mutarotation being referred to tautomeric change on the part either of the base or the acid.

In order to account for the experimental observations described in this paper we revert to the original view that asymmetric carbon compounds of simple molecular constitution are as a rule exceedingly susceptible to racemisation, owing to the mobility of the groups attached to the asymmetric atom. Moreover, we now advance the new idea, as applied to such compounds, that facile racemisation involves the complementary possibility of equally facile optical stabilisation, or " deracemisation," under appropriate conditions. Thus, a very labile asymmetric molecule, when submitted to a suitable asymmetric influence, will be transformed more or less completely into one of the two possible active modifications; but when the asymmetric influence is removed, the form present in excess will undergo auto-racemisation. In the example under notice, the most effective asymmetric influence yet discovered is provided by optically active hydroxyhydrindamine in acetone solution : the *l*-base transforms the *dl*-acid largely to *l*-acid, whilst the *d*-base transforms it in the same proportion to *d*-acid. An equilibrium is thus set up in the solution between

the diastereoisomeric salts *lBlA* and *lBdA* (or *dBdA* and *dBlA*), greatly to the advantage of the former. Upon dissolving the pure solid salt, *lBlA* (or *dBdA*), in various other organic solvents, a more or less rapid racemisation of the active acid occurs, resulting as a rule in the complete, or almost complete, conversion of the salt *lBlA* (or *dBdA*) into the partially racemic salt *lBdlA* (or *dBdlA*); moreover, it has been shown that the racemisation is accelerated remarkably by the addition of small quantities of water to the solvent. Thus, in 99·5% ethyl alcohol the downward mutarotation extended over a period of 23 hours, whereas in 90% ethyl alcohol it was complete in 12 minutes.

All the recorded observations were made at the ordinary temperature, and the only solvents submitted to special purification were methyl alcohol and acetone for use in making standard determinations of optical rotatory power. For purposes of recrystallisation, acetone of the purity necessary for ordinary analytical operations was used. More detailed observations, involving the use of carefully purified solvents at a constant temperature and a study of the effect of water and other catalysts, will be carried out in due course.

The results recorded for solutions in 99·5% ethyl alcohol and glacial acetic acid suggest that even in these solvents a state of equilibrium is attained between the salts *lBlA* and *lBdA*, which does not correspond with the presence of equimolecular proportions of the two salts. Thus, in 99·5% ethyl alcohol, the value of $M[\alpha]_D$ for the pure salt *lBlA* declined from $-180°$ to $-90°$, whilst the value for *lBdlA* rose from $-75°$ to $-83°$. Accepting $-90°$ as the equilibrium value, and $-180°$ as the value for the pure salt *lBlA*, this observation corresponds with an optical equilibrium mixture composed of 57% of *lBlA* and 43% of *lBdA*, or 14% of *lBlA* and 86% of *lBdlA*. The values observed in pure dry acetone solution leave no doubt as to the existence in this solvent of an equilibrium between the two diastereoisomeric salts, *lBlA* and *lBdA*, the former predominating considerably in amount. Equilibrium is attained in this solvent with great rapidity from either side. The salt *lBlA* showed a downward mutarotation from the original value $M[\alpha]_D = -256°$ until the attainment of the equilibrium value, $M[\alpha]_D = -187°$, in about an hour; on the other hand, the partially racemic salt, *lBdlA*, exhibited an upward mutarotation from the original value, $M[\alpha]_D = -71°$, to the same equilibrium value. The upward change appeared to take slightly longer than the downward one, but more refined measurements will be needed to establish this point definitely. The curves in Fig. 2 illustrate the main trend of these and other changes.

It is thus clear that in acetone solutions of the concentrations examined, the diastereoisomeric salts, *lBlA* and *lBdA* (or *dBdA* and *dBlA*), exist in dynamic equilibrium at the ordinary temperature in the proportion of about 81% of the former to 19% of the latter, and that by careful crystallisation the whole of the original *dl*-acid may be obtained in the form *lBlA* (or *dBdA*). In effect, although not strictly in accordance with definition, this result is tantamount to a partial asymmetric synthesis with complete theoretical efficiency. The following schemes represent (i) the usual course of events in the optical resolution of an externally compensated acid by a lævorotatory base, and (ii) the optical resolution of *dl*-chlorobromomethanesulphonic acid by *l*-hydroxyhydrindamine in acetone solution, under the conditions indicated :

$$\text{(i)}\quad \underset{}{2lB} + \underset{}{dAlA} = \underset{50\%}{lBlA} + \underset{50\%}{lBdA}.$$

$$\text{(ii)}\quad \underset{}{2lB} + \underset{}{dAlA} = \underset{81\%}{lBlA} \rightleftharpoons \underset{19\%}{lBdA}.$$

No displacement in the equilibrium was observed on diluting the solution in pure acetone from about 0·6 to 0·15%.

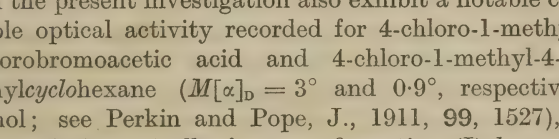
The progress of the separation of crystals of *l*-hydroxyhydrindamine *l*-chlorobromomethanesulphonate from a solution in ordinary acetone of *l*-hydroxyhydrindamine *dl*-chlorobromomethanesulphonate was traced by a periodical examination, during the crystallisation, of the salt remaining in the mother-liquor : the results showed that, in accordance with anticipation, the mother-liquor contained a large excess of the salt *lBlA* throughout the process. The lowest value observed for the residual dissolved salt was − 122°, corresponding with a mixture of 64% of *lBlA* with 36% of *lBdA*, notwithstanding the presence of traces of water in the acetone.

Owing to the insolubility of the salts in benzene, chloroform, etc., no observations have yet been practicable in non-miscible solvents. Neither of the salts exhibited any change in optical rotatory power when heated at 110° for 2 hours, but the salt *lBlA* showed a marked decline, indicative of partial racemisation, when kept at 160° for ½ hour. The tabular crystals of this salt lose their transparency when kept, but as yet no accompanying change in the rotatory power of the dissolved substance has been noticed.

By subtracting the molecular rotatory power of the salt *lBdlA* from that of the salt *lBlA*, determined in the same solvent under precisely similar conditions, a value is obtained for the molecular rotation exerted by the acid part of the molecule of the second salt; the values recorded in the fifth column of the above table were calculated in this way. The values given in the last column

for the salt *lBdA* have also been deduced algebraically from the values observed for the same two salts, listed respectively in the first and third columns. It is not desired to emphasise unduly the numerical significance of the values thus derived, nor to compare them in point of precision with ionic values; yet, in view of their common method of derivation, they afford an indication of the relative order of magnitude of corresponding molecular rotatory powers in different solvents. Moreover, results of great interest have been obtained by comparing the values for chlorobromomethanesulphonic acid with values derived in a similar way for chloroiodomethanesulphonic acid. For this purpose, determinations of the molecular rotatory powers, hitherto unavailable, of *d*- and *l*-hydroxyhydrindamine *d*-chloroiodomethanesulphonate were made in absolute methyl alcohol, glacial acetic acid, and acetone, in solutions having a concentration of about 1%. These two salts were prepared for the purpose from a specimen of barium *d*-chloroiodomethanesulphonate having $M[\alpha]_D = +37{\cdot}7°$ in 1% aqueous solution, and neither of the salts was purified by fractional crystallisation. No mutarotation was observed in any instance. The observed and derived values immediately concerned are tabulated below:

	$M[\alpha]_D$ of hydroxyhydrindamine salt of				$M[\alpha]_D$ derived for	
	Bromo-acid.		Iodo-acid.		Bromo-	Iodo-
Solvent.	*lBlA*.	*lBdlA*.	*dBdA*.	*lBdA*.	acid.	acid.
Methyl alcohol (absolute)	−180°	−71°	+122°	−35°	−109°	+44°
Glacial acetic acid	−184	−59	+118	−27	−125	+46
Acetone (pure) .	−256	−71	+192	−42	−185	+75



Thus, for both acids, the salts *dAdB* (or *lAlB*) yield the highest molecular rotatory power in acetone, whilst the values in methyl alcohol and acetic acid are considerably lower and practically identical in each instance for the two solvents. The ratio between the derived values of $M[\alpha]_D$ given in the last two columns is 2·5/1 in methyl alcohol, 2·7/1 in acetic acid, and 2·5/1 in acetone. Adopting a mean ratio 2·6/1, the calculated molecular rotatory power of the ion of chlorobromomethanesulphonic acid in dilute aqueous solution would thus be $M[\alpha]_D = \pm 98°$, based on the corresponding value observed for the ion of the iodo-acid, namely, $M[\alpha]_D = 37{\cdot}7°$, noted above.

Although chloroiodomethanesulphonic acid may not yet have been obtained optically pure, it is evident that a remarkable enhancement of molecular rotatory power attends the substitution of bromine for iodine in this simple molecule, and it will be a matter

of considerable interest to trace the quantitative optical effect of similar substitutions by means of a further application of the method now indicated.

The relationship just elucidated between the molecular rotatory powers of the hydroxyhydrindamine salts of these two acids appears even more striking when it is added that prior to making the above determinations of rotatory power for the salts of the iodo-acid we had failed to notice any downward mutarotation of *l*-hydroxyhydrindamine *l*-chlorobromomethanesulphonate when dissolved in acetone of ordinary purity. The constant value $M[\alpha]_D = -158°$, originally observed, was thus assumed to represent the molecular rotatory power of the pure salt *lBlA* in acetone. This value, taken in conjunction with the original value observed in the same solvent for the salt *lBdlA* (— 93°), led to the derived value $M[\alpha]_D = -64°$ for *lA*, whereas the above ratio 2·6/1 indicated $M[\alpha]_D = -194°$. It seemed likely, therefore, that the value for the pure salt *lBlA* was very much higher than $M[\alpha]_D = -158°$, and that the latter value had been attained through a rapid downward mutarotation to a point of equilibrium prior to polarimetric examination. By using scrupulously purified acetone and making the first polarimetric observation within 3 minutes of the first contact of solid with solvent, we were eventually successful in obtaining an initial value of $M[\alpha]_D = -256°$ for this salt, and in detecting the anticipated rapid fall to the equilibrium value; moreover, the initial value for the pure salt *lBdlA* was reduced in a similar way from — 93° to — 71°. The value of $M[\alpha]_D$ for *lA* thereby became — 186°, in place of the value — 64° first deduced, and thus approximated very closely to the anticipated value, — 194°.

The optical effect of configuration (I) thus appears to be numerically about 2·6 times as great as that of (II), and the high values observed in the present investigation also exhibit a notable contrast to the feeble optical activity recorded for 4-chloro-1-methyl*cyclo*hexyl-4-chlorobromoacetic acid and 4-chloro-1-methyl-4-chlorobromomethyl*cyclo*hexane ($M[\alpha]_D = 3°$ and 0·9°, respectively, in ethyl alcohol; see Perkin and Pope, J., 1911, **99**, 1527), which may be derived theoretically from configuration (I) by replacing the simple group SO_3H by a large complex radical, R (III) :

It is suggested that the low molecular rotatory powers exhibited by configurations (II) and (III) may be due largely to a steric

effect: comparing (I) and (II), the substitution of I for Br would leave less of the environment of the carbon atom available for H, Cl, and SO_3H; whilst, comparing (I) and (III), the substitution of R for SO_3H would lead to a still more pronounced curtailment of the space available for H, Cl, and Br. It will be interesting to investigate this idea further by the examination of other asymmetric substances of analogous constitution.

When separated from the optically active base, chlorobromomethanesulphonic acid racemises with extreme ease. Although the asymmetric influence of the base enables a distinctive crystalline β-naphthylamine salt to be isolated from *l*-hydroxyhydrindamine *l*-chlorobromomethanesulphonate, in admixture with β-naphthylamine dissolved in glacial acetic acid, the salt shows no optical activity immediately after solution in organic solvents, and when recovered from the solvent has undergone transformation into the β-naphthylamine salt deposited directly from a mixture of β-naphthylamine and *l*-hydroxyhydrindamine *dl*-chlorobromomethanesulphonate in glacial acetic acid.

Extremely interesting results were obtained by precipitating the various hydroxyhydrindamine salts by the addition of brucine acetate in acetone solution. The salt *lBlA* yielded a dextrorotatory brucine salt which gave a maximum original value of $[\alpha]_D = +6{\cdot}8°$ in glacial acetic acid solution, changing rapidly to a maximum lævorotation of $[\alpha]_D = -10{\cdot}4°$. The corresponding values for the brucine salt precipitated from the salt *lBdlA* were $-8{\cdot}0°$ and $-11{\cdot}2°$, respectively. The dextrorotation of the brucine salt *lBlA* was also established in acetone solution. Since it transpired that salts of brucine with inactive acids of closely related constitution evinced no measurable optical activity when dissolved in glacial acetic acid under similar conditions, the optical effects noticed in the above determinations must be ascribed to the chlorobromomethanesulphonic acid. Two important points then emerge. In the first place, the brucine salts, like the hydroxyhydrindamine salts, exhibit mutarotation, in this instance rising in a lævo-sense in glacial acetic acid; so that, unlike *l*-hydroxyhydrindamine, brucine appears to stabilise a pronounced excess of the lævo-modification of the acid in glacial acetic acid solution. Secondly, the exchange of bases appears to be accompanied by optical inversion on the part of the acid. In the latter event, it was anticipated that *d*-hydroxyhydrindamine *d*-chlorobromomethanesulphonate, although containing the dextrorotatory acid, would fail to yield a dextrorotatory brucine salt. A further experiment confirmed this supposition, the first value observed for this brucine salt being $[\alpha]_D = -6{\cdot}6°$, rising in 90 minutes to a maxi-

mum value of $-10{\cdot}0°$. These curious phenomena of optical inversion, reminiscent in some ways of the Walden change, will be submitted to further investigation; but, in general, polarimetric observations on the brucine salts are rendered difficult owing to their very sparing solubility, and consequent small optical rotation, even in glacial acetic acid. The application of heat is necessary to effect solution, and in all instances this process occasions mutarotation towards zero, since the active brucine salts lose their rotatory power completely when heated on the water-bath in glacial acetic acid solution for 2 or 3 hours. In the course of the investigation of the brucine salts of chlorobromomethanesulphonic acid, evidence was obtained indicating that the salt of the inactive acid is the least soluble of the various salts or mixtures of salts possible: it would therefore be impracticable in any case to resolve the acid by fractional precipitation with this base.

By using *d*-hydroxyhydrindamine the salts *dBdA* and *dBdlA* were readily prepared in a similar manner, and these were proved experimentally to be respectively enantiomorphous with the above-mentioned salts *lBlA* and *lBdlA*. By mixing equal weights of *dBdA* and *lBdlA* in absolute methyl alcohol, and thus annulling the optical rotation due to the basic portions of the molecules, it was possible to demonstrate a slowly fading optical activity on the part of the acid present. The first value observed, $M[\alpha]_D = +49°$, agrees well with the calculated value, $+108°/2$. Chlorobromomethanesulphonic acid is thus the simplest substance which has yet been proved capable of exhibiting optical activity in the amorphous condition. The activity vanished completely in 32 hours, the racemisation being much more rapid than in the case of the salt *dBdA* (or *lBlA*), in which a powerful restraint appears to be exerted on the process by the full equivalent of *d*- (or *l*-) base present.

According to the views which have now found mention, the production of two wholly racemic salts might be anticipated, one of which would separate on mixing either salt of the *d*-base with either salt of the *l*-base in acetone, and the other of which would be deposited by crystallising a similar mixture from glacial acetic acid. These expectations were realised, the first racemate, *lBlA* . *dBdA*, crystallising in glassy prisms, and the second, *lBlA*,*lBdA* . *dBdA*,*dBlA*, in short, glistening needles. Morphologically, the racemates resemble the component salts very closely, but are more soluble and have lower melting points.

Close parallels to the results now brought forward are to be discerned in the work of McKenzie and Smith (J., 1923, **123**, 1962; 1924, **125**, 1582) on catalytic racemisation. These authors have

shown, for example, that *l*-menthyl *d*-phenylchloroacetate, through the catalytic action of a drop of alcoholic alkali, passes into an equilibrium mixture containing a preponderating amount of *l*-menthyl *l*-phenylchloroacetate. They have also established (*Ber.*, 1925, **58**, 894) the directing influence of an optically active terpene group in converting a mixture of equal amounts of diastereoisomeric menthyl (or bornyl) esters quantitatively into a mixture of unequal amounts of the same esters; thus, the addition of a trace of alcoholic alkali to a mixture of equal quantities of *l*-menthyl *d*-phenylchloroacetate and *l*-menthyl *l*-phenylchloroacetate causes the latter ester to preponderate (57%) without any analytical separation having been effected. Similarly, in the present investigation it appears that water exerts a powerful catalytic action which in most solvents results in the final production of equal, or very nearly equal, amounts of the two diastereoisomeric salts, *lBlA* and *lBdA* (or *dBdA* and *dBlA*); in acetone solution, however, the equilibrium is displaced strongly in favour of the first salt, and the actual position of the equilibrium would appear to be influenced *inter alia* by the amount of water present. It seems likely that in all instances the asymmetric directing influence of the optically active hydroxyhydrindamine becomes operative through the interposition of a catalytic agent, which may well prove to be water, even in the carefully dried acetone used in making the more refined observations recorded herewith.

An example of the general principle we now outline for simple asymmetric carbon compounds is provided in the case of the asymmetric tin atom by the well-known investigations of Pope and Peachey on methylethylpropylstannonium *d*-camphorsulphonate and *d*-bromocamphorsulphonate: evaporation of aqueous solutions of these salts led in each instance to the deposition of the single substance, *dBdA*, owing to progressive racemisation of the salt remaining in the mother-liquor (P., 1900, **16**, 42, 116; compare also Mills and Bain, J., 1910, **97**, 1866). In the case of the active salts *lBlA* and *dBdA* now under consideration, a partly racemic salt of the type *l*(or *d*)*BdlA* was usually left upon evaporating solutions in acetone containing a little water, although under certain conditions an excess of the original salt was found in the residue. The deposited salts of the tin compound were, however, characterised by sparing solubility, whereas with the hydroxyhydrindamine chlorobromomethanesulphonates no deposition occurs from warm acetone containing small amounts of water until most of the solvent has volatilised. No evidence has been adduced of the stabilisation of an excess of one form of the optically active stannonium compound in solution, the mother-liquor of the salt

dBdA being apparently a solution of the partial racemate *dlBdA*; the solvent concerned in this instance, however, is water, which instantly racemises *d*- or *l*-chlorobromomethanesulphonic acid, even when combined with optically active hydroxyhydrindamine.

The conception of extreme mobility of the simple atoms or groups attached to an isolated carbon atom also accords with Le Bel's hypothesis of a similar mobility of groups in asymmetric quinquevalent nitrogen compounds of simple molecular constitution, and with the observations of A. Werner and others on the ready racemisation of asymmetric assemblages associated with isolated atoms of cobalt, chromium, etc. Further, it affords an explanation of the difficulties experienced in preparing optically active substances containing fewer than three carbon atoms in the molecule, and is in agreement with the fugitive optical activity in aqueous solution of chlorosulphoacetic acid and its salts, indicated by Porcher (*loc. cit.*) and recently demonstrated by Backer and Burgers (this vol., p. 233). Incidentally, the suggestion that the variations in rotatory power shown by different fractions of the normal *d*-hydroxyhydrindamine salt of this acid indicated its partial resolution is also upheld (Pope and Read, J., 1914, **105**, 814). We anticipate that asymmetric compounds containing two carbon atoms in the molecule will also display phenomena of the kind now described, and thus lend themselves to preparation for the first time in optically pure combinations by treatment with optically active bases in organic solvents. Through a systematic application of the method to asymmetric compounds of simple molecular constitution, it is hoped to gather much new information respecting the comparative mobility of groups in systems of the kind.

It seems worthy of note that in the case of the optically active tin derivatives prepared by Pope and Peachey, the two dextrorotatory acids employed each imposed a dextrorotatory orientation upon the asymmetric complex involved. Similarly, in the present investigation, dextrorotatory hydroxyhydrindamine gives rise to dextrorotatory chlorobromomethanesulphonic acid, whilst lævorotatory hydroxyhydrindamine and lævorotatory brucine each favour a lævorotatory configuration of the associated asymmetric system. It will be interesting to ascertain whether any generalisation is possible on this basis, especially in view of the fact, to which attention may be directed, that in the closely related process of partial asymmetric synthesis the optically active product exhibits in the great majority of instances the same sense of rotation as the directive asymmetric system. Thus, *l*-brucine hydrogen methylethylmalonate yields an excess of the *l*-valerate when heated

(Marckwald, *Ber.*, 1904, **37**, 349); *l*-menthyl benzoylformate upon reduction gives an excess of the *l*-mandelate, and upon treatment with magnesium methyl iodide an excess of *l*-phenylmethylglycollate; whilst from *l*-menthyl pyruvate a lævorotatory lactic acid may be prepared by reduction; moreover, the *l*-bornyl group sometimes exerts a less pronounced asymmetric influence than the more highly lævorotatory *l*-menthyl group (McKenzie, J., 1904, **85**, 1249; 1905, **87**, 1373; 1906, **89**, 365 and 688). The results now described afford a very definite indication of the profound influence which may be exerted by an optically active nucleus upon an associated potentially active system, and provide a close parallel to the quantitative partial asymmetric syntheses which appear to occur in nature. Moreover, in our opinion, substances possessing the readily controlled asymmetric mobility evinced by chlorobromomethanesulphonic acid are much more likely to be amenable to processes of complete asymmetric synthesis, accomplished in the absence of optically active material, than any asymmetric substances yet investigated with this object in view. We propose to submit this new idea to practical tests at a later stage in these investigations.

The enormous difference in optical stability between chlorobromomethanesulphonic acid and chloroiodomethanesulphonic acid could not have been predicted, and is difficult to explain. In both instances the great resistance offered to alkaline hydrolysis is worthy of remark. The distinction may possibly be determined to some degree by the greater atomic volume, lower mobility, and less active chemical nature of iodine as compared with bromine. Possibly also the different affinity value, evidenced by the formation of such derivatives as $Ph{\cdot}ICl_2$, has a bearing upon the matter. It is hoped to gather further evidence by an examination of the remaining dihalogenomethanesulphonic acids and various closely related substances.

In continuing this series of investigations, we reserve the application of the method described not only to compounds of the simple molecular constitution indicated above, but also to other types of organic derivatives which may be conceived to possess potential optical activity associated with high mobility of the asymmetric system and therefore unrecognisable by any of the methods hitherto utilised. The exceedingly delicate diagnostic method we now describe may well lead to the discovery of optical activity on the part of organic types which, like chlorobromomethanesulphonic acid, have as yet resisted all attempts at optical resolution.

Experimental.

Preparation of dl-*Chlorobromomethanesulphonic Acid.*—The crude barium salt was prepared in the manner described by Andreasch (*Monatsh.*, 1887, **7**, 159), by heating barium chlorosulphoacetate to 120—130° in a sealed tube for several hours with bromine (1 mol.) and a little water. Chloromethanesulphonic acid and other impurities were eliminated by taking advantage of the sparing solubility of brucine chlorobromomethanesulphonate. To a warm aqueous solution of the recrystallised barium salt was added a similar solution containing one-third the calculated quantity of brucine acetate or brucine hydrochloride. For an amount of salt corresponding to 30 g. of the acid a total volume of about 500 c.c. was found suitable. After keeping for several hours the crystalline separation of brucine salt was collected and washed well with cold water, whilst the filtrate was treated in a similar way with a like amount of brucine. Both separations consisted of pure brucine chlorobromomethanesulphonate; practically two-thirds of the original acid was obtained in this form, the remaining one-third being rejected. The *brucine* salt forms minute, glistening needles, which decompose at 275°. It is practically insoluble in all the ordinary solvents, the most favourable being boiling glacial acetic acid (Found: C, 47·6; H, 4·3. $C_{24}H_{28}O_7N_2ClBrS$ requires C, 47·7; H, 4·6%).

For purposes of further work the brucine salt was mixed with cold water and shaken with an excess of dilute ammonia, the brucine being extracted with chloroform; evaporation of the aqueous liquid furnished the pure ammonium salt. No optical activity could be established with specimens of the salt prepared in this way. The *ammonium* salt is freely soluble in water or alcohol and sparingly soluble in warm acetone. It is best crystallised from hot glacial acetic acid, in which it is moderately soluble; it forms glistening plates, m. p. 205° (decomp.) (Found: NH_3, 7·6, 7·7. $CH_5O_3NClBrS$ requires NH_3, 7·5%). When the salt was heated under reflux for 2 hours with an excess of 10% aqueous sodium hydroxide solution, hydrolysis occurred to a slight extent only, the proportion of halogen removed being less than 2% of the total amount present.

Treatment of dl-*Chlorobromomethanesulphonic Acid with* l-*Hydroxyhydrindamine in Acetone Solution.*—An aqueous solution containing 14·7 g. of pure *dl*-chlorobromomethanesulphonic acid was evaporated as completely as possible on the water-bath in an open dish. Upon covering the partly crystalline mass with acetone (15 c.c.) and stirring in solid *l*-hydroxyhydrindamine (10·4 g.; 1 mol.), a

thick homogeneous liquid was produced, and when the stirring was continued for a short time on the water-bath the whole mass suddenly crystallised. The slightly brown, crystalline mass weighed 25·1 g. when dry. It was very soluble in water, ethyl alcohol, or methyl alcohol, moderately soluble in boiling acetone, sparingly soluble in ethyl acetate, and practically insoluble in ether, benzene, chloroform, light petroleum, etc.

A solution of the dry product in boiling acetone of ordinary purity (about 275 c.c.) and a small quantity of methyl alcohol was filtered and allowed to crystallise. The crystalline separation which accrued overnight (11 g.) consisted mainly of large, well-defined, glistening plates, but the upper part of the mother-liquor was filled with long, radiating needles. The latter dissolved readily when the fraction was separated and warmed with acetone; the undissolved residue (5·4 g.) was composed entirely of plates, which when freshly dissolved in cold methyl alcohol to form a 2·5% solution gave $[\alpha]_D = -48{\cdot}2°$, whence $M[\alpha]_D = -173°$, calculated for hydroxyhydrindamine chlorobromomethanesulphonate. The combined mother-liquors were concentrated, and the ensuing crystalline separation was subjected to a prolonged systematic fractional crystallisation from hot acetone, to which a little methyl alcohol was added when necessary. As a result, two distinct kinds of fractions were obtained, one consisting of plates and the other of needles. The plates predominated in the earlier fractions, although occasionally these yielded needles. Mother-liquors which had been repeatedly concentrated yielded needles more frequently than plates, especially when it was found necessary to accelerate the deposition of crystals by the addition of ether. The bulk of the material from the fractionation was obtained in the form of plates, although of seventeen fractions eight consisted wholly of plates and seven wholly of needles. The two kinds of crystals showed little distinction in melting point, but possessed characteristic optical rotatory powers when dissolved in organic solvents. Ordinary methyl alcohol was used as solvent in all the preliminary determinations, and the following typical result may be quoted for the plates: 0·2573 g., dissolved in methyl alcohol and made up to 20·0 c.c. at the ordinary temperature, gave $\alpha_D = -1{\cdot}24°$ when examined at once in a 2-dcm. tube, whence $[\alpha]_D = -48{\cdot}2°$, and $M[\alpha]_D = -173°$, calculated for hydroxyhydrindamine chlorobromomethanesulphonate. Other determinations of $M[\alpha]_D$ recorded for similar fractions were $-176°$, $-172°$, $-173°$, and $-172°$. In the case of a typical fraction composed of needles, 0·2550 g. when dissolved and examined under similar conditions gave $\alpha_D = -0{\cdot}51°$, whence $[\alpha]_D = -20{\cdot}0°$, and $M[\alpha]_D = -72°$.

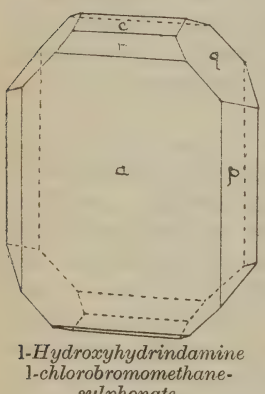
Of the results yielded by other fractions of the same kind, the following may be quoted as representative: $M[\alpha]_D = -72°$, $-73°$, $-72°$, and $-73°$. Of the seventeen fractions examined, only two gave intermediate values, namely, $M[\alpha]_D = -119°$ and $-92°$, respectively: both these fractions were obtained by evaporating the solvent to dryness on the water-bath and inoculating the warm liquid mass with a crystal of the higher rotatory power. The final mother-liquor was dark in colour, and upon evaporation yielded a dark and somewhat tarry residue. By conversion to brucine salt and subsequent careful treatment with cold dilute ammonia, a somewhat brown specimen (1 g.) of ammonium chlorobromomethanesulphonate was prepared from the final residue; this was optically inactive in 3·5% aqueous solution when examined polarimetrically in a 2-dcm. tube in sodium light.

For the reasons stated above, the plates and needles were regarded as the *l*-hydroxyhydrindamine salts of *l*-chlorobromomethanesulphonic acid and *dl*-chlorobromomethanesulphonic acid, respectively.

l-*Hydroxyhydrindamine* l-*Chlorobromomethanesulphonate*, $C_9H_{11}ON{\cdot}CHClBr{\cdot}SO_3H$.—The various fractions of this salt obtained in the course of the fractional crystallisation were mixed and recrystallised from warm acetone containing a small quantity of methyl alcohol. No difference was apparent in the properties of the substance after this treatment. Under the proper conditions the salt crystallises with remarkable facility and may be readily obtained in lustrous, tabular crystals, measuring up to 1 cm. in length. Through the courtesy of Mr. T. V. Barker, the following crystallographic description and goniometric characterisation of the substance have been kindly furnished by Miss Marie Bentivoglio, of the Department of Mineralogy, University of Oxford, to whom we express our grateful thanks:

"*l*-Hydroxyhydrindamine *l*-chlorobromomethanesulphonate forms colourless crystals which become opaque when kept for a few weeks. The habit is tabular, parallel to *a* (100); sometimes two *q* (011) faces are large and two prisms suppressed, so that the crystal appears polar.

"The crystals belong to the monoclinic system, and the elements are $a : b : c = 1{\cdot}3246 : 1 : 1{\cdot}0780$; $\beta = 114° 19'$.



"The forms present are *a*, *p*, *c*, *r*, *q* (Fig. 1), and these have the following values:

	a (100).	*p* (110).	*c* (001).	*q* (011).	*r* (101).
ϕ.....	90° 0′	*39° 38′	90° 0′	23° 07′	90° 0′
.....	90 0	90 0	*24 19	*49 27	57 20 (16)

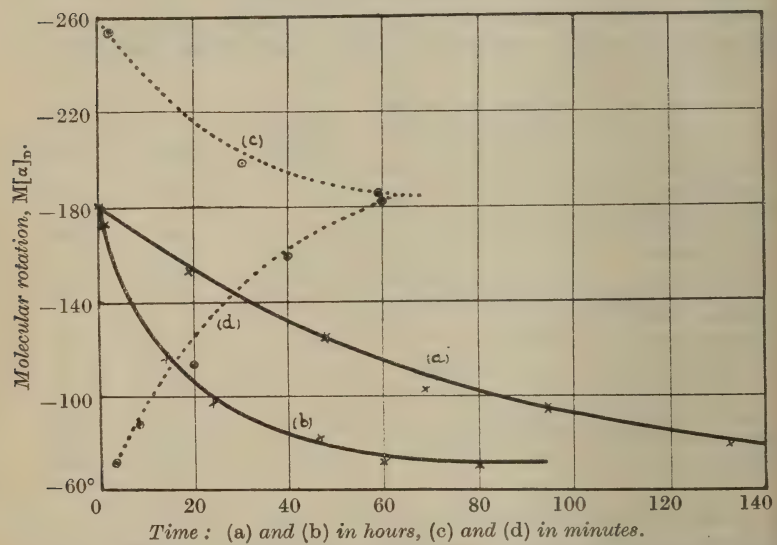
"Refractive index = 1·50."

l-Hydroxyhydrindamine *l*-chlorobromomethanesulphonate dissolves freely in water, or in methyl or ethyl alcohol at the ordinary temperature; it also dissolves readily in glacial acetic acid, and is moderately soluble in boiling acetone. It is very slightly soluble in hot ethyl acetate, but is practically undissolved by chloroform, benzene, ether, or light petroleum. It can only be recrystallised with certainty from warm acetone, to which the addition of a little methyl alcohol is permissible; as the solvent cools, the salt separates rapidly in the characteristic form, the initial deposition being facilitated in the case of a sterile solution by inoculation. When the acetone mother-liquors are allowed to evaporate to dryness in an open space at the ordinary temperature, the final separation usually consists mainly of needles of the partly racemic salt. In order to ascertain the relative stability of the two salts in contact with a saturated solution in ordinary purified acetone, a mother-liquor containing both plates and needles was kept in a desiccator, and after 3 days the needles had completely disappeared, whilst the plates had grown and maintained their lustre. *l*-Hydroxyhydrindamine *l*-chlorobromomethanesulphonate has a tendency to form supersaturated solutions, from which crystallisation takes place easily upon inoculation. Strong saturated solutions in warm methyl alcohol of ordinary purity redeposit the salt of the *l*-acid if cooled rapidly, but otherwise nothing but the partially racemic salt can be obtained from such solutions. In warm glacial acetic acid the salt of the *l*-acid is more readily soluble than the partially racemic salt, and a rapid and apparently complete conversion of the first-named salt to the second occurs in this solvent. When heated in a capillary tube, powdered *l*-hydroxyhydrindamine *l*-chlorobromomethanesulphonate loses its opacity at about 160° and decomposes at about 183° (Found: C, 33·8; H, 3·5. $C_{10}H_{13}O_4NClBrS$ requires C, 33·5; H, 3·6%).

FIG. 1.

l-Hydroxyhydrindamine l-chlorobromomethanesulphonate.

The optical rotatory powers of freshly made solutions of *l*-hydroxyhydrindamine *l*-chlorobromomethanesulphonate in the solvents utilised in the course of this investigation are summarised in the following table. The solutions were prepared as quickly as practicable, and heating was avoided if possible. With glacial acetic acid, and also with acetone at the higher concentration noted, it was found necessary, however, to warm the solvent on the water-



bath in order to effect solution. The interval which elapsed between the first contact with the solvent and the initial polarimetric observation was therefore appreciably longer in these two instances than in the others. The absolute methyl alcohol was dehydrated by means of metallic magnesium in presence of a trace of iodine (compare *Ber.*, 1923, **56**, 894). The "absolute" ethyl alcohol used contained about 0·5% of water. The acetone used for the original determination was of the purity required for ordinary analytical operations; but for the more dilute solutions very pure acetone was employed, which had been liberated from the sodium bisulphite compound and carefully dried and redistilled. The last-named solutions were prepared as rapidly as possible by shaking the finely powdered salt with the solvent at the ordinary temperature.

Solvent.	Approximate weight (g.) of salt in 20·0 c.c.	Time (minutes).	$[\alpha]_D$.	$M[\alpha]_D$.
Methyl alcohol (ordinary)	0·25	5	−48·6°	−174°
Methyl alcohol (absolute)	0·25	5	−50·0	−180
Ethyl alcohol (99·5%)	0·25	5	−50·0	−180
Acetone (ordinary)	0·25 (warmed)	30	−43·9	−158
Acetone (pure anhydrous)	0·10	20	−52·0	−187
Acetone (pure anhydrous)	0·05	10	−60·1	−216
Acetone (pure anhydrous)	0·025	3	−71·4	−256
Glacial acetic acid	0·25 (warmed)	10	−51·2	−184
Water	0·25	5	−16·9	− 60

All the solutions except those in water and acetone of ordinary analytical purity, which maintained their initial rotatory powers, exhibited marked downward mutarotation when kept at the ordinary temperature. The following typical series of values, selected from a mass of similar data, are sufficient to indicate the course of the changes. In methyl alcohol of ordinary purity, the initial molecular rotatory power of − 174° declined to − 115° in 14 hours, to − 97° in 24 hours, and reached a constant value of − 71° in 60 hours [Fig. 2 (*b*)]. In absolute methyl alcohol, the original value of − 180° fell to − 126° in 48 hours, − 102° in 70 hours, − 95° in 94 hours, − 86° in 146 hours, − 83° in 170 hours, and reached a constant value of − 71° in 220 hours [Fig. 2 (*a*)]. In absolute ethyl alcohol, the original value of − 180° declined to − 96° in 15 hours, and attained a final value of − 90° in 23 hours. In glacial acetic acid, the original value of − 184° fell to − 96° in 17 hours, and reached a constant value of − 66° in 35 hours.

Of these solvents, by far the slowest change thus occurred in absolute methyl alcohol. No mutarotation was apparent in a solution prepared by dissolving about 0·25 g. of the salt in warm acetone of ordinary purity, a constant value of $M[\alpha]_D = -158°$ being obtained. More dilute solutions prepared rapidly at the ordinary temperature in pure anhydrous acetone exhibited a strikingly rapid downward mutarotation to a constant value of $M[\alpha]_D = -187°$ [Fig. 2 (c)]. The most dilute solution indicated in the above table gave $M[\alpha]_D = -256°$ after 3 minutes, sinking to

FIG. 2.

Mutarotation of 1-*hydroxyhydrindamine chlorobromomethanesulphonates:* (a) lBlA *in absolute methyl alcohol,* (b) lBlA *in ordinary methyl alcohol,* (c) lBlA *in pure acetone,* (d) lBdlA *in pure acetone.*

$-198°$ in 35 minutes, and reaching the equilibrium value, $-187°$, in somewhat less than an hour; whilst the solution of twice this concentration gave $M[\alpha]_D = -216°$ 10 minutes after the first contact with the solvent, and $-188°$ after 45 minutes.

Upon removing the volatile solvents on the water-bath at any stage during the change, without attempting to exclude traces of water, the residue was found to consist wholly of the partly racemic salt, with a molecular rotatory power of about $-72°$ in ordinary methyl alcohol. In one instance, a residue obtained in this way from methyl alcohol was induced to crystallise on the water-bath by inoculation with a trace of the tabular form of crystal: the

molecular rotatory power of the residue thereby rose to $-87°$. The striking difference in the velocity of mutarotation exhibited by solutions in ordinary and carefully dried methyl alcohol led to an investigation of the effect upon the process of adding small quantities of water to ethyl alcohol used as a solvent in similar determinations. Such additions proved to exert a very remarkable accelerating influence upon the change. In a typical determination, 0·2500 g. of the salt when dissolved in cold 90% ethyl alcohol gave $\alpha_D = -0·79°$ 4 minutes after the first contact with the solvent, whence $[\alpha]_D = -31·6°$ and $M[\alpha]_D = -113°$. Owing to the very rapid fall in rotatory power, a second reading could not be taken conveniently until a further period of 4 minutes had elapsed, when the value observed was $\alpha_D = -0·45°$. A constant reading, $\alpha_D = -0·43°$, was reached 12 minutes after the first contact: the final value of $[\alpha]_D$ was thus $-17·2°$, and of $M[\alpha]_D$ $-62°$. A specimen of the pure powdered salt, after keeping at 160° for 30 minutes, gave $M[\alpha]_D = -149°$ when freshly dissolved in absolute methyl alcohol.

l-*Hydroxyhydrindamine* dl-*Chlorobromomethanesulphonate*.—The various fractions of the needle-shaped crystals deposited during the original series of recrystallisations were purified by a further recrystallisation from hot glacial acetic acid. Upon cooling, the solvent deposited rosettes of hard, glittering needles, which were collected and washed with ethyl acetate; further preparations of the substance were made by dissolving the tabular crystals in the same solvent, when the separation formed on cooling consisted entirely of the partially racemic salt. The crystals, which are unsuitable for goniometric examination, show straight extinction with strong double refraction. The refractive index is greater than 1·60.

The salt is much more soluble in acetone and in methyl and ethyl alcohol than the salt of the *l*-acid, and is also slightly soluble in boiling chloroform. It is practically insoluble in benzene, ether, or light petroleum. In glacial acetic acid it dissolves with greater difficulty than the isomeric salt; crystallisation occurs with great ease from this solvent, and the substance shows no tendency to form supersaturated solutions. It dissolves sparingly in boiling ethyl acetate, and separates in fine needles upon cooling. When a solution of the salt in a little hot glacial acetic acid is diluted with hot ethyl acetate the liquid gradually becomes filled with magnificent interlacing aggregates, composed of long, silky needles radiating from centres: this procedure affords the best method of purifying the substance. Moderately strong solutions of the partially racemic salt in acetone readily deposit the characteristic tabular crystals

of *l*-hydroxyhydrindamine *l*-chlorobromomethanesulphonate when allowed to cool. *l*-Hydroxyhydrindamine *dl*-chlorobromomethanesulphonate decomposes at 187° without the preliminary change noticed in the case of the other salt (Found: C, 33·7; H, 3·7. $C_{10}H_{13}O_4NClBrS$ requires C, 33·5; H, 3·6%).

Optical rotatory powers were determined in various solvents, under the conditions outlined for the isomeric salt, the concentration being approximately 0·25 g. of salt in 20·0 c.c. of solution; the resulting values agreed very closely with the corresponding values furnished by the salt of the *l*-acid after the completion of the mutarotative changes. The partially racemic salt exhibited no mutarotation in methyl alcohol, glacial acetic acid, or water. A slight upward mutarotation occurred in 99·5% ethyl alcohol, until the final value given by the isomeric salt was practically attained: the initial value, $M[\alpha]_D = -75°$, rose in 4 hours to $-80°$, and in 20 hours to $-83°$, and no further change was observed.

Very striking changes were traced in acetone solutions. In a preliminary series of observations, about 0·25 g. of the salt was dissolved in acetone of ordinary purity, by warming for 10 minutes on the water-bath and then making up the cooled solution to 20·0 c.c. with the solvent: the original molecular rotatory power of $-93°$ rose in 20 hours to $-147°$, and in 27 hours to a constant value of $-154°$. When evaporated to dryness on the water-bath, the solution yielded a crystalline residue which exhibited a molecular rotatory power of $-104°$ when freshly redissolved in acetone; after 20 hours the value had again risen to $-154°$, at which it remained constant. In a similar experiment, the residue recovered by evaporation on the water-bath gave an original value of $-148°$ when freshly dissolved in methyl alcohol; after 40 hours, the molecular rotatory power had declined to a constant value of $-74°$. When dissolved in 90% ethyl alcohol, this salt gave a constant molecular rotatory power of $-63°$.

A much more rapid upward mutarotation occurred in pure anhydrous acetone: 0·1014 g. of the salt, dissolved to 20·0 c.c., gave $[\alpha]_D = -18°$, 3 minutes after the first contact with the cold solvent, whence $M[\alpha]_D = -71°$. The successive values observed after 8 minutes and 20 minutes, respectively, were $M[\alpha]_D = -89°$, and $-124°$; the constant value, $-187°$, attained in about an hour, is identical with the equilibrium value furnished by the isomeric salt under similar conditions [Fig. 2 (d)]. The main relationships between the molecular rotatory powers displayed by the two isomeric salts in various solvents are summarised in the following table:

Solvent.	*l*-Hydroxyhydrindamine *l*-chlorobromomethane-sulphonate. Original $M[\alpha]_D$.	Final $M[\alpha]_D$.	*l*-Hydroxyhydrindamine *dl*-chlorobromomethane-sulphonate. Original $M[\alpha]_D$.	Final $M[\alpha]_D$.
Methyl alcohol (ordinary)	−174°	−71°	−72°	−72°
Methyl alcohol (absolute)	−180	−71	−71	−71
Ethyl alcohol (99·5%)	−180	−90	−75	−83
Ethyl alcohol ... (90%)	−113	−62	−63	−63
Acetone (ordinary)	−158	−158	−93	−154
Acetone (pure anhydrous) ...	−256	−187	−71	−187
Glacial acetic acid	−184	−66	−59	−59
Water	−60	−60	−60	−60

For the reasons already stated, a further examination was made into the nature of the process whereby the salt of the *dl*-acid after solution in acetone yields a separation of the isomeric salt of the *l*-acid. The partially racemic salt (4·4 g.) was dissolved in warm acetone of ordinary purity with the addition of a few drops of methyl alcohol, and upon allowing the solution to cool, a separation consisting wholly of tabular crystals was deposited. After the lapse of 50 minutes 5 c.c. of the clear mother-liquor were withdrawn, diluted to 20·0 c.c. with acetone, and examined polarimetrically in a 2-dcm. tube. By subsequently evaporating a measured portion of the diluted solution it was ascertained that the observed reading, $\alpha_D = -1{\cdot}02°$, corresponded to 0·2748 g. of the salt dissolved in 20·0 c.c. of acetone, whence $M[\alpha]_D = -131°$. After a further interval of 200 minutes, during which nothing but tabular crystals separated, 5 c.c. of the mother-liquor were found to contain 0·1790 g. of dissolved salt having a molecular rotatory power of −122°. It appears, therefore, that the solution in acetone always contains an excess of the salt *lBlA*, notwithstanding its continuous withdrawal during the process of crystallisation.

For purposes of comparison in two kinds of solvents giving rise to mutarotation, a specimen of l-*hydroxyhydrindamine benzenesulphonate* was prepared by mixing equivalent amounts of the free acid and base on the water-bath in presence of acetone containing a little water. The resulting crystalline solid separated from hot acetone containing a little methyl alcohol in clusters of glittering, anhydrous prisms, m. p. 198°, when the solution was allowed to cool (Found: C, 58·7; H, 5·7. $C_{15}H_{17}O_4NS$ requires C, 58·6; H, 5·5%).

The original molecular rotatory power of this substance in acetone

was — 140°, and a slight decline to a constant value of — 131° occurred in 20 hours. The salt recovered by evaporation on the water-bath gave a constant molecular rotatory power of — 75° in methyl alcohol. The original salt gave an initial value of — 100° in the same solvent, declining to a constant value of — 76° in 8 hours. A slight downward mutarotation was thus displayed in both types of solvent. *d*-Hydroxyhydrindamine acetate (J., 1912, **101**, 777) gave the constant value $M[\alpha]_D = + 61°$ in methyl alcohol, and in acetone declined from + 414° to + 382° in 44 hours.

Replacement of the Base in l-*Hydroxyhydrindamine* l- *and* dl-*Chlorobromomethanesulphonate.*—1. When *l*-hydroxyhydrindamine *l*-chlorobromomethanesulphonate was dissolved in warm acetone containing a trace of methyl alcohol and mixed with a solution of the calculated amount of brucine acetate in warm acetone, there was an immediate separation of well-defined crystalline needles. These were collected and washed with acetone, cold water, and again with acetone; the dry product represented an almost theoretical yield of brucine chlorobromomethanesulphonate. Owing to the sparing solubility of the salt, the determination of its optical rotatory power presented considerable difficulty; but readings were eventually obtained in acetone, which dissolves it slightly, and glacial acetic acid, which is the best solvent available for the purpose. A small quantity of the salt was heated on the water-bath for 20 minutes with acetone, so that a portion remained undissolved; after keeping for 24 hours at the ordinary temperature, the clear saturated solution gave $\alpha_D = + 0{\cdot}11°$ when examined polarimetrically in a 4-dcm. tube. In a further experiment, 0·1025 g. was completely dissolved in glacial acetic acid by heating on the water-bath for 25 minutes. The cold solution, when made up to 20·0 c.c. and examined forthwith in a 2-dcm. tube, gave $\alpha_D = + 0{\cdot}07°$, whence $[\alpha]_D = + 6{\cdot}8°$. A similar determination made upon a solution containing 0·2010 g. of the salt in 30·0 c.c. yielded the value $\alpha_D = + 0{\cdot}16°$ in a 4-dcm. tube. In a third determination an identical value was observed 15 minutes after the first contact with the solvent, but in 3 hours the solution exhibited no appreciable optical activity, and further readings were rendered impossible through the separation of crystals in the polarimeter tube. In a fourth determination, made upon a new preparation of the brucine salt, the initial value, $[\alpha]_D = + 6{\cdot}1°$, declined to zero in 45 minutes, to — 7·5° in 1·5 hours, and reached a constant value of — 10·4° in 3·5 hours; in this instance no crystallisation occurred. A fifth solution of the same kind when heated on the water-bath for 3 hours showed no appreciable optical activity in a 4-dcm. tube.

l-Hydroxyhydrindamine *dl*-chlorobromomethanesulphonate also yielded a brucine salt when treated in the manner described above; the two brucine salts were very similar in appearance, except that the second one crystallised in smaller needles than the first. A saturated solution of the second salt in acetone, prepared at the same time and in exactly the same manner as the corresponding solution of the first brucine salt, gave the value $\alpha_D = -0{\cdot}02°$ when examined polarimetrically in a 4-dcm. tube. This value, although difficult to establish with precision, is obviously different from the corresponding value, $\alpha_D = +0{\cdot}11°$, recorded above for the related salt. A solution of 0·1118 g. in glacial acetic acid, prepared in the manner described above and examined forthwith, gave $\alpha_D = -0{\cdot}13°$ in a 2-dcm. tube, whence $[\alpha]_D = -11{\cdot}2°$. In a second similar determination, 0·2010 g. made up to 30·0 c.c. with glacial acetic acid gave $\alpha_D = -0{\cdot}28°$ in a 4-dcm. tube, whence $[\alpha]_D = -10{\cdot}4°$. A third determination, made upon a new preparation of the brucine salt, gave an original value of $[\alpha]_D = -8{\cdot}0°$, which changed in the course of 9 hours to a constant value of $-10{\cdot}5°$. A fourth similar solution displayed no measurable optical activity after heating for 3 hours on the water-bath.

In several instances the brucine salt derived from *l*-hydroxyhydrindamine *l*-chlorobromomethanesulphonate crystallised from glacial acetic acid in the polarimeter tube, but no such behaviour was observed on the part of the second brucine salt, which thus appears to be the more soluble, or, at least, to have passed through the stage of the mutarotation corresponding to the least solubility.

Brucine *dl*-chlorobromomethanesulphonate, prepared by mixing aqueous solutions of equimolecular amounts of ammonium *dl*-chlorobromomethanesulphonate and brucine hydrochloride, dissolved with greater difficulty in hot glacial acetic acid than either of the brucine salts described above. When prepared by heating over a small flame and then examined immediately after cooling, a 0·5% solution showed no measurable optical rotation in a 2-dcm. tube, and the crystallisation of the substance in the tube rendered further observation impracticable. The various preparations of brucine salt obtained by fractional precipitation from aqueous solution showed similar behaviour when dissolved in glacial acetic acid, and thus consisted probably of brucine *dl*-chlorobromomethanesulphonate, as indicated below.

The optical inversion noticed upon precipitating *l*-hydroxyhydrindamine *l*-chlorobromomethanesulphonate with brucine acetate led to an examination of the optical rotatory power of the brucine salt prepared from an optically impure specimen of ammonium *l*-chloroiodomethanesulphonate, having $M[\alpha]_D = -28°$ in 1%

solution in glacial acetic acid. The brucine salt obtained by completely precipitating an aqueous solution of this ammonium salt by the addition of brucine hydrochloride had $M[\alpha]_D = -50°$ when dissolved to form a 0·6% solution in glacial acetic acid. No inversion was therefore apparent, and neither of these salts showed mutarotation in glacial acetic acid.

An investigation of a number of salts of brucine with optically inactive acids showed that such salts, when dissolved in glacial acetic acid to form solutions of the approximate molecular concentration indicated above, gave no measurable rotation when examined in a 4-dcm. tube in sodium light. The salts examined comprised brucine *dl*-chloroiodomethanesulphonate, brucine sulphate, and brucine benzenesulphonate. As a check, it was noted that the specimen of brucine sulphate used was appreciably active in 1% aqueous solution, the values observed being $[\alpha]_D = -24·4°$, and $M[\alpha]_D = -121°$ (Found: SO_4, 9·63; loss at 115° in 30 hours, 11·16. $B_2,H_2SO_4,6H_2O$ requires SO_4, 9·66; H_2O, 10·88%). *Brucine benzenesulphonate*, prepared by mixing the acid and base in presence of water and evaporating to dryness, crystallises from hot methyl alcohol, in which it is moderately soluble, in rosettes of glistening, anhydrous needles.

2. Of the many attempts made to replace the *l*-hydroxyhydrindamine in the above salts by an optically inactive base, avoiding water as a solvent, success was only achieved with benzidine and β-naphthylamine. Upon dissolving either of the *l*-hydroxyhydrindamine salts, with very gentle warming, in about ten times the weight of glacial acetic acid and adding at once to the cooled solution an equivalent quantity of benzidine dissolved in a like volume of the same solvent, an immediate and practically quantitative precipitation of the corresponding benzidine salt occurred. In each instance the salt consisted of minute needles, practically insoluble in water, acetone, or glacial acetic acid, and only slightly soluble in alcohol. About 0·1 g. of each salt was dissolved separately in absolute methyl alcohol on the water-bath, the cold solution being then made up to 20·0 c.c. with the solvent. About 10 minutes elapsed between first contact of the material with the solvent and the polarimetric observation, and no optical activity was observed in either instance.

3. The β-naphthylamine salts were prepared in a similar way, except that smaller amounts of glacial acetic acid were used. The β-naphthylamine salt obtained from *l*-hydroxyhydrindamine *l*-chlorobromomethanesulphonate was a crystalline powder, consisting of minute, glistening prisms, m. p. 210—240° (decomp.). The β-naphthylamine salt prepared from *l*-hydroxyhydrindamine *dl*-chloro-

bromomethanesulphonate was quite distinct in appearance from the salt just described: it consisted of well-defined, silky needles, which decomposed very definitely at 240°, without undergoing any preliminary change. The distinctions were confirmed by carrying out a second preparation of each salt. Neither of the β-naphthylamine salts was soluble in benzene or chloroform, but both were readily soluble in cold acetone or alcohol, and moderately soluble in warm glacial acetic acid. The salt obtained from the *dl*-acid appeared to be less soluble than the other, and either salt upon recrystallisation from glacial acetic acid yielded silky needles decomposing at 240°.

In each case, 0·15 g. of the original β-naphthylamine salt, when dissolved in cold acetone and made up to 20·0 c.c. with the solvent, failed to reveal any optical activity when examined polarimetrically in a 2-dcm. tube 5 minutes after the first contact with the solvent. A similar result was obtained by dissolving 0·2 g. in absolute methyl alcohol in an exactly similar manner. The residues recovered from the acetone and methyl alcohol solutions by allowing the solvent to evaporate at the ordinary temperature were identical in appearance.

d-*Hydroxyhydrindamine* d-*Chlorobromomethanesulphonate.*—A crystalline mass was readily obtained by mixing equivalent quantities of *d*-hydroxyhydrindamine and *dl*-chlorobromomethanesulphonic acid on the water-bath in presence of a little acetone, as described above for the *l*-base. When the product was recrystallised from warm acetone containing a little methyl alcohol, it yielded glistening plates, identical in appearance with crystals of *l*-hydroxyhydrindamine *l*-chlorobromomethanesulphonate: 0·2000 g. dissolved in absolute methyl alcohol at the ordinary temperature and made up to 20·0 c.c., gave $\alpha_D = +1{\cdot}00°$, when examined at once in a 2-dcm. tube, whence $[\alpha]_D = +50{\cdot}0°$, and $M[\alpha]_D = +180°$. The two salts crystallising in tabular form are thus enantiomorphously related. When the above solution was evaporated to dryness on the water-bath, the residue gave $M[\alpha]_D = +71°$ when redissolved in absolute methyl alcohol: the analogy between the enantiomorphous salts is thus complete.

The brucine salt derived from *d*-hydroxyhydrindamine *d*-chlorobromomethanesulphonate by precipitation in acetone solution was not noticeably different in appearance or solubility from the brucine salt derived in a similar way from the enantiomorphous substance. In this instance, however, no dextrorotation could be established by dissolving the brucine salt in glacial acetic acid: 0·1510 g., when dissolved in a few minutes by heating the solvent over a small flame and examined forthwith in the usual way, gave $\alpha_D =$

$-0{\cdot}10°$ in a 2-dcm. tube, whence $[\alpha]_D = -6{\cdot}6°$. A constant value of $[\alpha]_D = -10{\cdot}0°$ was attained after an interval of 90 minutes.

d-*Hydroxyhydrindamine* dl-*Chlorobromomethanesulphonate*.—The acetone mother-liquor from the salt just described was evaporated to dryness on the water-bath and the residue recrystallised from a small quantity of hot glacial acetic acid, with the addition of hot ethyl acetate in excess: the resulting long, silky needles gave a constant value of $M[\alpha]_D = +71°$ when dissolved in absolute methyl alcohol at the usual concentration, and exhibited the expected upward mutarotation when dissolved in acetone.

Wholly Racemic Forms of Hydroxyhydrindamine Chlorobromomethanesulphonate.—A solution of a mixture of equal weights of *l*- and *d*-hydroxyhydrindamine *dl*-chlorobromomethanesulphonate in a small amount of hot glacial acetic acid was diluted with hot ethyl acetate and allowed to cool. The crystalline separation which gradually ensued consisted wholly of rosettes of short, glistening needles. The substance, which was optically inactive, softened slightly at 155°, melted without decomposition at 175°, and recrystallised on cooling. In appearance it was very similar to *l*- or *d*-hydroxyhydrindamine *dl*-chlorobromomethanesulphonate, but was more soluble than these salts. The same substance resulted when a mixture of equal weights of *d*-hydroxyhydrindamine *d*-chlorobromomethanesulphonate and *l*-hydroxyhydrindamine *l*-chlorobromomethanesulphonate was treated similarly.

Upon crystallising the last-named mixture from acetone, in place of acetic acid, the resulting crystalline deposit contained the form of racemate just described, interspersed with large, glassy, transparent prisms, very similar in appearance to the original salts. These crystals, which melted at 160° and recrystallised on cooling, represented a second completely racemic form. A similar mixed deposit of needles and large prisms was also obtained by recrystallising the first racemic form from acetone. The interconversions shown by the constituent optically active salts thus persist in the racemates.

Exhibition of Optical Activity by Chlorobromomethanesulphonic Acid in Combination with an Optically Inactive Base.—Although no optical activity could be established when *l*(or *d*)-hydroxyhydrindamine in combination with *l*(or *d*)-chlorobromomethanesulphonic acid was replaced by a new optically inactive base, it was found that the optical activity of the acid in these salts persisted for a while when the activity of the combined hydroxyhydrindamine was neutralised by the addition of an equal weight of the salt containing the opposed optical form of this base in combination with the racemic acid. As an example, a mixture of

0·2024 g. of *d*-hydroxyhydrindamine *d*-chlorobromomethanesulphonate with 0·2024 g. of *l*-hydroxyhydrindamine *dl*-chlorobromomethanesulphonate was dissolved in cold absolute methyl alcohol and made up to 20·0 c.c. with the solvent. When examined in a 2-dcm. tube, 2 minutes after the first contact, an optical rotation of $\alpha_D = +0{\cdot}55°$ was observed, whence $[\alpha]_D = +13{\cdot}6°$, and $M[\alpha]_D = +49°$. In 4·5 hours the value of $M[\alpha]_D$ had declined to + 33°, in 7·25 hours to + 31°, in 28 hours to + 8°, and in 32 hours the optical activity had completely disappeared. The rate of change was thus considerably more rapid than that exhibited in the later stages of the mutarotation of *l*-hydroxyhydrindamine *l*-chlorobromomethanesulphonate in the same solvent.

The investigation will be extended, as occasion permits, in the various directions indicated. We express our acknowledgments to the Department of Scientific and Industrial Research for a maintenance grant to one of the authors (A.M.M.).

CCX.—*The Nitration of* m-*Chlorophenol.*

By Herbert Henry Hodgson and Francis Harry Moore.

The scanty literature on this subject prior to 1924 deals only with 3-chloro-6-nitrophenol (Laubenheimer, *Ber.*, 1876, **9**, 76; Uhlemann, *Ber.*, 1878, **11**, 1161), 3-chloro-4 : 6-dinitrophenol (Fries, *Annalen*, 1912, **389**, 305), and 3-chloro-2 : 4 : 6-trinitrophenol. Auwers and Deines (*Zentr.*, 1924, II, No. 18) have prepared 6- and 4-nitro-3-chlorophenols *via* the action of nitrous acid on 3-chloroaniline nitrate, but we have obtained very moderate yields by their method.

The present paper relating to the nitro-derivatives obtainable from *m*-chlorophenol by direct nitration is part of a systematic study of the chemistry of *m*-halogenated phenols.

The above mononitro-compounds have been prepared in purer form than any hitherto described and 3-*chloro*-2-*nitrophenol* has been obtained in excellent yield. 4 : 6-, 2 : 6-, and 2 : 4-Dinitro-3-chlorophenols are readily distinguishable by means of their characteristic silver salts.

Monosulphonation of *m*-chlorophenol at 100—120° appears to form exclusively 3-chlorophenol-4-sulphonic acid, owing to the usual directing influence of the hydroxyl group.

3-Chloro-2 : 4 : 6-trinitrophenol is obtained in a very pure con-

dition by the direct nitration of *m*-chlorophenol and removal of any dinitro-compound in steam. If, however, *m*-chlorophenol is sulphonated and then treated with an excess of nitric acid, a trinitro-sulphonic acid is formed which on hydrolysis yields 3-chloro-2 : 5 : 6-trinitrophenol as a product volatile in steam.

Evidence in support of the constitution assigned to 3-chloro-4-nitrosophenol by Hodgson and Moore (J., 1923, **123**, 2499) has been obtained by its oxidation to 3-chloro-4-nitrophenol.

Experimental.

Mononitration of m-*Chlorophenol.*

6- *and* 4-*Nitro*-3-*chlorophenols.*—*m*-Chlorophenol (24 g.), liquefied by alcohol (2 c.c.), was added slowly to a solution, kept below 25°, of 40 g. of concentrated sulphuric acid and 29 g. of sodium nitrate in 70 c.c. of water. After being stirred for 2 hours, the mixture was diluted with water (2 vols.). The solid was washed and steam-distilled. The yellow oil in the distillate solidified and after being pressed was again distilled in steam, when 3-chloro-6-nitrophenol, m. p. 41°, was obtained (Auwers and Deines, *loc. cit.*, give 39°) (Found : Cl, 20·4. Calc., Cl, 20·5%). The yield of crude product was 22%.

3-Chloro-4-nitrophenol, which remained in the distillation flask as a brown solid, m. p. 80—106° (yield 60%), crystallised in white, feathery needles, m. p. 121—122°, from dilute hydrochloric acid or water (Found : Cl, 20·4%). Auwers and Deines (*loc. cit.*) obtained faintly yellow needles, m. p. 120—121°, from benzene; the colour was possibly due to the action of atmospheric ammonia. We cannot confirm Uhlemann's statement (*loc. cit.*) that 3-chloro-6-nitrophenol melts at a second determination at 32° and regains its normal m. p. after several days.

Oxidation of 3-*Chloro*-4-*nitrosophenol.*—A solution of the nitrosophenol (2 g.) in 400 c.c. of water containing 20 g. of sodium hydroxide and 20 g. of potassium ferricyanide was acidified with sulphuric acid after being kept for 2 days. Ether extracted from the mixture a trace of a product which was volatile in steam and gave a red sodium salt, but the bulk of the extract was 3-chloro-4-nitrophenol, which melted at 121° after crystallisation from water (Found : Cl, 20·3%).

Oxidation with nitric acid of various strengths and with hydrogen peroxide produced similar results, but the yields were unsatisfactory.

3-*Chloro*-2-*nitrophenol.*—*m*-Chlorophenol (12·8 g.) was added slowly to 75 g. of oleum (27% SO_3), cooled after each addition.

The mixture was kept for 12 hours and then heated for 2 hours on a water-bath to complete the disulphonation. Nitric acid (4·5 c.c.; *d* 1·5) dissolved in 20 c.c. of oleum (27% SO_3) was added during 15 minutes to the cooled mixture, which was then kept for 2 hours. On dilution and hydrolysis in a current of steam, a viscous, yellow, opaque oil passed over which rapidly solidified; it separated in white, slender needles, m. p. 37·5°, from its yellow solution in light petroleum (yield 11 g.; 66%) (Found: Cl, 20·35. $C_6H_4O_3NCl$ requires Cl, 20·5%).

3-Chloro-2-nitrophenol is remarkable as being an *o*-nitrophenol which is colourless. It is readily turned yellow by atmospheric ammonia. Like its 6-nitro-isomeride, it has a distinctive odour; the 4-nitro-isomeride is odourless. The *silver* salt of 3-chloro-2-nitrophenol forms characteristic crimson festoons (Found: Ag, 38·2. $C_6H_3O_3NClAg$ requires Ag, 38·5%). The *methyl* ether was prepared by means of boiling aqueous sodium carbonate and excess of methyl sulphate. The product was steam-distilled and the white solid crystallised from dilute alcohol; m. p. 55° (Found: Cl, 18·7. $C_7H_6O_3NCl$ requires Cl, 18·9%). The *benzoate* could not be prepared in aqueous alkali hydroxide, but was readily obtained in aqueous sodium carbonate. It separated from alcohol in colourless crystals, m. p. 123° (Found: Cl, 12·1. $C_{13}H_8O_4NCl$ requires Cl, 12·7%).

Dinitration of m-*Chlorophenols.*

General Procedure.—The initial material is added gradually to a cooled mixed acid containing 98% sulphuric acid (15 vols.), 70% nitric acid (12 vols.), and water (9 vols.). After an interval, the mixture is warmed if necessary, diluted, and steam-distilled. The dinitro-products are all volatile with steam and crystallise well from water or dilute acids.

3-*Chloro*-4 : 6-*dinitrophenol.*—(*a*) The reaction mixture (1 g. of 3-chloro-6-nitrophenol and 3 c.c. of mixed acid; 3 c.c. of concentrated sulphuric acid were subsequently added) was kept for 2 hours and then heated for ½ hour on the water-bath. 3-Chloro-4 : 6-dinitrophenol was obtained in colourless crystals, m. p. 92—93°, from water or in stout prisms from light petroleum (Found: Cl, 16·1. Calc., Cl, 16·2%). A non-volatile product was 3-chloro-2 : 4 : 6-trinitrophenol, large, white needles, m. p. 114° (from water).

(*b*) The reaction mixture (1 g. of 3-chloro-4-nitrophenol and 4 c.c. of mixed acid) was kept over the week-end. The product had m. p. 92—93° (Found: Cl, 16·15%).

(*c*) 1 : 3-Dichloro-4 : 6-dinitrobenzene was boiled with aqueous sodium carbonate, and the solution acidified after filtration. The precipitate melted at 92° after being crystallised from water.

The identity of the three products in (*a*), (*b*), and (*c*) was established by the melting points of their mixtures.

3-*Chloro*-2 : 6-*dinitrophenol*.—(*a*) This was obtained from a reaction mixture of 2 g. of 3-chloro-2-nitrophenol and 12 c.c. of mixed acid. It is less volatile with steam than its 4 : 6-dinitro-isomeride and crystallises from dilute hydrochloric acid in white, feathery crystals, m. p. 114·5° (Found : Cl, 16·1. Calc., Cl, 16·2%). A non-volatile product was 3-chloro-2 : 4 : 6-trinitrophenol (Found : Cl, 13·2. Calc., Cl, 13·5%).

(*b*) A mixture of 4 g. of 3-chloro-2-nitrophenol and 4 c.c. of oleum (27% SO_3) was kept over-night (crystals of unchanged material separated), 4 c.c. of oleum were added and, 4 hours later, the mixture was heated on the water-bath to complete the sulphonation. It was then nitrated with 1 c.c. of nitric acid (*d* 1·5) dissolved in 2·5 c.c. of oleum. The product volatile with steam was 3-chloro-2 : 6-dinitrophenol. The liquor in the flask, on neutralisation with potassium carbonate, gave a bright yellow potassium salt (probably of 3-chloro-2 : 6-dinitrophenol-4-sulphonic acid) from which 3-chloro-2 : 6-dinitrophenol was obtained on hydrolysis.

(*c*) A mixture of 3 g. of *m*-chlorophenol and 7 c.c. of oleum (27% SO_3), after being kept for 2 hours, was nitrated with 0·8 c.c. of nitric acid (*d* 1·5) in 4 c.c. of oleum and kept for 1 hour. The volatile product of hydrolysis by steam was 3-chloro-2 : 6-dinitrophenol (mixed m. p.).

3-*Chloro*-2 : 4-*dinitrophenol*.—After 3 g. of 3-chloro-2-nitrophenol had been added slowly to 1·8 c.c. of sulphuric acid (100%) and 4 c.c. of oleum (27% SO_3), the mixture was kept for 6 hours, then heated on the water-bath for 2 hours, cooled, nitrated with 0·8 c.c. of nitric acid (*d* 1·5) in 4 c.c. of oleum, and kept for 1 hour. The steam-distillate, on cooling, deposited 3-chloro-2 : 6-dinitrophenol. The filtrate from this, on extraction with ether, gave up a solid, probably 3-chloro-2 : 4-dinitrophenol, which, after repeated fractional crystallisation from water, had m. p. 138—140° and gave a yellow silver salt insoluble in ammonia (Found : Cl, 15·9. Calc., Cl, 16·2%).

Direct Nitration of Disulphonated m-*Chlorophenol*.—After remaining for 20 hours at 10—15°, a solution of 4·2 g. of *m*-chlorophenol in 25 g. of oleum (27% SO_3) was nitrated with 2·7 c.c. of nitric acid (*d* 1·5) in 14 c.c. of oleum and kept for 1 hour. On hydrolysis in a current of steam, 3-chloro-2-nitrophenol distilled over first and was followed by 3-chloro-2 : 6-dinitrophenol, which separated, and 3-chloro-2 : 4-dinitrophenol, which was extracted with ether, from the distillate. The presence of 3-chloro-4 : 6-dinitrophenol was not detected.

Sulphonation and Nitration of 3-*Chloro*-4-*nitrophenol.*—A solution of 5 g. of the chloronitrophenol in 10 c.c. of oleum (27% SO_3) was cooled and immediately nitrated with 1·2 c.c. of nitric acid (*d* 1·5) in 5 c.c. of oleum. After the usual treatment 3-chloro-4 : 6-dinitrophenol, but not 3-chloro-2 : 4-dinitrophenol, was obtained. If, however, the sulphonation mixture was kept for 2 hours, or was warmed, before being nitrated, no 3-chloro-4 : 6-dinitrophenol was produced, the destruction of 3-chloro-4-nitrophenol by oleum being thus made manifest. 2- and 6-Nitro-3-chlorophenol are stable towards oleum.

Properties of the Dinitro-m-*chlorophenols.*—4 : 6-, 2 : 6-, and 2 : 4-Dinitro-3-chlorophenol are in the order of increasing solubility in water. The solutions are yellow. The silver salts are prepared from the ammonium salts and silver nitrate in neutral aqueous solution. The 4 : 6-dinitro-compound gives a characteristic yellow gel which slowly becomes crystalline (Found : Ag, 33·0. Calc., Ag, 33·2%). The 2 : 4-dinitro-compound forms yellow crystals (Found : Ag, 32·95%). The 2 : 6-dinitro-compound gives a red, crystalline substance which is much more soluble in aqueous ammonia or water than either of the other two (Found : Ag, 32·9%). The silver salts of 2 : 6-dinitrophenol and 4-chloro-2 : 6-dinitrophenol also are red.

The three dinitro-*m*-chlorophenols resist methylation and benzoylation by direct means. The mononitro-compounds are methylated only with difficulty.

Trinitration of m-*Chlorophenol.*

3-*Chloro*-2 : 4 : 6-*trinitrophenol.*—*m*-Chlorophenol (4 g.) dissolved in 6 c.c. of oleum (27% SO_3) was nitrated in the cold with 40 c.c. of nitric acid (70%), added gradually. The mixture, having been stirred for 1 hour, was gently boiled for 10 minutes and poured on to ice, and products volatile with steam (if any) were removed. The residue crystallised from dilute sulphuric acid in fern-like crystals and from water in rectangular prisms, m. p. 114° (Found : Cl, 13·2. Calc., Cl, 13·5%).

3-Chloro-2 : 4 : 6-trinitrophenol is readily soluble in alcohol, ether, benzene, or chloroform. Its sodium and silver salts are yellow; the former is moderately soluble in water, and the latter insoluble in aqueous ammonia. It is the ultimate product of nitration of all the mono- and di-nitro-3-chlorophenols mentioned above.

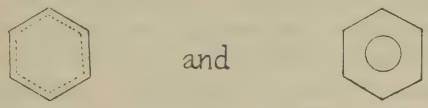
3-*Chloro*-2 : 5 : 6-*trinitrophenol.*—*m*-Chlorophenol (5 g.) dissolved in concentrated sulphuric acid (3 c.c.) was heated for 9 hours at 120°, cooled, and poured into 50 c.c. of water. The solution was

filtered from tar, treated with 15 c.c. of nitric acid (*d* 1·5), and, after being stirred for 30 minutes, was slowly heated and finally boiled for 5 minutes. Neutralisation of the cooled filtered solution with solid potassium carbonate caused the precipitation of a yellow product, which crystallised from water in characteristic old-gold clusters and from alcohol, in which it was moderately soluble, in small, yellow needles [Found : S, 7·5; Cl, 8·0. Calc. for $C_6Cl(OK)(NO_2)_3 \cdot SO_3K$, S, 7·6; Cl, 8·5%]. This salt was hydrolysed with boiling dilute sulphuric acid in a current of steam, and the volatile product, m. p. 112·5—113·5°, being somewhat soluble in water, was extracted from the distillate with ether (yield 2·7 g.) (Found : Cl, 13·2; N, 16·5. $C_6H_2O_7N_3Cl$ requires Cl, 13·5; N, 15·9%). The yellow, crystalline silver salt is insoluble in aqueous ammonia.

This steam-volatile trinitro-compound, produced from a monosulphonic acid in which the sulpho-group appears to be in position 4, is probably 3-chloro-2 : 5 : 6-trinitrophenol.

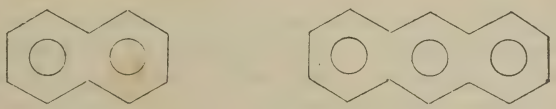
Traces of 4 : 6- and 2 : 4-dinitro-3-chlorophenol were detected when the original nitration mixture was steam-distilled without previous neutralisation.

The authors thank the British Dyestuffs Corporation for gifts of chemicals in connexion with this investigation.



TECHNICAL COLLEGE, HUDDERSFIELD. [*Received, December 17th,* 1924.]

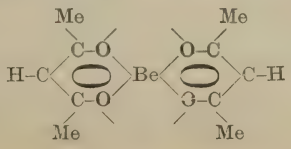
CCXI.—*Polynuclear Heterocyclic Aromatic Types. Part II. Some Anhydronium Bases.*



By JAMES WILSON ARMIT and ROBERT ROBINSON.

IT is a commonplace of the electronic theory of the atom and of valency that certain systems of electrons exist which by their association reach a stable condition, and an example may be found in the electron pair or duplet, the octet and dodecet, as well as in the special configurations, which are frequently assumed, of the valency electrons in nitrogen, carbon monoxide, and similar substances. The occurrence of many atoms in a molecule provides further opportunities for the emergence of electron groups of marked stability and, *ceteris paribus*, the possession of such groups confers chemical stability as shown, for example, by reduced unsaturation and a tendency to maintain the type. These are, of course, the chief characteristics of benzenoid systems, and here the explanation is obviously that six electrons are able to form a group which

resists disruption, and may be called the *aromatic sextet.** It is not supposed that the existence of the sextet involves a change in the total covalency exerted by the carbon atoms of the ring nor does the theory as employed below require any particular assumption in regard to the position of the electrons or their orbits in space. Thus the symbols

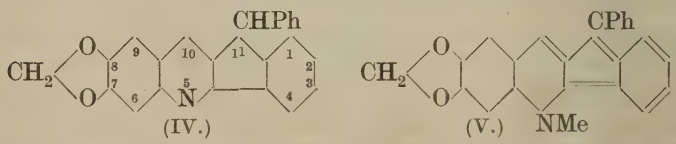


are each considered to express a view of one aspect of the problem and are not inconsistent. The first expression suggests a symmetrical distribution of electrons in the ring, and in regard to the covalencies should be taken as the interpretation of the second expression. The circle in the ring symbolises the view that six electrons in the benzene molecule produce a stable association which is responsible for the *aromatic* character of the substance.† Naphthalene and anthracene will be represented by the following formulæ

in which the deletion of the central connecting bonds is more apparent than real, because these attachments are by covalencies which involve the electrons of the sextets only. The aromatic character of thiophen and pyrrole requires the hetero-element to have contributed some of its free salt-forming electrons for the purpose of setting up a sextet, with the natural result that the basic character of these substances has been suppressed or largely diminished. In pyridine, the sextet can, however, be obtained without the help of the *lone pair* on the nitrogen atom. The

* In the ions of carboxylic acids, in the *cyclo*pentadienes and indene derivatives, and in many other types of *semi-aromatic* compounds, groups of two or four electrons may be assumed to occur.

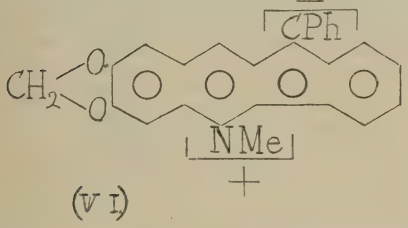
† The stability of beryllium acetylacetone and similar substances may be associated with the fact that the rings are aromatic and contain sextets. This is possible if the function of all the oxygen atoms is assumed to be identical as in the annexed formula.



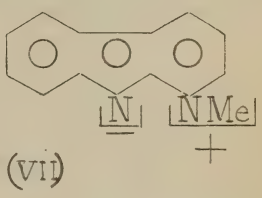
formulæ with sextets do not necessarily represent systems the aromatic character of which is of the most perfected kind. There is ample evidence that in some typical aromatic compounds the valency is unevenly distributed, and consideration of such a series as pyridine, benzene, naphthalene, anthracene, glyoxaline, thiophen, pyrrole, and furan serves to protect us from the unwarranted assumption that there are no gradations between the Kekulé formula and the symmetrical electronic structures which have been proposed for benzene. In discussing the possibility of the existence of the pentamethine nucleus in fusion with other rings, we pointed out (J., 1922, **121**, 828) that, on the basis of the cyclic conjugation theory, the forms I, II, and III might occur.

(I.) (II.) (III.)

On applying the restriction on the cyclic conjugation theory which is now suggested, namely, that the number of electrons must be such that sextets can be formed in each ring, it is clear that II and III cannot satisfy the condition.* The type represented by I remains theoretically possible, and we have prepared a compound which appears to contain such a nucleus. 6-Aminopiperonal and 3-phenylindanone condensed in alcoholic solution with the aid of potassium hydroxide, producing the quinoline derivative (IV), the methosulphate of which yields, on decomposition with hot aqueous alcoholic potassium hydroxide, the anhydronium base (V).



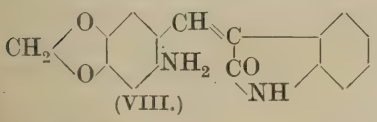
(IV.) (V.)



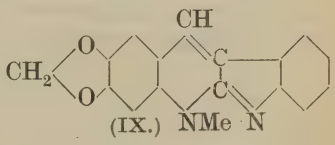
Utilising the free electrons on the nitrogen atom, 24 electrons are available for aromatic sextet formation as shown in (VI). Here the quadrivalent nitrogen is positively charged, whilst the pentamethine ring is negatively charged; (V) and (VI) represent extreme conditions, and the true structure doubtless lies between the two. (V) is not stable, because the right-hand benzene ring is

* The unsaturated nature of *cyclo*octatetraene suggests that a stable group of eight electrons analogous to the aromatic sextet is not formed.

not aromatic, and (VI) is not stable because it is a dipole; the tendencies to aromatic sextet formation and to neutralisation of the charges work in opposite directions and must reach some compromise. There is a very large class of substances which can similarly be regarded as normally occupying an intermediate position between a fully polarised aromatic phase and a neutralised quinonoid or ethenoid phase and these are usually anhydro-derivatives of aromatic *onium* hydroxides of various kinds. We propose to term these compounds *anhydronium bases*, since, although extremely diverse in form, they exhibit very similar chemical properties. Anhydronium bases derived from the methohydroxides of 4-carboline derivatives have been already described (Perkin and Robinson, J., 1919, **115**, 951; Kermack, Perkin, and Robinson, J., 1922, **121**, 1877; Robinson and Robinson, J., 1924, **125**, 832), whilst, in addition, 5-methyl-5-*iso*carboline has been recently prepared (Robinson and Thornley, J., 1924, **125**, 2169). We have now shown that 3-carboline methohydroxide loses water with the formation of an anhydride (VII). A corresponding substance in



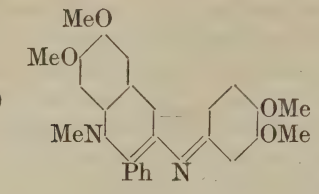
(VI)

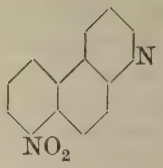


(VII)

the quinindoline series was obtained indirectly by condensation of 6-aminopiperonal with oxindole followed by treatment of the resulting aminopiperonylideneoxindole (VIII) with methyl sulphate and then with alcoholic potassium hydroxide, closing the ring with elimination of water.

(VIII.)

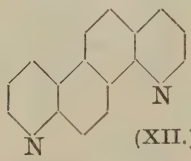




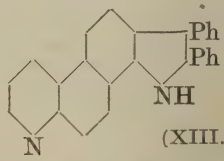
(IX.)

The base (IX) is represented in the quinonoid form, but it will be understood that we regard its actual mean condition as being something intermediate between this and the arrangement analogous to (VII). This remark applies to all formulæ here presented whether in the full polar aromatic conditions or as quinones. A bright scarlet anhydronium base in the 4-carboline series (harmine type) has been prepared by the decomposition of phenyldiveratro-

harmyrine methosulphate with sodium hydroxide and has the constitution (X).

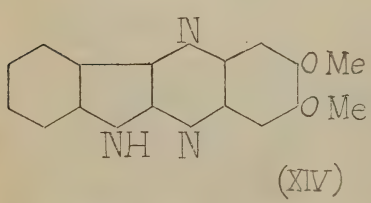


(X.)

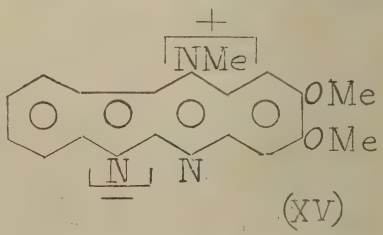


(XI.)

Anhydronium bases of what is fundamentally the glyoxaline or pyrazole type can therefore be obtained in the 3-, 4-, or 5-carboline series, the two nitrogen atoms in different rings being separated by one, two, or three carbon atoms. It was of interest to find out whether much greater separation is possible and experiments were undertaken with this object. The nitration of β-naphthaquinoline was studied by Claus and Besseler (*J. pr. Chem.*, 1898, **57**, 49), but the constitution of the mononitro-derivative was not determined. We have oriented the substance (XI) by the observation that the related aminonaphthaquinoline is converted by an application of the Skraup reaction into a naphthadiquinoline (XII), which may also be obtained from 1 : 6-naphthylenediamine in a similar manner.



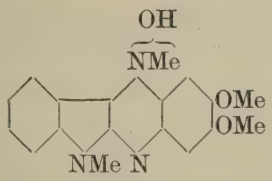
(XII.)

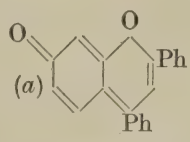


(XIII.)

Amino-β-naphthaquinoline was changed to an indole derivative (XIII) by condensation with benzoin under conditions similar to those used by Japp and Murray (J., 1894, **65**, 889) in analogous cases. The results obtained on decomposing the methosulphate of (XIII) were ambiguous and indicated oxidation. We have also investigated the alkylation of an indophenazine derivative (XIV). In view of such facts as the weak basic character of the amidines

(XIV)

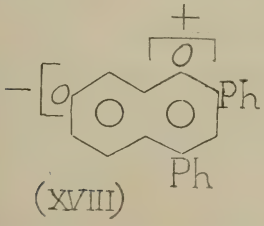




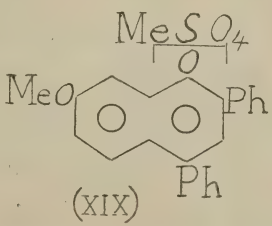
(XV)

and the circumstance that *p*-phenylenediamine is a stronger base than the *m*-isomeride, it seems most probable that the first methyl

group will attach itself to the quinoxaline nitrogen which is the more remote from the nitrogen of the indole nucleus, but there is no direct proof of this. On such an assumption, the anhydronium base derived from the methohydroxide of (XIV) will have the constitution (XV). This orange-red substance can be converted into a remarkably stable methohydroxide (XVI).



(XVI.)



(XVII.)

It has already been stated that the anhydronium bases include many types and among these are the glyoxalines, pyrazoles, α- and γ-aminopyridines, α- and γ-pyridones, α- and γ-pyrones, carbolines and *iso*carbolines, diazo-oxides and diazoimines * derived from *o*- and *p*-hydroxy- and amino-diazonium hydroxides, fuchsones and fuchsonimines, quinopyridanes, pyranhydrones, derivatives of methylenexanthane, etc. Thus the anhydropyranol (XVII) can also be represented as a phenol-betaine (XVIII), and it is the anhydr-

(XVIII)

(XIX)

onium base derived from hydroxydiphenylbenzopyrylium hydroxide. As such, it shows the normal behaviour of its type and adds on methyl sulphate so as to form the pyrylium salt (XIX) by direct addition of a methyl group to the quasiquinonoid oxygen atom.

Finally, it is necessary to indicate an important consideration. The formation of an anhydronium base invariably involves a redistribution of the charge unless the positive and negative centres in the dipole are so powerfully basic and acidic that the substance is definitely a betaine. It is convenient to keep the latter separate and to reserve the expression *anhydronium base* for the compounds which are recognisably intermediate between neutral and fully polarised forms. The redistribution of charge referred to can only

* On this hypothesis, the action of methyl iodide on a diazo-oxide or diazoimine should result in the replacement of the diazo-group by iodine and the simultaneous attachment of methyl to oxygen or nitrogen, respectively.

take place if the system connecting the charged centres is a conducting system. In other words, the necessary changes in covalency must be, not merely possible, but facile, and this will be the case only with definitely conjugated systems. There must always be a possible mechanism for the transfer of the charge in accordance with the electronic theory of conjugation as in the scheme:

and this will be the case if the formula of the substance can be constructed on the classical valency theory with alternate single and double bonds. For example, if the oxygen in (XVII) is at (*a*), the condition cannot be satisfied, and therefore 6-hydroxy-2 : 4-diphenylbenzopyrylium hydroxide should not yield an anhydronium base, although it might give a betaine on the model of (XVIII). The conception of the electrical conductivity of conjugated systems is implicit in all the suggestions relating to the mechanism of addition to such systems made by Kermack and Robinson (J., 1922, **121**, 427), and for experimental evidence we can turn to graphite, each one of the layers of which must be regarded as comprising a single fully conjugated aromatic system.

Experimental.

7 : 8 - *Methylenedioxy* - 11 - *phenylindenoquinoline* (IV).—Aqueous potassium hydroxide (5 c.c of 50%) was added to a cold solution of 6-aminopiperonal (3·9 g.) and 3-phenylindanone (5·1 g.) in ethyl alcohol (45 c.c.), when the liquid darkened and a red, crystalline precipitate slowly formed. Next day the separation had become copious and the substance was collected, washed with alcohol, and dried at 100° (6·6 g.). The compound crystallises from benzene in hexagonal prisms or in microscopic needles if the solution is rapidly cooled; it has m. p. 245—246° (Found: C, 81·6; H, 4·8; N, 4·3. $C_{23}H_{15}O_2N$ requires C, 81·9; H, 4·5; N, 4·2%). The base is moderately readily soluble in hot benzene or chloroform, very sparingly soluble in hot alcohol, and almost insoluble in ether or light petroleum. The red solution in sulphuric acid exhibits intense violet fluorescence, changing to blue fluorescence on dilution with water. Unlike the related methylenedioxyindenoquinoline (Part I, p. 831), this phenyl derivative is precipitated by the addition of water to its solution in glacial acetic acid. The *hydrochloride*, decomp. 247°, and the *picrate*, decomp. 236°, crystallise in yellow needles. The *methosulphate* separated in the course of 30 minutes from a boiling solution of the base (3 g.) and methyl sulphate (27 c.c.) in benzene (130 c.c.). The precipitate (3·8 g.) crystallised

from ethyl alcohol in pale yellow needles, m. p. 233° (Found : S, 7·0. $C_{25}H_{21}O_6NS$ requires S, 6·9%). The salt is moderately readily soluble in hot water and its aqueous and alcoholic solutions exhibit intense bluish-violet fluorescence. The *methiodide*, obtained directly or by double decomposition of the methosulphate, is sparingly soluble in water and alcohol and crystallises from the latter in small, pale yellow needles, m. p. 241—242° (decomp.).

Anhydro-7 : 8-*methylenedioxy*-11-*phenylindenoquinoline Methohydroxide* (V, VI).—On addition of aqueous potassium hydroxide (5 c.c. of 50%) to a hot solution of the preceding methosulphate (1 g.) in aqueous alcohol (80 c.c. of 50%), there was an immediate separation of pale green, very slender, microscopic needles. The mixture was boiled for 1 minute, filtered hot, and the residue well washed with hot alcohol and dried in a vacuum at 100° until its weight was constant (0·65 g.) (Found : C, 81·4; H, 5·0; N, 4·2. $C_{24}H_{17}O_2N$ requires C, 82·0; H, 4·8; N, 4·0%). The substance is readily soluble in chloroform to an emerald-green solution, and by careful addition of light petroleum it can be precipitated in small, green needles which darken at 226°, progressively decompose at higher temperatures, and finally melt to a black liquid at 246—247°. It is less readily soluble in benzene or toluene and undergoes decomposition in these media, which change is, however, no doubt due to oxidation. The base is slightly soluble in boiling water, the solution exhibiting bright blue fluorescence, and with acids the methosalts of the parent base are regenerated. The *picrate* crystallises in pale yellow needles which sinter at 221° and melt at 226°. The readily soluble *methiodide* of this anhydro-base is a pale yellow substance which gives an orange, amorphous precipitate with potassium hydroxide in aqueous solution. The new compound is easily soluble in cold water to a yellow fluorescent solution and is clearly a methohydroxide. It shows no tendency to give an anhydro-base and behaves exactly as would be anticipated if the methylation had proceeded so as to produce the group $-CMePh-$. A quite similar case was described in Part I (p. 834), and we are of the opinion that the analogy supports our view of the nature of the substance which is now under discussion. The green colour of the base may, however, be due to impurity.

3-*Methyl*-3-iso*carboline* (VII).—3-Carboline (Lawson, Perkin, and Robinson, J., 1924, **125**, 626), prepared by the improved method of Robinson and Thornley (*ibid.*, p. 2169), readily yields a *methosulphate* when its solution in hot nitrobenzene is treated with a solution of neutral methyl sulphate in toluene. The derivative is readily soluble in water and but sparingly soluble in alcohol, from which it crystallises in stellate clusters of pointed needles.

A concentrated aqueous solution was decomposed by an excess of warm 40% potassium hydroxide, and the base at once extracted by a large volume of light petroleum. The solution was dried with powdered potassium hydroxide and then with anhydrous barium oxide, filtered, and distilled with every precaution to avoid access of moist air. At a certain stage, crystallisation of the anhydro-base commenced and after cooling the small, yellow prisms, m. p. 140°, were collected (Found : in material dried at 95° in a high vacuum, C, 78·8; H, 5·6. $C_{12}H_{10}N_2$ requires C, 79·1; H, 5·5%).

The base is soluble in water, the solution being colourless and having an alkaline reaction. Aqueous acid solutions do not exhibit fluorescence. The base combines with methyl iodide to form a nearly colourless salt, which with silver oxide gives an alkaline, faintly fluorescent solution. The methohydroxide so obtained is precipitated by the addition of sodium hydroxide and exhibits no tendency to give an anhydro-base.

6′-Aminopiperonylideneoxindole (VIII).—Aqueous potassium hydroxide (8 c.c. of 60%) was added to a cold solution of oxindole (3 g.) and 6-aminopiperonal (3·2 g.) in methyl alcohol (40 c.c.). The precipitate of fine, orange needles which formed when the darkened liquid was stirred was washed with methyl alcohol, dried at 100°, and twice crystallised from ethyl alcohol to remove persistent inorganic contamination. The deep orange needles (3·1 g.) obtained decomposed at 226° (Found : C, 68·3; H, 4·7. $C_{16}H_{12}O_3N_2$ requires C, 68·6; H, 4·3%). The base is to some extent soluble in boiling water to an orange solution, it is freely soluble in acetic acid or nitrobenzene and sparingly soluble in benzene. The mineral acid salts are sparingly soluble, pale yellow, crystalline substances. The *picrate* crystallises from ethyl alcohol in deep yellow needles, which darken at 235° but do not melt at 300°. The orange solution in sulphuric acid is not fluorescent, but if the salts of the base are decomposed by alkali and the product is dissolved in sulphuric acid, the solution exhibits intense bluish-violet fluorescence, which is clearly due to the formation of methylenedioxyquinindoline. The diazo-solution from the base is pale yellow and gives a crimson coloration with alkaline β-naphthol. The *methosulphate* (*6′-methylamino-piperonylideneoxindole methyl hydrogen sulphate*) was obtained in the following manner. The base (1·5 g.) was dissolved in nitrobenzene (30 c.c.) and toluene (30 c.c.), a solution of neutral methyl sulphate in toluene (10 c.c. of 75%) added to the boiling mixture, and the lamp removed. The derivative, which separated in a few minutes as a flocculent precipitate of yellow needles, was crystallised from 50% alcohol, washed with ether, and dried at 120° (1·2 g.) (Found : S, 7·8. $C_{18}H_{18}O_7N_2S$ requires S, 7·9%). The salt darkens at 289°,

but does not melt at 300°. It is sparingly soluble in water or ethyl alcohol, but more readily soluble in a mixture of the two. The open-chain structure is indicated chiefly by the fact that the solution in sulphuric acid is not at once fluorescent, but on standing for a few minutes acquires a phenomenal bluish-violet fluorescence.

10 : 11-*Anhydro*-7 : 8-*methylenedioxyquinindoline* 10-*Methohydroxide* (IX).—The pale lemon-yellow needles that formed almost immediately when aqueous potassium hydroxide (10 c.c. of 60%) was added to the preceding methosulphate (1 g.) dissolved in boiling aqueous alcohol (80 c.c. of 50%) were crystallised from alcohol, in which they were moderately readily soluble, and dried in a vacuum at 120° (0·5 g.), the substance becoming deep orange whilst seeming to retain the crystalline structure (Found : C, 74·0; H, 4·5; N, 10·3. $C_{17}H_{12}O_2N_2$ requires C, 73·9; H, 4·4; N, 10·2%). This base, m. p. 244°, is relatively stable and can be sublimed when carefully heated. It dissolves in sulphuric acid, the solution exhibiting a beautiful bluish-violet fluorescence. The mineral acid salts and the picrate crystallise in yellow needles. On boiling with water, reversion to the methohydroxide of the quinindoline derivative was observed.

Py-N-*Methylphenyldiveratro*iso*harmyrine* (X).—A solution of phenyldiveratroharmyrine (3 g.) (Lawson, Perkin, and Robinson, *loc. cit.*) in benzene (100 c.c.) was boiled with neutral methyl sulphate (3 g.) for 5 minutes, and the orange-yellow, crystalline product was washed with benzene, crystallised from ethyl alcohol (in yellow needles), and dried at 120° (Found : C, 59·9; H, 5·2. $C_{27}H_{28}O_8N_2S$ requires C, 60·0; H, 5·2%). In alcoholic solution, this salt exhibits bright green fluorescence. Its yellow, aqueous solution was decomposed with sodium hydroxide, the scarlet precipitate washed with aqueous sodium hydroxide, dried in a vacuum, and dissolved in a considerable volume of hot benzene. This solution was dried with potassium hydroxide, and most of the solvent distilled, when the new base crystallised in bright scarlet, dense clusters of prismatic needles which darken above 140°, are chocolate at 240°, black at 260°, and melt at 264° with further decomposition (Found : in material dried at 110° in a high vacuum; C, 72·7; H, 5·7; N, 6·4. $C_{26}H_{24}O_4N_2$ requires C, 72·9; H, 5·6; N, 6·5%). The solution in neutral solvents such as ether or benzene has a fine violet fluorescence, but in alcohol or water the base gives a yellow solution with green fluorescence and has obviously reverted to phenyldiveratroharmyrine methohydroxide. Its yellow solution in sulphuric acid exhibits intense yellowish-green fluorescence and becomes deep ivy-green on heating. The base forms a *methiodide* which is sparingly soluble in ethyl alcohol and crystallises in slender, short, microscopic,

yellow needles, m. p. 266—267°. This salt exhibits green fluorescence in solution and gives no precipitate with ammonia or sodium carbonate in aqueous solution (solutions of the anhydro-base are so precipitated), whilst with sodium hydroxide in excess it gives a pale yellow precipitate of a stable methohydroxide, soluble in water.

(1 : 6)-*Naphthadiquinoline* (XII).—β-Naphthaquinoline was nitrated according to Claus and Besseler (*loc. cit.*), and the nitro-derivative reduced in the following manner : A solution of crystallised sodium sulphide (45 g.) in water (50 c.c.) was gradually added to a boiling solution of nitro-β-naphthaquinoline (16 g.) in aniline (100 c.c.), causing a vigorous reaction. The liquid was boiled for 30 minutes, the aniline distilled in steam, and the residue crystallised from 30% aqueous alcohol, 8 g. of amino-β-naphthaquinoline, m. p. 158°, being obtained. The diquinoline was obtained by the methods (A) and (B). (A) A mixture of amino-β-naphthaquinoline (13 g.), nitrobenzene (7·5 g.), sulphuric acid (20 g.) and glycerol (25 g.) was heated (oil-bath at 150—160°) during 6 hours. The base was rendered to ether (6 extractions), and the solution dried and concentrated to small bulk, when pale yellow needles (2·1 g.) slowly separated. The substance is sparingly soluble in ether, benzene, or alcohol (Found : C, 83·3; H, 4·6; N, 12·5. $C_{16}H_{10}N_2$ requires C, 83·5; H, 4·4; N, 12·2%).

(B) 5-Nitro-2-naphthylamine (3·4 g.) was gradually added to 60% acetic acid (60 c.c.) and iron filings (10 g.) at the temperature of the steam-bath. When the red colour had disappeared, water (100 c.c.) was added, and the solution was boiled for 5 minutes and filtered into dilute sulphuric acid (150 c.c. of 25%); the colourless needles of 1 : 6-naphthylenediamine sulphate obtained on cooling were dried (6·1 g.). A mixture of this sulphate (6 g.), nitrobenzene (4 g.), glycerol (16 g.), and sulphuric acid (16 g.) was heated (oil-bath at 155—165°) for 4·5 hours. The diquinoline was extracted from the solution, diluted and made strongly alkaline, by means of ether and 0·6 g. was ultimately obtained in colourless needles, by crystallisation from acetone. The substances prepared by methods (A) and (B) or a mixture of the two melted at 183·5—184·5°. Both specimens dissolve in dilute sulphuric acid, the colourless solutions exhibiting a bright blue fluorescence. The *sulphate* prepared from either of the specimens darkens above 250° and melts indistinctly at 268°.

5 : 6-(2 : 3-*Diphenylindolo*) (6 : 7)-*quinoline* (XIII).—An intimate mixture of amino-β-naphthaquinoline (7 g.), its dihydrochloride (3 g.), and benzoin (20 g.) was heated at 180—190° for 4 hours. The product was extracted by boiling benzene (150 c.c.) for 10 minutes, and the reddish-brown residue was separated from the hot

solution and triturated with aqueous potassium hydroxide. The isolated, washed, and dried product crystallised from nitrobenzene (50 c.c.) in colourless platelets (4 g.), which began to decompose at 298° (Found : C, 88·0; H, 5·0; N, 7·9. $C_{27}H_{18}N_2$ requires C, 87·6; H, 4·9; N, 7·6%). This base is very sparingly soluble in most organic solvents and forms very sparingly soluble, yellow salts with mineral acids. The solution in sulphuric acid exhibits green fluorescence which is persistent on dilution with water. When a trace of sodium nitrite or potassium dichromate is added to the sulphuric acid solution, an intense emerald-green coloration is developed. The *acetate* crystallises from glacial acetic acid in yellow needles decomposing above 300° (Found : C, 77·5; H, 5·4. $C_{27}H_{18}N_2,C_2H_4O_2,H_2O$ requires C, 77·7; H, 5·4%). A 75% solution (20 c.c.) of methyl sulphate in toluene was added to a boiling solution of the base (2 g.) in nitrobenzene (60 c.c.), the source of heat removed, the mixture cooled, ether added (200 c.c.), and the product (2·6 g.) crystallised from boiling alcohol, the *methosulphate* being obtained in intense yellow needles which become scarlet at about 165°; it is almost insoluble in boiling water (Found : S, 6·3. $C_{29}H_{24}O_4N_2S$ requires S, 6·5%). The decomposition of this methosulphate by alcoholic potassium hydroxide gave a crimson precipitate of microscopic needles, m. p. 225° (decomp.) if quickly heated, but we were unable to reach a definite conclusion in regard to the nature of the substance. It is reconverted by mineral acids into yellow, crystalline salts.

2 : 3-*Dimethoxyindophenazine* (XIV).—This substance was readily obtained by a slight modification of the method employed by Schunck and Marchlewski in the preparation of indophenazine (*Ber.*, 1895, **28**, 2528). 4 : 5-Dinitroveratrole (8 g.) was reduced in boiling acetic acid solution (200 c.c. of 50%) by the addition of zinc dust. When the colour changed from red to pale yellow, the solution was filtered and added to isatin (5 g.) dissolved in boiling acetic acid (125 c.c. of 20%). The yellow precipitate was collected after 5 minutes, washed with hot water, and dried at 150° (5·1 g.). The substance is readily soluble in hot nitrobenzene; it is sparingly soluble in boiling ethyl acetate or toluene, and separates from the latter in slender, yellow needles, m. p. 284° (Found : C, 68·8; H, 5·0; N, 15·1. $C_{16}H_{13}O_2N_3$ requires C, 68·8; H, 4·7; N, 15·0%). The neutral solutions have a violet-blue fluorescence and the cherry-red solution in sulphuric acid becomes deep purple on the addition of a trace of sodium nitrite or potassium dichromate. Mineral acid salts are bright yellow; the *hydrochloride*, m. p. 290° (decomp.), dissolves in water, the solution being yellow with green fluorescence, and in concentrated hydrochloric acid forming a blood-red solution.

The *picrate* crystallises from acetone in pale yellow needles, m. p. 254°. The *methosulphate* crystallised in large, flat, rectangular prisms on cooling a mixture obtained by the addition of a solution (100 c.c. of 75%) of methyl sulphate in toluene to a hot solution of the base (1·5 g.) in nitrobenzene (30 c.c.); a further quantity was precipitated by ether, the total yield being 2 g. The derivative crystallises from methyl alcohol in prisms, m. p. 247° (Found : S, 7·7. $C_{18}H_{19}O_6N_3S$ requires S, 7·9%). It is readily soluble in water, the solution exhibiting blue fluorescence, and is more sparingly soluble in alcohol.

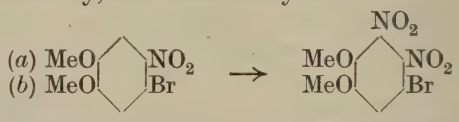
2 : 3-*Dimethoxy*-5 (or 11)-*methyl*iso*indophenazine*(XV).—Potassium hydroxide (15 c.c. of 50%) was added to a boiling solution of the dimethoxyindophenazine methosulphate (2·7 g.) in 50% alcohol (60 c.c.). The deep red solution, on cooling, deposited voluminous, slender, scarlet needles which were washed with ether and dried at 120° (2·4 g.). The substance can be crystallised by careful addition of light petroleum to its benzene solution in scarlet needles sintering at 257° and melting at 261°, or from alcohol containing potassium hydroxide in scarlet prisms (Found : C, 69·3; H, 5·3; N, 14·4. $C_{17}H_{15}O_2N_3$ requires C, 69·6; H, 5·1; N, 14·3%). This base is moderately readily soluble in ethyl acetate or benzene, very readily soluble in chloroform, and sparingly soluble in ether. Like the parent dimethoxyindophenazine, it can be sublimed by careful heating in a tube. On boiling with water, an orange solution is obtained, and this becomes yellow after the addition of an acid. The *methiodide* crystallises in deep yellow needles, m. p. 205° (decomp.). If the dimethoxyindophenazine methosulphate is decomposed by potassium hydroxide in 50% alcohol in the cold, and the precipitate crystallised from the same solvent, slender, yellow needles, m. p. 278° (decomp.), of the *methohydroxide* are obtained (Found : C, 65·7; H, 5·2. $C_{17}H_{17}O_3N_3$ requires C, 65·6; H, 5·5·%). This substance is moderately readily soluble in hot water, forming a yellow solution. *Dimethoxymethyl*iso*indophenazine dimethosulphate* was obtained when a mixture of the anhydro-base (1·5 g.), methyl sulphate (10 c.c. of a 75% solution in benzene), and benzene (50 c.c.) was boiled until the red colour had completely disappeared. The precipitated yellowish-green, microscopic needles were washed with ether and dried at 100° (1·5 g.). The substance is very readily soluble in water and somewhat readily soluble in alcohol, from which it crystallises in orange needles, m. p. 238° (Found : S, 11·6. $C_{21}H_{27}O_{10}N_3S_2$ requires S, 11·7%). The solutions of the salt exhibit green fluorescence.

2 : 3-*Dimethoxy*-6-*methylindophenazine* 11 (or 5)-*Methohydroxide* (XVI).—Aqueous potassium hydroxide (10 c.c. of 50%) was added

to a hot solution of the preceding dimethosulphate (1 g.) in 50% alcohol (40 c.c.), when a momentary darkening occurred, giving place almost at once to an orange-yellow colour. The hot filtered solution soon deposited glistening, yellowish-orange needles (0·6 g.) and after recrystallisation from alcohol the substance melted at 164° (Found : C, 66·3; H, 6·0; N, 13·2. $C_{18}H_{19}O_3N_3$ requires C, 66·4; H, 5·9; N, 12·9%). The same substance was obtained by decomposition of dimethoxydimethylindophenazonium iodide. It is readily soluble in benzene, chloroform, alcohol, or acetone, sparingly soluble in alcohol or ether, and insoluble in light petroleum. The orange-yellow solution in dilute acids exhibits green fluorescence and the yellow solution in sulphuric acid becomes red when gently heated. Curious results followed on an attempt to introduce a third methyl group into the molecule. The base (0·5 g.), m. p. 164°, was heated in boiling benzene solution (16 c.c.) with methyl sulphate (4 c.c. of 75% solution in benzene) for 10 minutes. The dark brown oil which separated solidified on scratching and was collected and decomposed by aqueous-alcoholic potassium hydroxide. The product crystallised from aqueous alcohol in nearly colourless, silky needles, m. p. 85° (0·27 g.) (Found : C, 66·2; H, 6·2%). The compound appears to be different from the initial isomeride. It is much more soluble than the latter (m. p. 164°) and has a lower m. p. Possibly a methyl group has migrated to a new position, a suggestion which is clearly free from theoretical difficulty.

7-*Methoxy*-4-*phenylflavylium Salts* (XIX).—Anhydro-7-hydroxy-2 : 4-diphenylbenzopyranol (1 : 4) (1·5 g.), methyl sulphate (15 c.c. of a 75% solution in benzene), and benzene (50 c.c.), all of which had been carefully dried, were mixed and the liquid was boiled until the red colour had changed to orange-yellow. On cooling, pale yellow, glistening needles separated, and these were washed with ether and dried (1·2 g.) (Found : S, 7·4. $C_{23}H_{20}O_6S$ requires S, 7·5%). This *methosulphate*, m. p. 179°, is readily soluble in alcohol, acetic acid, acetone, or hot dilute hydrochloric acid, forming yellow solutions which exhibit very intense bluish-green fluorescence. The salt is to some extent hydrolysed by water. Addition of ether to the original mother-liquor from the preparation precipitates a yellow, amorphous substance (S, 9·1%), which behaves in the same manner as the methosulphate with solvents and in the preparation of the ferrichloride. The latter, namely, 7-*methoxy*-4-*phenylflavylium ferrichloride*, was prepared in the usual manner and crystallised from acetic acid in feathery, yellow needles, m. p. 191° (Found : C, 51·8; H, 3·1. $C_{22}H_{17}O_2Cl_4Fe$ requires C, 51·7; H, 3·3%). The salt was prepared for comparison from 7-hydroxy-2 : 4-diphenylbenzopyranol dimethyl ether (Bülow and Sicherer, *Ber.*, 1901, **34**,

2380), and a mixture of the specimens melted at 190—191°. The m. p., 185°, previously given for this ferrichloride (Crabtree, Robinson, and Turner, J., 1918, **113**, 877) is too low. This substance gives a negative result in a Zeisel estimation, probably on account of the insolubility of the iodide, and after the addition of phenol the production of methyl iodide could be observed.

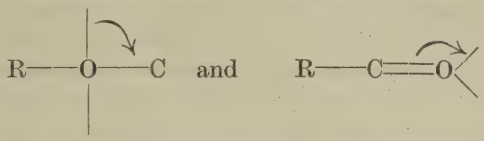


The authors' thanks are due to the Department of Scientific and Industrial Research for grants which enabled one of them (J. W. A.) to take part in the investigation.

THE UNIVERSITIES OF ST. ANDREWS AND MANCHESTER. [*Received, April 6th,* 1925.]

CCXII.—*The Nitration of* m-*Meconine.*

By JNANENDRA NATH RÂY and ROBERT ROBINSON.



IN 1917 Jones and Robinson (J., **111**, 905) directed attention to a number of benzene substitution reactions which appeared to show that when two identical groups such as alkyloxy coexist in a molecule and direct substituents to different positions, the influence of the one which is in the *o*- or *p*-position to a negative * group is weakened so that the other alkyloxy- or similar group controls the direction taken by the reaction. For example, in the nitration of 4-bromo-5-nitroveratrole, the nitro-group diminishes the directive power of the methoxyl (*b*) in the *p*-position to a greater extent than that of (*a*) in the *m*-position and therefore the latter induces substitution, apparently abnormally, ortho to nitroxyl.

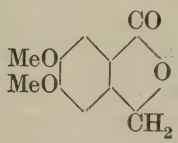
The criticisms of this hypothesis which have since been published have all been vitiated by the failure to recognise that the directing groups corresponding to (*a*) and (*b*) must be *identical* and therefore have been ignored, but, nevertheless, the development of the electronic theory of conjugation, whilst supplying the explanation of the phenomenon, also suggests a restriction to be placed on its scope. One of the most fundamental properties of oxygen and nitrogen, exhibited in carbon compounds, is expressed in terms of the electronic theory in the statement that bivalent oxygen and

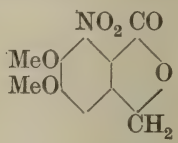
* At the time, such groups as NO_2, CO_2H, SO_3H were called negative, and this is, of course, still permissible if the general polarity is the circumstance which ought to be emphasised.

tervalent nitrogen tend to increase the covalency at their single bindings, especially when attached to unsaturated systems, whereas there is a tendency to reduce the covalency of doubly linked oxygen or nitrogen. The free electrons on the oxygen and nitrogen are diminished in number in the former case and augmented in the latter. These changes are represented by the schemes :

In the first case, the oxygen becomes charged positively and in the second negatively. Now in the carbethoxyl and acid amide groups these tendencies can co-operate without disturbance of the octets and this is sufficient to explain the failure of the ester group to

exhibit marked carbonyl reactivity and of the amide group to function as a strong basic centre. The positive charge on the carbon of the carbonyl group is neutralised from the chain and so does not seek foreign negative ions, whilst, in the amide group, the free electrons in the nitrogen octet are equally occupied in the chain to some extent; and it is these free electrons which impart the basic properties to ammonia. A similar neutralisation of the functions of groups like RO and C=O can occur if these are separated by an *even* number of unsaturated atoms (compare *Chemistry and Industry Review*, 1925, **44**, 18, 456), because in that case polarisation is possible without producing charges on intermediate atoms of the chain and without disturbing the octets.* We can therefore well understand the partial neutralisation of the directive power of methoxyl by a nitroxyl group situated in the *p*-position to it as shown in the annexed expression and, further, we suggest that the





neutralisation considered by Jones and Robinson is always of this type. At present the effect can be predicted with confidence only when the directing group is derived from –OH, $-NH_2$, or –SH and

* We use the octet theory here, as always, in order to give a standard of numerical comparison. It does not affect the theory if the stable electronic configurations have more or less than 8 electrons, provided that the number tends to remain constant.

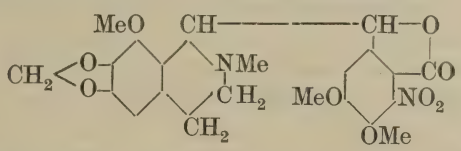
when the neutralising group is of the type $-NO_2$, –CO–R, etc. Certainly CO_2H is not such a group, being, as explained above, a self-contained assemblage. On the other hand, the carbonyl of phthalide is beyond doubt a more activating carbonyl than the carbonyl of an ordinary ester group. This is shown by condensation reactions of the methylene group in the ortho-position and on our theory means that the –CO–O– complex is not so completely satisfied in itself as it is in a typical ester. Therefore a similarly situated –CO–NH– should contain a more basic nitrogen atom than that of an ordinary amide; and this is the case, for phthalimidine has definite basic properties.

The opportunity to test this matter arose when Edwards, Perkin, and Stoyle (this vol., page 198) described an elegant synthesis of *m*-meconine (I) by the condensation of veratric acid with formaldehyde in presence of hydrochloric acid.

(I.) 

(II.)

As demanded by the theory which has been discussed above, this substance gives on nitration its 6-*nitro*-derivative (II), and we venture to suggest that such a result cannot be satisfactorily explained on any theory of the mechanism of aromatic substitution which is not based on electronic conceptions of valency. The constitution of (II) was proved by its conversion into a corresponding *bromo*-m-*meconine*, which is also obtained by applying the method of Edwards, Perkin, and Stoyle to 2-bromoveratric acid, the orientation of the groups in the molecule of which has been placed beyond question. Hope and Robinson (J., 1911, **99**, 1163) showed that phthalide contains a reactive $-CH_2-$, because it condenses with cotarnine to form anhydrocotarninephthalide. The poor yield was improved and became almost quantitative when a nitroxyl was introduced into the *o*- or *p*-position to the methylene group. The condensation is also facilitated, although to a less striking extent, when a nitroxyl group is introduced in the *m*-position to the methylene group (compare P., 1911, **27**, 229). A new example of this phenomenon is now forthcoming, since we are able to prepare *anhydrocotarnine-nitro*-m-*meconine* by a direct condensation of the components indicated.



Experimental.

Preparation of m-*Meconine* (I).—The method of Edwards, Perkin, and Stoyle (*loc. cit.*) gives improved yields if the following slight

modification is adopted. A solution of veratric acid (50 g.) in hot acetic acid (250 c.c.) is, after the introduction of concentrated hydrochloric acid (200 c.c.) and aqueous formaldehyde (60 c.c. of 40%), heated on the steam-bath for 12 hours, cooled, tarry matter precipitated by the addition of a little water, and the brown liquid treated with charcoal, filtered, and concentrated in a vacuum to about one-fifth of its volume. Further tarry material is precipitated from the hot solution by addition of not too much water, and, after filtration, *m*-meconine is thrown down by further dilution with water and neutralisation with sodium carbonate. The *m*-meconine, crystallised from aqueous ethyl alcohol, has m. p. 155° and the yield averages 30 g.

6-*Nitro*-4 : 5-*dimethoxyphthalide* (II).—*m*-Meconine (13 g.) was gradually added with agitation to nitric acid (22 c.c.; *d* 1·42) at 0°; after a few hours the mixture was added to water, and the precipitate collected and extracted with boiling alcohol (30 c.c.). The residue crystallised from boiling acetic acid in colourless needles, m. p. 183—184° (yield 6—7 g.) (Found: C, 50·4; H, 3·4. $C_{10}H_9O_6N$ requires C, 50·2; H, 3·7%). This substance is sparingly soluble in hot alcohol and exhibits the behaviour of a lactone. Unlike nitromeconine, it does not give an intense coloration on treatment with hot alkaline solutions and this is clearly due to the fact that the methylene and nitroxyl groups are in the *m*-position to each other.

Anhydrocotarnine-6-*nitro*-4 : 5-*dimethoxyphthalide*,

—A mixture of nitro-*m*-meconine (3 g.), cotarnine (3 g.), and ethyl alcohol (300 c.c.) was boiled for 1·5 hours and then concentrated to one-fourth of its bulk and cooled. The crystalline deposit was isolated, treated with glacial acetic acid, and, after dilution with water and filtration, the base was precipitated by means of ammonia, collected, washed, and dried (2·5 g.). The base is very sparingly soluble in most neutral organic solvents and is best crystallised from boiling toluene–alcohol, from which it separates in well-defined, rectangular plates, m. p. 200° (decomp.) (Found: C, 57·8; H, 4·7, 4·8, 5·5; $C_{22}H_{22}O_9N_2$ requires C, 57·6; H, 4·8%). The base is readily soluble in dilute hydrochloric acid and acetic acid to a colourless solution. It is stable to hot dilute hydrochloric acid, but is gradually decomposed by boiling acetic acid with formation of cotarninium acetate

and nitro-*m*-meconine. It is, however, much more stable to hot acetic acid than anhydrocotarnine-nitromeconine; ease of formation and ease of decomposition going together in this series as in most others.

6-*Amino*-4 : 5-*dimethoxyphthalide*.—Nitro-*m*-meconine (11 g.) was gradually added to a hot solution of crystallised stannous chloride (35 g.) in concentrated hydrochloric acid (65 c.c.), when a clear liquid resulted, and the reaction was completed by heating on the steam-bath for 30 minutes. After dilution with water (250 c.c.) the cooled solution deposited crystals, which were isolated and treated with sodium bicarbonate in hot aqueous suspension. The substance crystallised from aqueous alcohol in colourless, feathery needles, m. p. 158° (yield about 6 g.) (Found: C, 57·0; H, 5·3. $C_{10}H_{11}O_4N$ requires C, 57·4; H, 5·3%). The amine is readily soluble in concentrated hydrochloric acid, but is precipitated on the addition of water. In suspension in dilute hydrochloric acid it can be diazotised, giving a bright yellow diazonium salt, which couples with β-naphthol to form a red azo-compound.

6-*Bromo*-4 : 5-*dimethoxyphthalide*.—(A) A solution of amino-*m*-meconine (6 g.) in 6% hydrochloric acid (60 c.c.) was diazotised at 0° and added to a solution of cuprous bromide (prepared from 2·4 g. of copper sulphate, potassium bromide and sulphur dioxide) in hydrobromic acid (4 c.c.; *d* 1·49). The reaction was completed by heating, and, after cooling, the precipitated solid was collected and crystallised from boiling water containing a little alcohol. The almost colourless, prismatic needles had m. p. 223°, alone or mixed with a specimen prepared by the following method.

(B) A mixture of 2-aminoveratric acid (7·1 g.) (Pschorr and Sumuleanu, *Ber.*, 1899, **32**, 3410), water (50 c.c.), and concentrated hydrochloric acid (10 c.c.) was treated at 0° with sodium nitrite (2·7 g. in water, 20 c.c.), the clear diazo-solution added to one of cuprous bromide (from 2·4 g. of copper sulphate) in hydrobromic acid (4 c.c.; *d* 1·49), and the reaction completed by heating on the steam-bath, evolution of nitrogen being first observed at 80°. The crude 2-bromoveratric acid which separated on cooling was crystallised from hot aqueous acetic acid and had m. p. 200° (yield 4—5 g.). Zincke and Francke (*Annalen*, 1896, **293**, 187) give m. p. 201°, their initial material being hemipinimide (compare Kühn, *Ber.*, 1895, **28**, 810).

A mixture of 2-bromoveratric acid (4 g.), aqueous formaldehyde (5·5 c.c. of 40%), concentrated hydrochloric acid (20 c.c.), and acetic acid (30 c.c.) was heated on the steam-bath during 10 hours. The product was added to water (250 c.c.), the precipitate of unchanged acid removed, and the filtrate concentrated to about 50 c.c. in a

vacuum and then neutralised with solid sodium bicarbonate. The solid which gradually separated crystallised from boiling water containing a little alcohol in colourless, prismatic needles, m. p. 223° (Found: C, 44·3; H, 3·1. $C_{10}H_9O_4Br$ requires C, 43·9; H, 3·3%).

THE UNIVERSITY, MANCHESTER. [*Received, May 13th*, 1925.]

CCXIII.—*The System Sodium Sulphite–Sodium Hydroxide–Water.*

By DALZIEL LLEWELLYN HAMMICK and JOHN ALEXANDER CURRIE.

A STUDY of this system was undertaken in order to find out the nature of the solid phases in equilibrium with solutions containing sodium sulphite and hydroxide. As our object was this, rather than the exact form of the solubility curve showing the amount of solids in solution, we did not aim at an accuracy of more than $\pm$ 0·5% in our analyses.

Sodium sulphite was prepared by passing sulphur dioxide into a solution of A.R. sodium carbonate (The British Drug Houses), precautions being taken throughout that air should not come into contact with the solution. Slightly more sulphur dioxide was passed in than would be sufficient to form the sulphite, in order to eliminate the danger of a double salt of sulphite and carbonate crystallising. Any hydrogen sulphite that might thus be formed would be turned into the normal salt when mixed with the soda solution in the solubility vessel. In practice, it was found that the normal salt came down under these conditions. The solution thus prepared was transferred, in contact with hydrogen only, to an electrically heated glass evaporator through which was passed a current of purified hydrogen. When a good crop of crystals had been deposited, the liquid was drained off, the crystals were washed and dried in an atmosphere of hydrogen, and stored in a vacuum desiccator over soda sticks.

The salt was tested for sulphate and rejected if any was found to be present. It was then analysed as sulphate, no specimen being used that had SO_3 lower than 63·2%, theory requiring 63·47%.

Sodium hydroxide. For the preparation of solutions up to 20% NaOH Cornog's method was used (*J. Amer. Chem. Soc.*, 1921, **43**, 2573). For stronger solutions we took advantage of the fact that from very strong solutions of sodium hydroxide nearly all the carbonate present is precipitated (Freeth, *Phil. Trans.*, 1922, **223**, 35). By allowing saturated solutions of the best soda sticks (The British

Drug Houses) to reach equilibrium at a temperature slightly above that of the isotherm we were studying, we obtained a solution of sodium hydroxide on filtering that was as strong as we required and that gave no precipitate with barium chloride solution. The suspensions complained of by Freeth were not observed, the solution being quite clear after filtering through Gooch asbestos.

Water. All water used in preparing the materials and making up solutions was distilled and then boiled under reduced pressure for ½ hour.

Solubility Determinations.—Complexes of approximately known composition were made up in one of two kinds of vessel. When the strength of the sodium hydroxide in solution did not exceed 25%, we used very wide test-tubes of Duro resistance glass closed by tight-fitting rubber stoppers through which a stirrer passed, fitted with a mercury seal. For stronger solutions, a silver vessel was employed similar to that used by Freeth (*loc. cit.*). Glycerol was used as a seal and lubricant, precautions being taken that none of it should leak into the solution.

The vessels were placed in an ordinary gas-regulated thermostat for the isotherms at 20°, 25°, and 32°, the temperature of which did not vary by more than $\pm 0{\cdot}1°$. For the isotherm at 0·15°, ice was placed in a well-lagged thermostat, and kept near the bottom with wire netting. The thermostat was then filled with water and kept well stirred; by this means and by renewing the ice every 48 hours the temperature never varied by more than 0·05°.

After equilibrium had been obtained—about 24 hours for weak solutions and 36—48 for strong ones was found to be sufficient—the contents of the vessel were rapidly transferred to a filter. This was so designed that the separation of the solution and moist solid could be carried out in the thermostat, a precaution found to be necessary when the soda content of the solution was either very weak or very strong. The whole operation was carried out as rapidly as possible.

Analysis.—After they had been weighed, the solutions and moist solids were made up in water to suitable volumes, portions of which were analysed. The sulphite was first oxidised to the sulphate by treatment with pure hydrogen peroxide solution and after standing a short time the excess of peroxide was decomposed by boiling. The sulphite was then estimated as barium sulphate and the hydroxide by titration, the water being obtained by difference. The results were plotted by the usual Schreinemakers method on a triangular diagram (see Figs. 1 and 2).

Results.—The isotherms at 0·15° and 32° are shown in the diagrams. The isotherms at 20° and 25°, being of the same general

form as that at 0·15°, have not been shown. The figures are given below. Compositions are given in weight per cent.

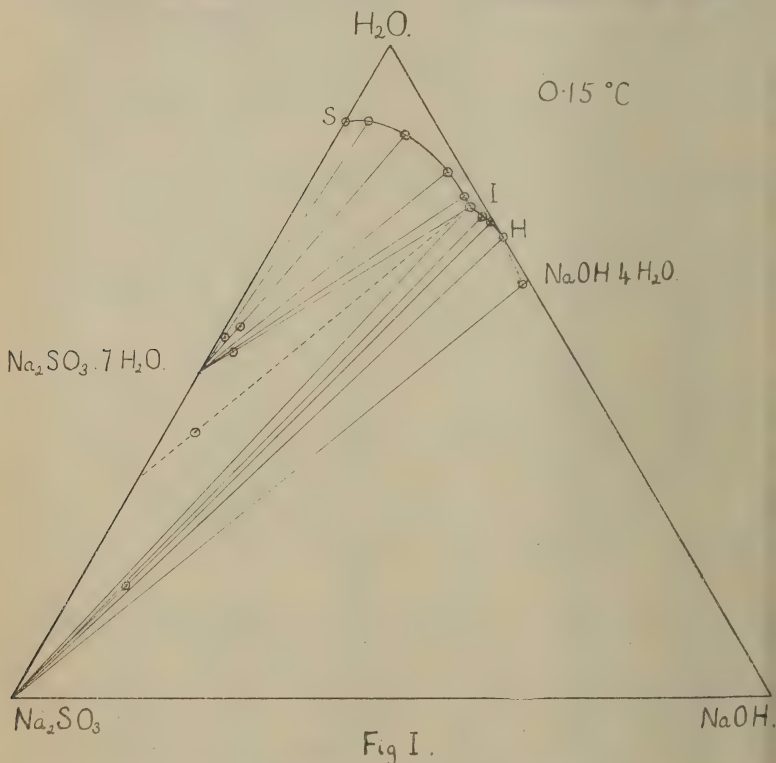

Fig I.

The isotherm at 0·15° is shown in Fig. I. The results obtained at 20° and at 25° give curves resembling Fig. I except that the heterogeneous region $Na_2SO_3,7H_2O$–S–I becomes smaller; in this region complexes separate into solutions of concentrations along S-I and sodium sulphite heptahydrate. Solutions of compositions given by I–H are in equilibrium with anhydrous sodium sulphite. The

point H, which lies very close to the side H_2O–NaOH (the solubility of sulphite being very small in excess of sodium hydroxide) represents the composition of the liquid in equilibrium with anhydrous sodium sulphite and sodium hydroxide tetrahydrate. Similar points were not realised experimentally at the other temperatures.

The isotherm at 32·0° (Fig. II) shows that at that temperature sodium sulphite heptahydrate cannot exist in contact with any aqueous solution. This is in accordance with the results obtained by Lewis and Rivett (J., 1924, **125**, 1156), who found the transition

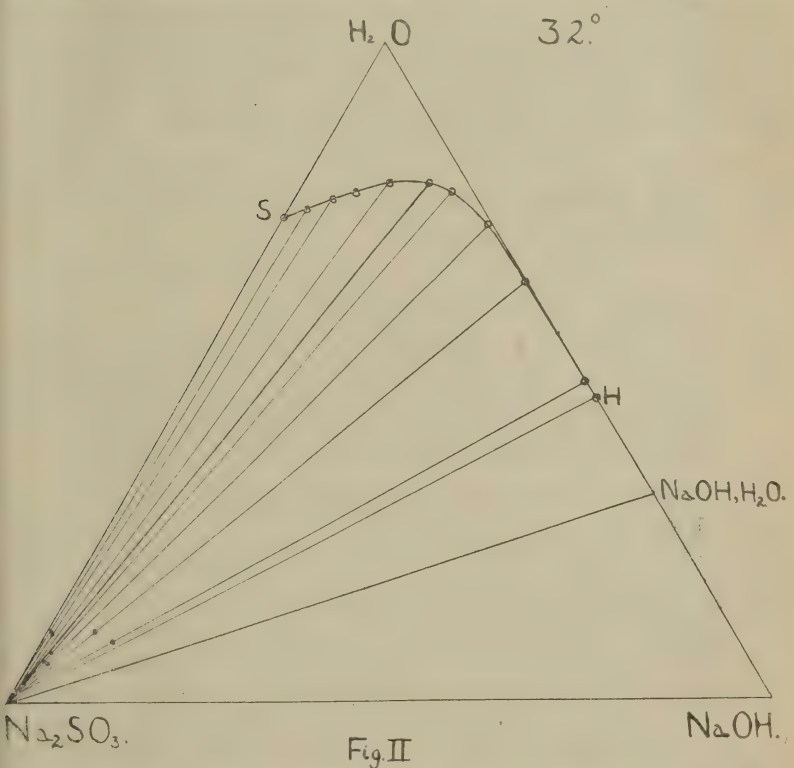

Fig. II

point between anhydrous and hydrated sodium sulphite to lie at 31·5°. The fact that heptahydrate appeared as a solid phase in the isotherm at 25° is in conflict with the result obtained by Hartley and Barrett (J., 1909, **95**, 1178), who record 22° as the transition point. Recently, however, Foerster, Brosche, and Norberg-Schulz (*Z. physikal. Chem.*, 1924, **110**, 450), as the result both of solubility measurements and dilatometer experiments, have concluded that the transition point lies at 33·4°.

The above discrepancies seem at first sight hard to reconcile.

Lewis and Rivett (*loc. cit.*) have, however, established the fact that anhydrous sulphite may exist in more than one metastable solid phase, particularly in the presence of sodium sulphate, which appears in solid solution in the sulphite crystals. Different solid phases in equilibrium would readily account for the comparatively small difference between the transition point found by Foerster and by Lewis and Rivett. Moreover, the latter workers record (*loc. cit.*, p. 1166) a temperature of 39° as the transition point between one form of anhydrous sulphite and the hydrated form ; this temperature is almost as much above Rivett and Lewis's value for their most stable form as Barrett and Hartley's is below. It therefore does not seem impossible that Barrett and Hartley really obtained the most stable form of anhydrous sulphite and that their transition temperature of 22° represents the true transition point.

The authors wish to thank Messrs. Brunner Mond & Co. for a grant which has partly covered the cost of this investigation.

CCXIV.—*Oxidation Products of Oleic Acid. Part I. Conversion of Oleic Acid into Dihydroxystearic Acid and the Determination of the Higher Saturated Acids in Mixed Acids from Natural Sources.*

By ARTHUR LAPWORTH and EDWARD NEVILLE MOTTRAM.

THE authors have suggested that an accurate estimation of higher saturated acids in a sample of oleic acid might be carried out by oxidation methods (*Biochem. J.*, 1925, **19**, 17, footnote).

Hazura and Grüssner (*Monatsh.*, 1888, **8**, 180) were able to detect oleic acid in mixtures by oxidising it to dihydroxystearic acid. Edmed (J., 1898, **73**, 627), Le Sueur (J., 1901, **79**, 1313), and Nicolet (*J. Amer. Chem. Soc.*, 1922, **44**, 1139) investigated the conversion of oleic into dihydroxystearic acid, but obtained results which clearly indicate that their experiments were not made under very favourable conditions. Edmed (*loc. cit.*) stated that practically quantitative yields of the dihydroxy-acid can sometimes be obtained, but unfortunately gave no clue to the necessary conditions.

Robinson and Robinson (this vol., p. 177) obtained excellent yields of the dihydroxy-acid by oxidising in dilute alkaline solution at 0°. Based on that observation, privately communicated some three years ago, a long series of systematic experiments has been carried out by the present authors and it is now possible to state

that the conditions essential for the nearly perfect conversion of oleic acid into dihydroxystearic acid are: (1) a low temperature (0—10°) during the oxidation process; (2) a concentration of oleic acid (in the form of its sodium or potassium salt) not exceeding 0·1%; (3) a concentration of the added aqueous permanganate solution not exceeding 1%; (4) a very short period of reaction, 5 minutes being sufficient for oxidation of nearly the whole of the oleic acid present; * (5) a slight excess of alkali should be present from the beginning of the oxidation, otherwise there is a danger of hydroxyketostearic acid being formed.

The observations can be applied to the analysis of comparatively impure samples of oleic acid, and in particular to the estimation of the proportion of all saturated fatty acids which are not volatile in steam, as, for example, stearic, palmitic and myristic acids. Even when much linolic or linolenic acid is present, their oxidation products (namely tetrahydroxy- and hexahydroxy-stearic acids) being insoluble in cold light petroleum and their degradation products either insoluble in light petroleum or volatile in steam, it seems probable that the method can be modified so as to afford a simple means of isolating the higher saturated fatty acids present in the mixed acids from many natural sources.

Detailed Analytical Method.†—The clear solution of sodium salts obtained by warming about 5 g. of the "oleic acid" on the water-bath with an equal weight of caustic soda, dissolved in 500 c.c. of water, is cooled, 4 litres of ice-cold water are added, and the whole is well shaken at 10° while 400 c.c. of 1% potassium permanganate solution are added quickly. After 5 minutes, the liquid is decolorised with sulphur dioxide, and concentrated hydrochloric acid (150 c.c.) added. The white, flocculent precipitate (A) of crude solid dihydroxystearic acid is drained for a short time, washed with about 50 c.c. of light petroleum (this greatly accelerates its subsequent drying: the petroleum washings are reserved),‡ and dried to a constant weight at the ordinary temperature in a vacuum desiccator.

* It is not desirable to submit the resulting dihydroxystearic acid to further action of the permanganate, and if it is desired to obtain the most precise results, a further conversion of the very small quantity of unchanged oleic acid is necessary and it is best to proceed as hereinafter described. For many purposes the results obtained by omission of the second oxidation process would be accurate enough.

† The solubility of dihydroxystearic acid in petroleum (b. p. 80—100°) is not more than 0·002 g. in 100 c.c. at 15°, and therefore negligible in applying this method.

‡ The aqueous filtrate contains no appreciable quantities of higher fatty acids, but does contain about 0·15 g. of products of lower molecular weight, such as nonoic, octoic, azelaic and suberic acids, formed by breaking down of a small fraction of the dihydroxystearic acid.

It is now extracted with 100—150 c.c. of warm light petroleum (b. p. about 70—80°), the whole cooled, filtered, and the residue (B) of nearly pure dihydroxystearic acid washed with several successive quantities of cold solvent. The petroleum extracts and washings are united and evaporated.*

The residue left on evaporation of the petroleum extracts is distilled with steam to remove traces of volatile fatty acids, and treated with low-boiling petroleum. This readily extracts the non-volatile acids, which, after evaporation of the solvent, are heated on the water-bath until constant in weight. On cooling, the residue (D) sets to a waxy solid and represents the higher saturated fatty acids present in the original sample of " oleic acid." †

Examples.—(1) A sample of oleic acid, O_1, was isolated from olive oil and purified through the barium salt (Lapworth and Mottram, *loc. cit.*). Its " first setting-point " (*loc. cit.*) was 12·55° and a break in the setting-point curve of its mixtures with pure palmitic acid took place with 4·7% of added palmitic acid. As the break corresponds with a total percentage 7·2 $\pm$ 0·5 of palmitic acid, O_1 consisted of 97·5 $\pm$ 0·5% of oleic acid and 2·5 $\pm$ 0·5% of palmitic acid.

Results of analyses by the above method : (*a*) 4·97 g. and (*b*) 3·06 g. of O_1 gave 0·1 g. and 0·07 g., respectively, of higher saturated acids, or 2·0 and 2·25%.

These three results agree very satisfactorily with one another. The weight of dihydroxystearic acid, free from fatty acids, obtained in (*a*) was 5·23 g. or 96% of the calculated amount (5·45 g.) from the 4·87 g. of pure oleic acid present. In case (*b*) the weight was again 95—96% of the calculated quantity. The loss of 4% was in part accounted for by the presence of 0·09 g. of azaleic (or suberic) acid, which, in case (*a*), was actually isolated from the aqueous filtrate and had evidently arisen by further oxidation of part of the dihydroxystearic acid.

* In order to effect, if desired, a complete conversion of the small quantity of oleic acid which still remains, the residue left on evaporation of the petroleum is oxidised as described above : 50 c.c. of cold *N*/10-sodium hydroxide and 100 c.c. of ice water; 15 c.c. of 1% potassium permanganate solution; 10 c.c. of concentrated hydrochloric acid. The precipitate (C) is washed with water, dried at the ordinary temperature, and extracted with cold light petroleum; about 0·05 g. of dihydroxystearic acid remains on the filter.

† " Non-saponifiable " constituents in the original sample are not, in the authors' experience, to be found in the residue (D), at least not in appreciable quantity. If thought desirable, however, the quantity of such constituents can easily be determined by the usual method, or perhaps more simply by dissolving the residue (D) in a little methyl alcohol, adding excess of methyl-alcoholic barium hydroxide, evaporating to complete dryness, and extracting the residue with dry acetone, in which barium hydroxide and barium salts of saturated fatty acids are insoluble.

The "saturated fatty acid," as isolated, melted at 57°, and doubtless consisted mainly of palmitic acid (m. p. 62·5°).

(2) *Total mixed acids from olive oil.* Olive oil was completely hydrolysed and the resulting mixed acids (O_2) were isolated. These had an iodine number = 88 and contained 1·4% of "unsaponifiable matter."

5·0 G. of O_2, treated as above described, gave 0·78 g. of higher saturated fatty acids (waxy, pale yellow solid, m. p. 53—54°) or 15·6%. On the assumption, then, that O_2 contained only the following constituents, its composition was roughly: Oleic acid, 72; linolic acid, 12—13; unsaponifiable matter, 1·4; higher saturated acids, 14—15%.* The total weight of dihydroxystearic acid isolated was 4·1 g. This doubtless contained tetrahydroxystearic acid arising from the linolic acid present, and other experiments have shown it to be purely fortuitous that this weight again represents 96% of the weight of dihydroxystearic acid theoretically obtainable from the oleic acid estimated as present in the mixed acids.†

The "unsaponifiable matter" in the 0·78 g. of higher saturated fatty acids, determined by the methyl-alcoholic baryta method (footnote, p. 1630), was a negligible quantity (only 0·02 g.).

(3) A sample of a commercial product sold as "pure oleic acid" yielded 16% of solid saturated fatty acids; but the weight of "dihydroxystearic acid" was very appreciably less (only 3·4 g. from 5 g.) than in the case of example (2). The manipulations offered no greater difficulties than in the previous cases.

The work described in the present paper was begun under the auspices of the Oils and Fats Committee of the Food Investigation Board. A grant from the Department of Scientific and Industrial Research to one of us (E. N. M.) rendered it possible for him to take part in the research and is gratefully acknowledged.

THE UNIVERSITY, MANCHESTER. [*Received, May 5th,* 1925.]

* The main object of the experiment was to ascertain whether the presence of so much linolic acid would affect the ease of filtration of the crude hydroxystearic acid, and from this point of view the results were all that could be desired. It now seems probable that estimates formed by previous workers of the proportion of oleic acid in the mixed acids from olive oil have been decidedly too high and those of the saturated fatty acids too low. This conclusion is also consistent with the experience which the writers had previously had in analyses of fractions of lead salts made in purifying oleic acid.

† Judging from the results of experiments which the authors have made on the production of hydroxyketostearic acid, the yield of dihydroxystearic acid may fall off very rapidly if the proportion of acids more highly unsaturated than oleic acid exceeds a certain maximum.

CCXV.—*The Action of Hydrogen Peroxide on Limonene.*

By James Sword.

The oxidation of limonene with hydrogen peroxide (2 mols.) in acetic acid solution gives $\Delta^{8(10)}$-*p*-menthene-1 : 2-diol as the main product, a small yield of terpin hydrate, an aldehyde, etc. Larger quantities of the oxidising agent produce a variety of oxygenated compounds and resinous substances.

Since hydrogen peroxide has no action on hydrocarbons of the terpene series in solvents such as ether, it would appear that acetic acid takes a real part in the reaction, possibly by the formation of peracetic acid. This is supported by the fact that the reaction proceeds more quickly the larger the quantity of solvent used; a certain minimum amount is necessary for the reaction to go to completion in any length of time.

Experimental.

The limonene used was obtained from oil of bitter orange (J., 1907, **91**, 1872) and had b. p. 175·5—176·5°, $[\alpha]_D^{15°}$ + 96·89°, $d^{15°}$ 0·8453, $n^{15°}$ 1·4759.

100 C.c. of it in glacial acetic acid (375 c.c.) were shaken continuously for 14—18 days with perhydrol, added gradually (total 180 c.c.). The solution was neutralised with sodium carbonate, and extracted with ether, on occasions up to 40 times. The extract on concentration deposited about 1 g. of terpin hydrate, m. p. 116—117° (in a sealed tube) (Found: C, 62·8; H, 11·5%), and on evaporation left an oil, which was hydrolysed with methyl-alcoholic barium hydroxide, yielding an oil (*a*). This, on distilling under reduced pressure, gave three fractions: (i) a mobile oil, b. p. 110—112°/10 mm., (ii) the main fraction, a viscous oil, b. p. 140—143°/10 mm., from which a glycol (*b*) was isolated, (iii) a semi-vitreous solid, b. p. 150—152°/10 mm. These were all unsaturated, the unsaturation decreasing with increase of boiling point, and gave sodium derivatives [Found: for (i), Na, 9·5; for (ii), Na, 22·7; for (iii), Na, 16·1. $C_{10}H_{16}(ONa)_2$ requires Na, 21·3%. $C_{10}H_{17}\cdot ONa$ requires Na, 13·0%].

By using the residual oil from the preparation of the sodium compounds (only a small quantity of sodium was used for a relatively large amount of oil) the glycol (*b*) was finally induced to crystallise. Thereafter it could be crystallised directly from (*a*). The residual oil after its removal yielded a small quantity of a *p*-nitrobenzoate, m. p. 79°, gave with ethereal hydrogen bromide a dihydrobromide which crystallised from ethyl alcohol in pearly plates, m. p. 44—45° (Found: Br, 53·5. $C_{10}H_{16},2HBr$ requires

Br, 53·6%), and on distillation with steam yielded an unsaturated oil (Found: C, 72·0; H, 9·9%. 0·1818 G. absorbed 0·165 g. of bromine), from which no nitrobenzoate was obtained, and no solid on hydration.

The glycol (*b*) is soluble in about 10 parts of water and much more soluble in alcohol or ether. It will crystallise only when hydrated. The hydrate is efflorescent and contains three molecules of water, all of which can be removed over sulphuric acid in a vacuum desiccator in the course of 4—5 days. If dried too rapidly, it liquefies and then sets to a hard, vitreous solid. This, in conjunction with the fact that the hydrate has no definite melting point but begins to melt about 20° below the melting point of the anhydrous substance, indicates that there is an intermediate hydrate of lower melting point. Its solution in alcohol is optically inactive. The anhydrous substance is snow-white, melts sharply at 67·5°, and is clearly the $\Delta^{8(10)}$-*p*-menthene-1 : 2-diol described by Prileschaev (*Ber.*, 1909, **42**, 4814) (Found: C, 70·6; H, 10·5. Calc., C, 70·6; H, 10·7%).

From the original oxidation products a small quantity of an acid was isolated by means of its silver salt [Found: Ag, 55·4. $C_6H_{12}(CO_2Ag)_2$ requires Ag, 55·7%.]

The author wishes to acknowledge his indebtedness to Professor G. G. Henderson for his interest in the work.

The University of Glasgow. [*Received, April 28th,* 1925.]

CCXVI.—*Hydroxybenzils.*

By John Thompson Marsh and Henry Stephen.

Schönberg and his collaborators (*Ber.*, 1922, **55**, 1174, 3746, 3753) have shown that the oxidation of benzoins gives rise to benzils of two types, *viz.*, yellow compounds of the normal type, having the α-diketonic structure and characteristic properties, and colourless ψ-benzils, to which Schönberg ascribes a peroxidic structure which accounts for their slight reactivity towards the usual ketonic reagents.

Up to the present, few examples of colourless benzils were known (compare Irvine, J., 1907, **91**, 541; Vörlander, *Ber.*, 1911, **44**, 2455; Schönberg and Kraemer, *loc. cit.*, p. 1174; Schönberg and Malchow, *loc. cit.*, p. 3748) and only in one case, 4 : 4′-dibenzyloxybenzil, has the coloured diketone been converted into the colourless peroxide (Schönberg and Bleyberg, *loc. cit.*, p. 3753), and the latter, by

crystallisation from various solvents, reconverted into the coloured benzil. Schönberg therefore regards the two forms as being in equilibrium both in solution and at the melting point:

$$RO\cdot C_6H_4\cdot\underset{\underset{O}{|}}{C}—\underset{\underset{O}{|}}{C}\cdot C_6H_4\cdot OR \rightleftharpoons RO\cdot C_6H_4\cdot\underset{\underset{O—O}{|\quad|}}{C=C}\cdot C_6H_4\cdot OR.$$

By applying Hoesch's method of synthesising aromatic hydroxyketones (*Ber.*, 1915, **48**, 1122) to acyl cyanides and resorcinol and phloroglucinol, we have prepared the eight following colourless hydroxybenzils; the colours produced when they are dissolved in concentrated sulphuric acid are recorded:

2 : 4-Dihydroxybenzil, $C_6H_3(HO)_2\cdot CO\cdot COPh$, red.
2 : 4-Dihydroxy-2′-methoxybenzil, $C_6H_3(HO)_2\cdot CO\cdot CO\cdot C_6H_4\cdot OMe$, greenish-brown.
2 : 4-Dihydroxy-4′-methoxybenzil, $C_6H_3(HO)_2\cdot CO\cdot CO\cdot C_6H_4\cdot OMe$, purple.
2 : 4-Dihydroxy-3′ : 4′ : 5′-trimethoxybenzil, $C_6H_3(HO)_2\cdot CO\cdot CO\cdot C_6H_2(OMe)_3$, blue.
2 : 4 : 6-Trihydroxybenzil, $C_6H_3(HO)_3\cdot CO\cdot COPh$, red.
2 : 4 : 6-Trihydroxy-2′-methoxybenzil, $C_6H_2(HO)_3\cdot CO\cdot CO\cdot C_6H_4\cdot OMe$, reddish-brown.
2 : 4 : 6-Trihydroxy-4′-methoxybenzil, $C_6H_2(HO)_3\cdot CO\cdot CO\cdot C_6H_4\cdot OMe$, purple.
2 : 4 : 6-Trihydroxy-3′ : 4′ : 5′-trimethoxybenzil, $C_6H_2(HO)_3\cdot CO\cdot CO\cdot C_6H_2(OMe)_3$, greenish-blue.

With the exception of the last, these compounds darken before melting with decomposition. This change is not due to conversion of peroxide into diketone, for the acetyl derivatives remain colourless above their melting points.

The hydroxybenzils crystallise from dilute alcohol or dilute acetic acid in colourless needles. Their pink solutions in aqueous sodium hydroxide, on warming, become deep red, and on acidification the benzils are precipitated as bright yellow needles, from which the colour does not completely disappear on crystallisation; the melting points, however, are identical with those of the colourless forms. We have so far not obtained a pure, stable, coloured form of the above colourless benzils.

On account of the action of the alkali, methylation of the hydroxybenzils was not successful. Attempts to demethylate those compounds containing methoxy-groups did not give very satisfactory results.

The trihydroxybenzils give a purple coloration with ferric chloride solution, but only a faint colour was noticed with the dihydroxy-compounds. Both di- and tri-hydroxybenzils reduce Fehling's solution.

The solutions of the hydroxybenzils in organic solvents are colourless even on boiling and are stable towards hydroxylamine, phenylhydrazine, *p*-nitrophenylhydrazine, semicarbazide, and *o*-phenylenediamine, and the hydroxybenzils do not undergo the benzilic acid transformation.

From these facts, the authors are of the opinion that these

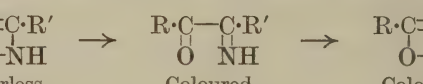
compounds are peroxides both in the crystalline form and in solution.

Experimental.

Preparation of Acyl Cyanides.—The following method differs in certain details from that suggested by Claisen (*Ber.*, 1898, **31**, 1023) and utilised by Mauthner (*Ber.*, 1908, **41**, 921; 1909, **42**, 189) and is of general application. It is a great improvement on the method of heating acid chlorides with cyanides of heavy metals.

A solution of the acid chloride (1 mol.) and pure hydrogen cyanide (4 mols.) in dry ether (5 vols.) was cooled in ice while anhydrous pyridine (4 mols.) was added gradually during 1 hour, and the mixture kept in ice-water for 12 hours. The pyridine hydrochloride was removed by filtration, and the ether and excess of pyridine by distillation, the latter under diminished pressure, and the residue of cyanide, having been freed from traces of pyridine hydrochloride by filtration in ethereal solution, was either distilled or crystallised.

This method avoids treatment with water and thereby eliminates any possibility of hydrolysis of the cyanide, to which the majority of the acyl cyanides are prone. In the cases investigated, the cyanides were usually sufficiently pure for condensation after evaporation of the ether. The yields are good.



Benzoyl cyanide crystallises in pale yellow needles, m. p. 32°, from ligroin (compare Wöhler and Liebig, *Annalen*, 1832, **3**, 267).

o-*Methoxybenzoyl Cyanide.*—To prepare the requisite chloride, *o*-methoxybenzoic acid (1 mol.) was dissolved in thionyl chloride (1½ mols.) and the solution subsequently warmed on the water-bath for ½ hour; the excess of thionyl chloride was removed under diminished pressure, and the acid chloride distilled; b. p. 136°/12 mm. The duration of heating should not be longer than that stated, since thionyl chloride tends to demethylate the acid chloride. The same remarks apply to the preparation of *p*-methoxy- and 3 : 4 : 5-trimethoxy-benzoyl chlorides. Phosphorus pentachloride may be used in place of thionyl chloride, but gives poorer yields. o-*Methoxybenzoyl cyanide* crystallises from ligroin in long, yellow needles, m p. 56°, b. p. 161°/12 mm. (Found: C, 67·15; H, 4·2. $C_9H_7O_2N$ requires C, 67·1; H, 4·35%). It is readily soluble in most organic solvents and is rapidly hydrolysed by water.

p-Methoxybenzoyl cyanide has m. p. 63—64°, b. p. 150°/12 mm., and 3 : 4 : 5-trimethoxybenzoyl cyanide, m. p. 136—137° (compare Mauthner, *loc. cit.*). *Cinnamoyl cyanide*, m. p. 114—115°, was made by the acylation of hydrogen cyanide for the first time (compare Claisen and Moritz, *Ber.*, 1880, **13**, 2124).

Preparation of Benzils.—Dry hydrogen chloride was passed

rapidly for 2½ hours into a solution of the acyl cyanide (1 mol.) and resorcinol (or phloroglucinol) (1·1 mols.) in dry ether. *p*-Methoxy- and 3 : 4 : 5-trimethoxy-benzoyl cyanides, which are sparingly soluble in ether, were dissolved in chloroform and added to the ethereal solution of resorcinol (or phloroglucinol). The presence of chloroform hastened the deposition of the ketimine salt. The solution, which in every case turned red, was kept in ice for 3 days. The deposited ketimine hydrochloride was washed with ether, dissolved in just sufficient water, and the solution warmed to 60° and treated with sodium acetate, which precipitated the white, crystalline ketimine. This was readily soluble in dilute hydrochloric and sulphuric acids, the latter solution depositing a crystalline sulphate, generated ammonia when gently warmed with dilute aqueous sodium hydroxide, and was converted into the colourless benzil by boiling aqueous sodium acetate, the golden-brown colour of the solution soon fading to pale yellow. The following changes therefore probably occur during the hydrolysis :

Aqueous solutions of the ketimine hydrochlorides required several hours' warming on the water-bath before hydrolysis was complete.

2 : 4-*Dihydroxybenzil* has m. p. 239°, turning reddish-brown at about 234° (Found : C, 69·8; H, 4·2. $C_{14}H_{10}O_4$ requires C, 69·4; H, 4·1%).

2 : 4-Dihydroxybenzil was described by Finzi (*Monatsh.*, 1905, **26**, 1128) as a brown, amorphous substance, m. p. 239°. We were unable to make the dioxime and repetition of Finzi's experiment for the preparation of its hydrochloride failed to give the result he stated.

2 : 4-*Diacetoxybenzil* was prepared by boiling a solution of the benzil in acetic anhydride for 4 hours and pouring it into water, when the acetyl compound separated as a thick, pasty mass which soon solidified. It crystallised from alcohol in colourless needles, m. p. 159° (Found : C, 66·5; H, 4·4. $C_{18}H_{14}O_6$ requires C, 66·25; H, 4·3%).

The same method was employed for the preparation of the acetyl derivatives of the other benzils.

2 : 4-*Dihydroxy*-2′-*methoxybenzil* has m. p. 223° after darkening at about 210° (Found : C, 66·3; H, 4·5. $C_{15}H_{12}O_5$ requires C, 66·2; H, 4·4%). The *diacetyl* derivative has m. p. 144° (Found : C, 64·4; H, 4·7. $C_{19}H_{16}O_7$ requires C, 64·1; H, 4·5%).

2 : 4-*Dihydroxy*-4′-*methoxybenzil* has m. p. 234° after darkening at about 225° (Found: C, 66·3; H, 4·6%), and the *diacetyl* derivative has m. p. 178·5° (Found: C, 64·3; H, 4·6%).

2 : 4-*Dihydroxy*-3′ : 4′ : 5′-*trimethoxybenzil* has m. p. 257° after turning pink at 175°, yellow at 200°, and darkening at about 245° (Found: C, 61·6; H, 5·0. $C_{17}H_{16}O_7$ requires C, 61·45; H, 4·8%). The *diacetyl* derivative has m. p. 155° (Found: C, 60·3; H, 4·7. $C_{21}H_{20}O_9$ requires C, 60·6; H, 4·8%).

2 : 4 : 6-*Trihydroxybenzil* has m. p. 287° after darkening at about 260° (Found: C, 65·2; H, 4·2. $C_{14}H_{10}O_5$ requires C, 65·1; H, 3·9%). The *triacetyl* derivative has m. p. 248° (Found: C, 62·6; H, 4·4. $C_{20}H_{16}O_8$ requires C, 62·5; H, 4·2%).

2 : 4 : 6-*Trihydroxy*-2′-*methoxybenzil* has m. p. 235° after darkening at about 200° (Found: C, 62·8; H, 4·3. $C_{15}H_{12}O_6$ requires C, 62·5; H, 4·2%). 2 : 4 : 6-*Triacetoxy*-2′-*methoxybenzil* has m. p. 135°.

2 : 4 : 6-*Trihydroxy*-4′-*methoxybenzil* has m. p. 262° after darkening at about 250° (Found: C, 62·7; H, 4·2%). Its *triacetyl* has m. p. 241° (Found: C, 61·0; H, 4·4. $C_{21}H_{18}O_9$ requires C, 60·8; H, 4·3%).

2 : 4 : 6-*Trihydroxy*-3′ : 4′ : 5′-*trimethoxybenzil* has m. p. 187° (Found: C, 58·6; H, 4·8. $C_{17}H_{16}O_8$ requires C, 58·7; H, 4·6%). The *triacetyl* derivative has m. p. 258° (Found: C, 58·1; H, 4·4. $C_{23}H_{22}O_{11}$ requires C, 58·3; H, 4·6%).

The triacetoxybenzils are only moderately soluble in alcohol and were crystallised from alcohol–acetic acid.

CCXVII.—*Studies of the Glucosides. Part III. The Synthesis of "Thioindican."*

By JAMES CRAIK and ALEXANDER KILLEN MACBETH.

MACBETH and PRYDE (J., 1922, **121**, 1660) deduced the constitution of indican from a study of the hydrolytic products of the methylated glucoside, and hoped to synthesise the glucoside itself through the condensation of tetra-acetylbromoglucose and derivatives of indoxyl. From preliminary attempts it would appear that indoxyl in relatively large amounts is necessary for successful condensation. In view of the difficulty in obtaining sufficient quantities of this material, and of the ease with which it oxidises, it was decided to standardise the experimental methods by examining the conditions in the case of the condensation of tetra-acetylbromoglucose and 3-oxy(1)thionaphthen.

The work described in this paper is outlined in the following scheme:

Experimental.

Tetra-acetylbromoglucose is most conveniently prepared in small quantities by a method devised in the St. Andrews Laboratories. Acetyl bromide (40 g.) is added to anhydrous glucose (10 g.) in a flask immersed in cold water and attached to a reflux condenser. After about 10 minutes a vigorous reaction sets in and the glucose has all dissolved in about ½ hour. The product is poured into ice-water (300 c.c.), and the resulting solid twice washed with sodium bicarbonate solution and then with water until free from acid. The dried ethereal solution of the residue is concentrated greatly, and the addition of light petroleum precipitates an oil which solidifies within 12 hours. Rapid recrystallisation from amyl alcohol gives a pure white, crystalline product which keeps for several months in a desiccator over soda–lime or calcium chloride (yield 10—12 g.).

3-Oxy(1)thionaphthen was prepared by Smiles and McClelland's method (J., 1921, **119**, 1813). We obtained better yields by keeping the temperature at 40—45° during the initial condensation of the 2-thiolbenzoic acid and ethyl acetoacetate and allowing the reaction to continue for about 2 hours.

Condensation of Tetra-acetylbromoglucose and 3-*Oxy*(1)*thionaphthen.*—Attempts to effect the condensation in ethereal solution by shaking with silver oxide gave a product containing a considerable quantity of " thioindigo," from which none of the tetra-acetyl glucoside could be isolated. The best results were obtained by heating tetra-acetylbromoglucose (25 g.) and 3-oxy(1)thionaphthen (13 g.) with quinoline (10 g.) for about 2 hours at 105—110° in an atmosphere of carbon dioxide. The product was poured into ice-water (300 c.c.), extracted with ether, and the extract was washed free from quinoline with *N*-sulphuric acid, then with sodium

bicarbonate solution and water until free from acid. After evaporation of the ether, a rapid steam distillation removed the excess of oxythionaphthen. Thereafter the water was distilled off under reduced pressure, and the dry residual syrup reacetylated by acetic anhydride (60 c.c.) and pyridine (60 c.c.). The crude tetra-acetyl glucoside was obtained by pouring the acetylation mixture into ice-water and ether and washing as described above. The red syrupy residue from the ethereal extract was dissolved in hot alcohol (150 c.c.), and hot water carefully added until turbidity was just appearing. The brown solid obtained on standing yielded in the best experiments about 2·5 g. of white needles, m. p. 106°, of the *tetra-acetyl glucoside* after repeated crystallisation from 60% alcohol. The glucoside is insoluble in water but soluble in the usual organic solvents. In acetone it has $[\alpha]_D + 7{\cdot}4°$ (Found: C, 54·7; H, 4·8; S, 6·7. $C_{22}H_{24}O_{10}S$ requires C, 55·0; H, 5·0; S, 6·7%).

In some experiments, the product obtained was a dark syrup which could not be crystallised even after reacetylation. It contained no bromine, did not reduce Fehling's solution, and analysis showed it to consist essentially of the tetra-acetyl glucoside; and on deacetylation it yielded the parent glucoside.

Deacetylation of the Tetra-acetyl Glucoside.—(a) *With barium hydroxide.* Barium hydroxide (45 c.c. of 0·174 *N*-solution) was added to a hot solution of the tetra-acetyl glucoside (0·8268 g.) in alcohol (40 c.c.). After some minutes barium was precipitated by a stream of carbon dioxide, and the carbonate filtered and washed with alcohol. The united filtrates on evaporation under diminished pressure gave a red syrup, which was extracted with boiling alcohol, and hot water added to the filtrate till turbidity was just appearing. On cooling, "*thioindican*" (I) separated as a mass of fine, glistening needles, coloured pink by traces of "thioindigo." Recrystallised with the aid of a little norit, it gave a pure white product (0·15 g.), m. p. 73·5°, which behaved as a glucoside and did not reduce Fehling's solution until after hydrolysis. It was soluble in alcohol or acetone, and insoluble in ether, light petroleum, or water. The rotation, showing a low dextro-value, was too small at the low concentration available to give a trustworthy reading (Found: C, 53·6; H, 5·3. $C_{14}H_{16}O_6S$ requires C, 53·8; H, 5·1%).

(b) *Alcoholic ammonia.* In this more satisfactory method, the tetra-acetyl glucoside (0·8 g.) was dissolved in a solution of dry ammonia in absolute alcohol. After 10 hours the greater part of the ammonia was removed by a current of air, and the residual solution evaporated under diminished pressure at a bath temperature of 20°. Acetamide was removed by extracting the product

six times with water (10 c.c.), and the residue crystallised as described in (a). Yield 0·13 g. (25% of the theoretical).

Since the red syrup already referred to proved to be essentially glucosidic, it was subjected to hydrolysis as described above. Acetamide and other impurities were removed by repeated extraction with ether. Addition of light petroleum to a concentrated alcoholic solution of the residue precipitated a red solid which on repeated crystallisation from aqueous alcohol yielded fine, white needles of the parent glucoside, m. p. 73·5°.

Estimation of the oxythionaphthen content of the glucoside by simultaneous hydrolysis and condensation with isatin in aqueous hydrochloric acid solution according to the method for estimating indican in plant extracts (Orchardson, Wood, and Bloxam, *J. Soc. Chem. Ind.*, 1907, **26**, 4) gave results which were much too low even when the acid concentration was considerably increased and the time of refluxing greatly extended. The characteristic red condensation product was obtained in a yield of only 48%, the low m. p. of the glucoside and its insolubility in water being doubtless the cause. The estimation may, however, be carried out satisfactorily in alcoholic solution. A solution of "thioindican" (0·0405 g.) in alcohol (100 c.c.) containing isatin (0·23 g.) and concentrated hydrochloric acid (20 c.c.), when boiled under reflux for 10 hours, gave 0·0364 g. of the red condensation product ($C_{16}H_9O_2N_2S$). Theory requires 0·0362 g.

We are indebted to the Department of Scientific and Industrial Research for a grant which enabled one of us (J. C.) to participate in the work.

THE UNIVERSITY, ST. ANDREWS.
THE UNIVERSITY, DURHAM. [*Received, May 14th*, 1925.]

CCXVIII.—*Echitamine.*

By JOHN AUGUSTUS GOODSON and THOMAS ANDERSON HENRY.

THE alkaloid echitamine was first prepared by Gorup-Besanez (*Annalen*, 1875, **176**, 88) from the bark of *Alstonia scholaris*, R.Br. (*Echites scholaris*, L.) and was the subject of much controversy between O. Hesse (*Annalen*, 1875, **176**, 326; **178**, 49 (with Jobst); 1880, **203**, 144; *Ber.*, 1880, **13**, 1841) and Harnack (*Arch. exp. Path. Pharm.*, 1877, **7**, 126; *Ber.*, 1878, **11**, 2004; 1880, **13**, 1648) in the course of which it was shown that Harnack's ditaine (derived from "dita bark," a native name for the bark of *A. scholaris*) is identical with echitamine. Hesse's observations on the alkaloid

were largely confirmed by Bacon (*Philippine J. Sci.*, 1906, **1**, 1007). The position arrived at may be summarised thus: *A. scholaris* bark contains at least two alkaloids: (*a*) ditamine, amorphous, isolated by extracting with ether the residue from an alcoholic extract of the bark, rendered alkaline with ammonia, and (*b*) echitamine (ditaine), obtained by extraction of the same residue, rendered alkaline with solution of sodium or potassium hydroxide, with chloroform, after the removal of ditamine. It is clear from this preliminary work that echitamine is a strong base which, unlike ditamine, cannot be liberated from its salts by ammonia, and the separation of the two alkaloids is based on this fact. The first description of echitamine was given by Hesse (*Annalen*, 1880, **203**, 144), who stated that the free base (echitammonium hydroxide) formed glassy prisms, $C_{22}H_{30}O_5N_2,3H_2O$, m. p. 206°, $[\alpha]_D^{15°} - 28{\cdot}8°$ in alcohol, lost $3H_2O$ at 80° and a fourth molecule of water at 105° in a vacuum, forming a new base, $C_{22}H_{28}O_4N_2$, weaker than the original, but yielding the same hydrochloride, $C_{22}H_{28}O_4N_2,HCl$. Harnack, on the contrary, assigned the formula $C_{22}H_{30}O_4N_2,HCl$ to the hydrochloride.

In addition to *A. scholaris*, several other species of *Alstonia* have been examined. Hesse found in *A. constricta* the amorphous bases porphyrine and chlorogenine (subsequently renamed alstonine) and the crystalline alkaloid, alstonidine (*Annalen*, 1865, Suppl. IV, p. 40; 1880, **205**, 360; *Ber.*, 1878, **11** ,1546. Compare von Muller and Rummel, J., 1879, **35**, 31; Oberlin and Schlagdenhauffen, *J. Pharm.*, 1879, **28**, 576). From a Java species, *A. spectabilis*, R. Brown, Hesse obtained echitamine, ditamine and two other alkaloids, echitenine and alstonamine, the last-named substance being crystalline (*Ber.*, 1878, **11**, 1546; *Annalen*, 1880, **203**, 170), but could find no trace of Scharlec's alstonine (*Genees. Tijd. Ned. Ind.*, 1863, **10**, 209).

Much work has also been done on the sterols and other crystalline, non-nitrogenous substances of Alstonia species. Jobst and Hesse found in *A. scholaris* bark, echikautschin (amorphous); echicerin, $C_{30}H_{48}O_2$, m. p. 157°, $[\alpha]_D + 63{\cdot}75°$; echitin, $C_{32}H_{52}O_2$, m. p. 170°, $[\alpha]_D + 75{\cdot}25°$; echitein, $C_{42}H_{70}O_2$, m. p. 195°, $[\alpha]_D + 85{\cdot}4°$, and echiretin, $C_{35}H_{56}O_2$ (amorphous).

From the dried latex of *Alstonia costulata*, Miq. (*Dyera costulata*, Hook) Sack and Tollens isolated a similar series of sterols (*Ber.*, 1904, **37**, 4110), which Cohen (*Arch. Pharm.*, 1907, **245**, 236) subsequently identified with lupeol, and α- and β-amyrins, and Ultée (*Chem. Weekblad*, 1914, **11**, 456) found the same three constituents in the latex of *A. scholaris*.

The material used in the present investigation consisted of bark

derived from *A. congensis*, Engler. The first sample was collected in the Cameroons by Dr. Lehmann, and for it and the supplies subsequently received from the Cameroons, the Conservator of Forests, Gold Coast, and the Director of Forests, Nigeria, the authors are indebted to the kindness of Dr. Hill, Director of the Royal Botanic Gardens, Kew.

The results of the present investigation confirm Hesse's empirical formula for echitamine, and many of the unexplained points recorded by Hesse and Harnack in the course of their controversy as to the formula of echitamine are accounted for by the fact now established that echitamine is a methyl ester and is hydrolysed with great ease, forming the new base *demethylechitamine*, $C_{21}H_{26}O_4N_2$. It is also shown that echitamine contains a methylimino-group, but whether this has a tertiary or secondary nitrogen is uncertain, as the alkaloid appears to yield a crystalline nitroso-derivative. For the same reason, it is uncertain whether one or two hydroxyl groups are present, as the second acetyl group in the diacetylechitamine now described may indicate the presence of either a hydroxyl group or a secondary nitrogen atom.

Finally, the fact that the parent alkaloid and all the derivatives described give an intense blue colour with Hopkin and Cole's glyoxylic reagent for tryptophan (*Proc. Roy. Soc.*, 1901, **68**, 21) must be taken to mean that echitamine has an indole nucleus, and support for this view is given by the production of an indole-like base, as one product, when echitamine is distilled with alkalis.

A. congensis bark, like other barks of this genus, contains much amorphous alkaloid in addition to echitamine and yields a large quantity of non-nitrogenous products. Of the latter, one substance, a well-crystallised lactone, $C_9H_{14}O_3$, was isolated as a by-product in the purification of echitamine and has been characterised. It is converted by sodium hydroxide into a crystalline sodium salt, $C_9H_{15}O_4Na$, and yields a monoacetyl derivative, so that its formula may be extended thus, $HO\cdot\overline{C_8H_{15}CO\cdot O}$.

For some of the echitamine used in this investigation the authors are indebted to Prof. F. L. Pyman, F.R.S., who isolated it from the bark of another species, *A. Gillettii*, kindly supplied by Fr. Just. Gillet, Curator of the Botanic Gardens, Kisanti, Belgian Congo.

The various Alstonia barks are used in the localities where they occur, as remedies for malaria, but so far no attempt has been made to use echitamine in medicine. The authors are indebted to Dr. J. Trevan of the Wellcome Physiological Research Laboratories for the observation that echitamine hydrochloride is toxic to mice

in doses of 0·3 to 0·5 mg. per 20 g. and that it acts by paralysis of the medulla.

In connexion with the use of the bark in malaria Major Brown of the Wellcome Bureau of Scientific Research found that the hydrochloride was not toxic to protozoa (Glaucoma) at a concentration of 0·03%, but became so at a concentration of 0·0025% in presence of *N*/800-alkali (compare Bacon, *loc. cit.*).

Experimental.

The finely-ground bark (1 kg.) was exhausted with hot alcohol, the concentrated solution poured into warm 1% acetic acid (500 c.c.), and the filtrate from this concentrated to 200 c.c. After agitation with ether (extract A) and chloroform (extract B) in turn to remove wax and other impurities, the liquor was rendered alkaline with sodium hydroxide solution and the liberated alkaloids were dissolved out with chloroform. The residue from the chloroformic solution was dissolved in alcohol, and the liquid rendered slightly acid with hydrochloric acid (10%) and set aside. Echitamine hydrochloride gradually crystallised and was collected, washed with a little alcohol, and recrystallised from water. The yield of crystalline hydrochloride from different samples of *A. congensis* bark varied considerably.

	Gold Coast.	Nigeria.	Cameroons.
Total alkaloid %	0·38 to 0·56	0·11 to 0·12	0·18
Echitamine hydrochloride %	0·18 to 0·34	0·03 to 0·04	0·09

As few data are recorded by previous workers regarding the base and its salts, the opportunity has been taken to characterise these substances.

The hydrochloride obtained was identical with echitamine hydrochloride from *A. scholaris* bark. When crystallised quickly from water, it forms long, anhydrous needles, m. p. 295° (corr.; decomp.), $[\alpha]_D^{15°}$ − 58° (in water; $c = 1\%$) (Found : C, 62·6, 62·9; H, 7·1, 7·1; N, 6·4; Cl, 8·4, 8·5. $C_{22}H_{28}O_4N_2$, HCl requires C, 62·8; H, 6·9; N, 6·9; Cl, 8·4%). When crystallised slowly from water, it forms stumpy prisms, m. p. 292° (corr.; decomp.), $[\alpha]_D^{15°}$ − 54·3° ($c = 1·028$; water) (Found : loss at 100° in a vacuum, 4·79. Calc. for $C_{22}H_{28}O_4N_2,HCl,H_2O : H_2O$, 4·15%). Both forms of the hydrochloride are neutral to litmus. Hesse (*loc. cit.*) records for his hydrochloride $C_{22}H_{28}O_4N_2,HCl$, $[\alpha]_D$ − 57° ($c = 2$; water). The hydrobromide, similarly obtained, forms transparent prisms, m. p. 258° (air-dry; corr.; decomp.), 268° (dry; corr.; decomp.), $[\alpha]_D^{15°}$ − 43·5° for the hydrated salt ($c = 0·804$ in water) (Found : C, 56·4; H, 6·5; Br, 16·9. Calc. for $C_{22}H_{28}O_4N_2,HBr$: C, 56·8; H, 6·3; Br, 17·2%. Loss on drying at 105° in a vacuum, 3·7. Calc. for $C_{22}H_{28}O_4N_2,HBr,H_2O$:

H_2O, 3·7%). Hesse gives the formula $C_{22}H_{28}O_4N_2,HBr,2H_2O$ to his hydrobromide.

The hydriodide, similarly prepared, crystallises from water in long, anhydrous prisms, m. p. 267° (corr.; decomp.) (Found: C, 51·4; H, 5·9; I, 24·0. Calc. for $C_{22}H_{28}O_4N_2,HI$: C, 51·6; H, 5·7; I, 24·8%).

The sulphate is more soluble than the halide salts, separates only after considerable concentration of the neutralised solution, and is best recrystallised by adding alcohol to a strong solution of the salt in water. It forms rosettes of needles, which decompose from 275° onwards; $[\alpha]_D^{15°}$ — 51·6° (c = 2·58 in water) [Found for air-dry salt: loss at 100° in a vacuum, 2·4. $(C_{22}H_{28}O_4N_2)_2,H_2SO_4,H_2O$ requires H_2O, 2·04%. Found in dry salt: H_2SO_4, 11·46. Calc., H_2SO_4, 11·31%].

The *nitrate*, obtained by neutralising the base in chloroform with N/10-nitric acid, separates, on cooling the concentrated aqueous solution, in elongated pyramids, $C_{22}H_{28}O_4N_2,HNO_3,2H_2O$, m. p. 127° (air-dry; corr.; decomp.), 176° (dry; corr.), $[\alpha]_D^{15°}$ — 51·4° (air-dry salt in water; c = 1·01) (Found: loss on drying in a vacuum over sulphuric acid, 8·15. Calc., 7·45%. Found in dry salt: C, 58·9; H, 6·8. Calc., C, 59·0; H, 6·5%).

The neutral oxalate, $(C_{22}H_{28}O_4N_2)_2,H_2C_2O_4$, was only obtained as a gelatinous precipitate, although Hesse (*loc. cit.*) obtained it crystalline (Found: C, 63·9; H, 6·7. Calc., C, 64·3; H, 6·8%). When the calculated quantity of oxalic acid is added to a solution of the base in alcohol, the neutral oxalate first formed dissolves and on adding a little water and removing the alcohol by distillation in a vacuum, rosettes of needles of *echitamine hydrogen oxalate*, $C_{22}H_{28}O_4N_2,H_2C_2O_4,2H_2O$, m. p. 238° (corr.; decomp.), separate on cooling (Found: loss on drying at 100° in a vacuum, 6·3. Calc., H_2O, 7·05%. Found in dry salt: C, 61·0; H, 7·0. Calc., C, 60·7; H, 6·4%).

The picrate is precipitated when picric acid solution is added to the hydrochloride dissolved in water. The air-dry substance softens at 50°, decomposes at 98°, and loses in a vacuum at atmospheric temperature over sulphuric acid 41·3%, corresponding to $24H_2O$. On recrystallisation from dilute alcohol it forms minute rosettes of needles, $C_{22}H_{28}O_4N_2,C_6H_2(OH)(NO_2)_3,2H_2O$, which behave like the air-dry substance on heating (Found: loss on drying in a vacuum over sulphuric acid, 5·5. Calc., 5·6%. Found in dry substance: C, 54·6; H, 5·1. Calc., C, 54·8; H, 5·1%).

Determinations of methoxyl and methylimino-groups by the usual methods on the hydrochloride and hydriodide gave the following results. Hydrochloride: Found; MeO, 7·2; NMe, 7·6. Calc.

for MeO, 7·4; NMe, 6·9%. Hydriodide: Found; MeO, 6·0, 6·1; NMe, 6·0. Calc. for MeO, 6·1; NMe, 5·7%.

Diacetylechitamine Hydrochloride.—Echitamine hydrochloride was mixed with a few drops of pyridine and heated at 100° with six parts by weight of acetic anhydride. On cooling, the diacetyl derivative separated in silky masses of needles and more was obtained by concentrating under reduced pressure. After recrystallisation from ethyl acetate the substance had m. p. 271° (corr.; decomp.) [Found in substance dried at 105° in a vacuum: C, 61·7; H, 6·7; Cl, 6·8; MeO, 6·6; acetic acid (by hydrolysis with phosphoric acid), 26·2. $C_{22}H_{26}O_4N_2Ac_2,HCl$ requires C, 61·8; H, 6·6; Cl, 7·0; MeO, 6·2; acetic acid, 23·8%].

Hydrolysis of Echitamine.—The base used in preparing the salts described above was obtained by dissolving the hydrochloride, as isolated (p. 1643), in water, adding sodium hydroxide, and extracting with chloroform. If complete removal of this solvent by distillation is attempted, the base decomposes as already recorded by Hesse (*Annalen*, 1880, **203**, 144), who called the product oxyechitamine and gave it the formula $C_{22}H_{28}O_5N_2$. The change is probably more profound than Hesse supposed, but the substance has not been examined in the course of this work. The solvent can, however, be largely removed by distillation and the residue, dissolved in alcohol, used for the preparation of salts, but it has not been possible to induce the base to crystallise, though Hesse, as already stated, obtained a base which he at one time regarded as a crystalline tetrahydrate, $C_{22}H_{28}O_4N_2,4H_2O$. In the course of attempts to crystallise the base, water was added (after some days) to a solution in alcohol, prepared as described, and on long standing this deposited crystalline material, more of which was slowly obtained by continued dilution with water.

The same substance was produced more rapidly by heating echitamine hydrochloride in sealed tubes at 120° during 6 hours with 0·24*N*-sodium hydroxide solution (20 c.c. per g. of hydrochloride). It can be recrystallised from hot 70% alcohol and then forms prisms or hexagonal plates, m. p. 290° (air-dry; corr.; decomp.) or 268° (dry; corr.; decomp.). It is sparingly soluble in alcohol, chloroform, or water and is neutral to litmus. It forms a *hydrochloride* crystallising in prisms from hot water, m. p. 306° (corr.; decomp.), which is acid to litmus and much less soluble in water (1 in 209, approx.) than echitamine hydrochloride (1 in 76 approx.) (Found for air-dry base: C, 62·2; H, 7·5; loss in a vacuum at 130°, 8·7. $C_{21}H_{26}O_4N_2,2H_2O$ requires C, 62·0; H, 7·4; H_2O, 8·9%. Found for base dried at 130° in a vacuum: C, 68·0, 68·3; H, 7·3, 7·3; N, 7·8. $C_{21}H_{26}O_4N_2$ requires C, 68·1; H, 7·1; N, 7·6%.

Found for hydrochloride, dried at 100° in a vacuum: C, 62·1, 62·2; H, 6·8, 6·8; Cl, 8·7. Calc. for $C_{21}H_{26}O_4N_2$,HCl: C, 62·0; H, 6·7; Cl, 8·7%).

These analyses indicate that the new base contains $-CH_2$ less than echitamine, and determinations showed that it still contained a methylimino-group but had lost the methoxyl group of echitamine (Found for air-dry base: MeO, 0; NMe, 7·1. $C_{21}H_{26}O_4N_2$ requires NMe, 7·8%. Found for dry hydrochloride: MeO, 0; NMe, 6·8. $C_{21}H_{26}O_4N_2$,HCl requires NMe, 7·1%). The new base is therefore called *demethylechitamine* and all its reactions indicate that the methyl group has been lost from a carbomethoxy-group. This assumption accounts for the neutrality to litmus of demethylechitamine and the acidity to litmus of the hydrochloride, echitamine being strongly alkaline and its hydrochloride neutral to this indicator. The new base, like echitamine and all its salts, gives an intense blue coloration with Hopkin and Cole's glyoxylic reagent for tryptophan.

Action of Nitric Acid on Echitamine.—Harnack stated (*Ber.*, 1878, **11**, 2004) that a carmine-red base was produced by the action of concentrated nitric acid on echitamine, but the substance was not analysed or further described. When nitric acid (18 c.c.) is added to echitamine nitrate (3·19 g.) in water (180 c.c.) and the solution is warmed at 100°, it becomes red, then green, and finally yellow. When sodium hydroxide solution is added to the cooled liquid, a red base is precipitated; and a little more can be recovered by extraction with chloroform. A solution of the red base in dilute alcohol on concentration and standing deposits rosettes of minute needles (yield 1·4 g.), but the bulk of it remains amorphous. After recrystallisation the air-dry base began to decompose at 156° and after drying at 105° in a vacuum showed shrinkage at 163° (corr.) and frothed at 184° (corr.). It is almost insoluble in water, forms a red solution in alcohol and in chloroform a yellow solution with a red fluorescence [Found in air-dry base: loss at 105° in a vacuum, 12·1. $C_{22}H_{26}O_4N_2(NO_2)_2$,$4H_2O$ requires H_2O, 13·2%. Found in base dried at 105° in a vacuum: C, 55·6; H, 6·0; N, 11·6. Calc.: C, 55·7; H, 5·5; N, 11·8%].

The red base still contains intact the methoxyl group of echitamine (Found in dry base: MeO, 6·9. Calc., 6·5%).

The red colour is sharply changed to yellow on neutralisation with acid, and on adding standard alkali to a solution of a known weight of the base in a known excess of standard acid a sharp end-point is reached when a slight permanent red precipitate is formed. A molecular-weight determination by this method gave 474 [Calc. for $C_{22}H_{26}O_4N_2(NO_2)_2$, M, 489]. The red base appears therefore to be a simple dinitro-derivative of echitamine, but the change is

probably more far-reaching than is indicated by the empirical formula.

On treatment with sodium nitrite and dilute hydrochloric acid at 0°, echitamine gives a small yield (8%) of a substance crystallising from ether in rosettes of yellow needles, which shrinks at 140° and melts at 157° (decomp.) and, as it gives Liebermann's reaction, is probably a nitroso-derivative.

Distillation of Echitamine with Alkalis.—When echitamine is heated dry with soda-lime or with an aqueous solution of potassium hydroxide (50%), an alkaline, aqueous distillate is obtained when the temperature is kept below 250°. On neutralisation with hydrochloric acid and redistillation, this affords a distillate which when poured on a hot, oxidised copper spiral yields formaldehyde, due to the presence of methyl alcohol liberated by the hydrolysis of the carbomethoxy-group already referred to (p. 1646). The aqueous liquor in the distillation flask, on evaporation to dryness, left a small quantity of a hydrochloride.

The distillation was continued up to 310° and finally under reduced pressure until nothing more came over. The distillates thus obtained were acidified and extracted with ether, which removed 0·68 g. (from 8·6 g. of alkaloid) of an oil, having a pronounced fæcal odour. This oil gave a red coloration with Ehrlich's reagent, an orange colour with Nelson's solution, and dyed a pine splint, moistened with hydrochloric acid, red. It appeared therefore to be an indole derivative, but no well-defined product could be obtained from it. The acid mother-liquor was rendered alkaline and again extracted with ether, which removed 0·3 g. of a base from which also no crystalline derivatives could be obtained. The alkaline mother-liquor was then distilled, the distillate collected in dilute hydrochloric acid, and the salt produced isolated by the addition of alcohol to the highly concentrated liquor. The crystalline hydrochloride so obtained contained 52·5% of chlorine (Calc. for $CH_3 \cdot NH_2, HCl$: Cl, 52·5%).

The products of this distillation are therefore methyl alcohol, methylamine, an indole derivative, and a third base.

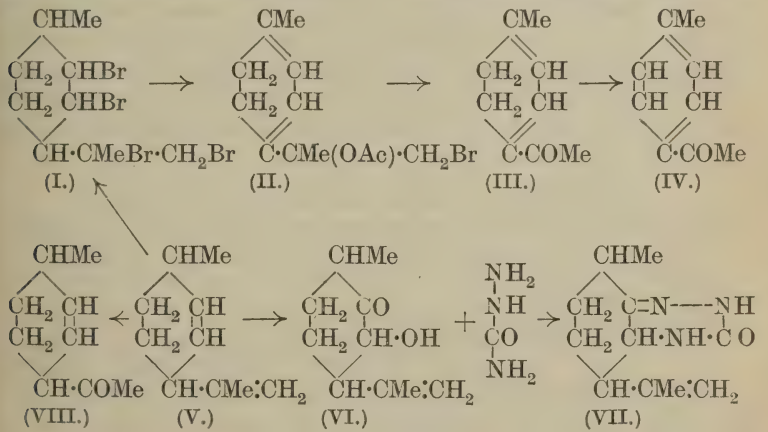
Non-alkaloidal Constituents.

Isolation of a Lactone, $C_9H_{14}O_3$.—No attempt has been made to isolate the components of the waxy and other materials removed in extracts A and B (p. 1642) in the purification of the acetic acid solution, but as these materials retained some alkaloid they were extracted with dilute hydrochloric acid, which was then rendered alkaline with ammonia and re-extracted with chloroform. In this way a crystalline, nitrogen-free product was isolated, more of which

was obtained from the mother-liquors remaining from the separation of crude echitamine hydrochloride. The total yield amounted to 0·02% by weight of the bark used. No evidence has been obtained that this substance is a decomposition product of echitamine. It crystallises from hot water in colourless prisms or long needles, m. p. 74—77° (air-dry; corr.) or 103° (dry; corr.), and has $[\alpha]_D^{15°}$ + 49·9° (air-dry substance in water, $c = 2·5$) or + 56·4° (dry substance in water, $c = 2·5$), is neutral in reaction, fairly soluble in water or chloroform and sparingly soluble in ether (Found: loss on drying in a vacuum at 60° and finally at 90°, 9·84. $C_9H_{14}O_3,H_2O$ requires H_2O, 9·57%. Found in dried substance: C, 63·4, 63·7; H, 8·4, 8·5. $C_9H_{14}O_3$ requires C, 63·5; H, 8·3%).

No methoxyl or dioxymethylene group is present. The substance dissolves in solutions of sodium hydroxide, and the excess of alkali can be titrated back by standard hydrochloric acid with phenolphthalein as indicator. Such determinations indicated that the hydrated substance neutralised 20·7% of sodium hydroxide (Calc., 21·3%) and the dry substance, 23·5% (Calc., 23·5%). A solution in the calculated quantity of sodium hydroxide solution was concentrated, and kept after the addition of dry alcohol, when the corresponding *sodium* salt was obtained as a hygroscopic, crystalline substance (Found: loss on drying at 90—100° in a vacuum, 15·99. Calc. for $2H_2O$, 14·63%. Found in dry salt: Na, 10·64. Calc. for $C_9H_{15}O_4Na$: Na, 10·94%). The substance is therefore a *lactone* of an acid $C_9H_{16}O_4$.

On boiling the lactone with five times its weight of acetic anhydride for 1 hour, concentrating the solution under reduced pressure to half its volume, pouring into water, and extracting with ether we obtained a *monoacetyl* derivative which could not be crystallised (Found for substance dried in a vacuum at 105°: C, 62·5; H, 7·8. $C_9H_{13}O_3Ac$ requires C, 62·2; H, 7·6%). On hydrolysis with alkali and distillation of the resulting liquid, after addition of excess of sulphuric acid, 32·1% of acetic acid was obtained as determined by titration (acetic acid required for $C_9H_{13}O_3Ac$, 28·3%). The residue in the flask, on thorough extraction with chloroform, yielded 79·3% by weight of the original substance used (Calc. for $C_9H_{14}O_3$ from $C_9H_{13}O_3Ac$, 80·2%). The recovered lactone had m. p. 98—100° and $[\alpha]_D^{15°}$ + 55·8° after drying in a vacuum at 100°.



WELLCOME CHEMICAL RESEARCH LABORATORIES,
LONDON. [*Received, May 18th,* 1925.]

CCXIX.—*Chenopodium Oil. Part II. The Hydrocarbon Fraction.*

By Thomas Anderson Henry and Humphrey Paget.

The presence of a lævorotatory component in the hydrocarbon fraction of chenopodium oil was first recognised by Kremers (*Pharm. Rev.*, 1907, **25**, 155), and since then numerous efforts have been made to isolate and identify it. Nelson obtained, by bromination of the hydrocarbon fraction, a substance which he regarded as *l*-limonene tetrabromide (*J. Amer. Chem. Soc.*, 1920, **42**, 1204), but on repeating this work the authors found that the product so obtained was optically inactive, differed in crystalline form and physical constants from all the known terpene tetrabromides, and therefore could not be *l*-limonene tetrabromide, but must be derived from a terpene so far unknown. Up to that time only *p*-cymene and α-terpinene had been definitely recognised as present (J., 1921, **119**, 1714).

The authors now show that Nelson's tetrabromide (I) on treatment with silver acetate yields an acetoxybromide (II), which is oxidised by chromic acid to *p*-tolyl methyl ketone (IV), probably through the dihydroketone (III). These reactions are best explained

by the assumption that the tetrabromide is derived from the terpene $\Delta^{2\cdot8(9)}$-*p*-menthadiene (V). Support for this view is obtained from the fact that the total hydrocarbon fraction on treatment with chromic acid is partly oxidised to dimethylacetonylacetone (derived from α-terpinene) and a hydroxy-ketone, $C_{10}H_{16}O_2$ (VI), the semicarbazone of which readily loses water, like other *o*-hydroxy-ketones derived from hydroaromatic substances

(compare Manasse, *Ber.*, 1897, **30**, 668), forming a base, $C_{11}H_{17}ON_3$ (VII). Further, the total hydrocarbon fraction on oxidation by permanganate yields a minute quantity of a substance, $C_9H_{14}O$, which may be tetrahydro-*p*-tolyl methyl ketone (VIII). The substances $C_{10}H_{16}O_2$ and $C_9H_{14}O$ are not obtainable by the separate oxidation of any of the known components (*p*-cymene, α-terpinene, *l*-limonene; see below) of the total hydrocarbon fraction, and it is consequently assumed that they come from the terpene * yielding the tetrabromide.

The same formula has been used already for Tschugaeff's *iso*-limonene (*J. Russ. Phys. Chem. Soc.*, 1904, **36**, 988) and Aschan's diprene (*Annalen*, 1924, **439**, 221), neither of which has been fully described, and it is possible that further work may prove all three to be identical, in which case the name *iso*limonene should have priority. It is of interest to note that all three occur along with limonene.

The removal of the readily oxidisable components (α-terpinene and terpene *A*) by partial oxidation of the total hydrocarbon fraction with chromic acid leaves a mixture of *p*-cymene and the lævorotatory component, the identity of which has been a subject of conjecture since 1907. On bromination followed by removal of the *p*-cymene, which inhibits crystallisation, *l*-limonene tetrabromide was isolated in good yield and the presence of *l*-limonene was confirmed by the formation of its characteristic oxidation products, hydroxyterpenylic and lævulic acids. It is also shown that on oxidation by permanganate in acetone, *l*-limonene yields an oily lactone acid, $C_9H_{14}O_5$, derived from a dihydroxy-dicarboxylic acid, $C_9H_{16}O_6$, for which the constitution

$$OH\cdot CHMe\cdot CH_2\cdot CH_2\cdot \overset{*}{C}H[CH(OH)\cdot CO_2H]\cdot CH_2\cdot CO_2H$$

is suggested, since it furnishes lævulic and acetic acids by oxidation with chromic acid, fission taking place at $\overset{*}{C}$. This acid is closely related to two acids,

$$CH_2Ac\cdot CH_2\cdot CHAc\cdot CH_2\cdot CO_2H \longrightarrow CO_2H\cdot CH_2\cdot CH_2\cdot CH(CO_2H)\cdot CH_2\cdot CO_2H,$$

mentioned, without description, by Tiemann and Semmler (*Ber.*, 1895, **28**, 2150) as resulting from the oxidation of limonene erythritol.

In the course of this work large quantities of the total hydrocarbon fraction of chenopodium oil have been worked up, and from the first runnings of these a few c.c. of a substance, which is probably *sym*-dimethylethylene oxide, C_4H_8O, was isolated.

* To save space, and to avoid further additions to the synonymy of terpenes, this component is referred to later as terpene *A*.

The following substances have now been identified as components of chenopodium oil.

p-Cymene.	*sym*-Dimethylethylene oxide (?).	Ascaridole.
α-Terpinene.	Butyric acid.	Ascaridole glycol.
$\Delta^{2,8,9}$ *p*-Menthadiene.	Methyl salicylate.	Ascaridole glycol anhydride.
l-Limonene.	Salicylic acid.	

The chief interest of chenopodium oil lies in its use as an anthelmintic, and it is being employed on a large scale in anti-hookworm campaigns in various parts of the world. Drs. Smillie and Pessôa, who have been engaged in researches on hookworm disease under the auspices of the Brazilian Government and the Rockefeller Foundation in Brazil, have kindly tested pharmacologically and clinically the chief components of chenopodium oil isolated in these laboratories, and their results have been published elsewhere (*J. Pharm. Expt. Ther.*, 1924, **24**, 359). They show that ascaridole, the chief component of the oil, is a remarkably efficient anthelmintic, and that none of the other constituents can be regarded as of value for this purpose.

Experimental.

When a receiver cooled in ice and salt was inserted during the separation of the hydrocarbon fraction from ascaridole by distillation at low pressure, a small amount of a colourless, volatile, pungent-smelling liquid was collected. On redistilling this, a little was obtained at 65—75°/760 mm., the greater part boiling between 120—170°, and consisting chiefly of terpenes and *p*-cymene. After drying over potassium carbonate, the lower-boiling fraction had b. p. 64—78°, $d_{15^\circ}^{15^\circ}$ 0·837, $d_0^{0^\circ}$ 0·8409, $[\alpha]_D^{15^\circ} + 0{\cdot}10^\circ$, $n_D^{20^\circ}$ 1·3968 to 1·3981, *M* (vapour density) 70·2 (Found: C, 66·4; H, 12·4. C_4H_8O requires C, 66·7; H, 11·1%; *M*, 72).

The odour and the characters of this substance indicate that it might be one of the butylene oxides (possibly *sym*-dimethylethylene oxide), b. p. 56—57; $d_0^{0^\circ}$ 0·8344, but, as the figures given above show, the small quantity obtained was still highly impure.

The hydrocarbon fraction distilled between 170° and 185°/760 mm. but all attempts to isolate fractions of constant boiling point failed; considerable separation was, however, effected by repeated slow distillation through a 12-bulb Young dephlegmator. Four litres of the hydrocarbon fraction so treated gave the following results:

Fraction	1	2	3	4	5
B. p.	170—174°	174°	174—175°	175—175·5°	175·5—176°
Amount (g.)	20	40	150	1100	30
α (1-dcm.) ...	−14°	−15°	−16°	−17°	−17·5°
Fraction	6	7	8	9	
B. p.	176—177°	177—178°	178—180°	180—184°	
Amount (g.)	800	800	900	150	
α (1-dcm.) ...	−18°	−19°	−20°	−18·5°	

α-Terpinene nitrosite could be obtained from all these fractions, while only fractions 1 to 4 gave the tetrabromide, m. p. 117°, characteristic of terpene *A*, the best yield being obtained from fraction 1. Fraction 4 was repeatedly redistilled to furnish a little more of fractions 1 to 3, and the residue used with fractions 6, 7, and 8 for the identification of the lævorotatory component. It was shown previously (*loc. cit.*, 1717) that the α-terpinene present in these fractions could be removed by agitation with Beckmann's chromic acid mixture, leaving the lævorotatory terpene mixed with *p*-cymene, and this mixture is referred to later as fraction B. It has the following average characters: b. p. 176·5° to 177°/758 mm., $d_{27.5°}^{23.5°}$ 0·8545, $[\alpha]_D^{15°}$ − 23·08°, $n_D^{20°}$ 1·48637 [Found: C, 89·1, 88·9, 88·8; H, 10·9, 10·6, 10·65%, which corresponds with a mixture of terpenes $C_{10}H_{16}$ (C, 88·2; H, 11·8) and *p*-cymene $C_{10}H_{14}$ (C, 89·6; H, 10·4) in proportion 40 : 60, and 63% of *p*-cymene can be isolated from it by oxidation with permanganate in acetone (see below)]. It yields no terpinene nitrosite, nor any of the oxidation products of α-terpinene, and no terpene *A* tetrabromide could be obtained from it.

Examination of Fraction B.

Bromination.—On bromination by the method already described (*loc. cit.*, p. 1717) a yellow, viscous oil was obtained which, even after standing for several months below 0°, deposited no crystals and gradually changed to a nearly solid tar. If, however, the freshly-brominated product, freed from chloroform and hydrogen bromide by aspiration, was quickly distilled until the bulk of the *p*-cymene was removed at about 105°/10 mm., the residual brown oil, on standing, became filled with leafy crystals, m. p. 104° after recrystallisation from alcohol. A mixture with an equal quantity of *d*-limonene tetrabromide melted at 124° and showed no depression of melting point on further admixture with dipentene tetrabromide. A mixture with the tetrabromide of terpene *A* (m. p. 117°) melted at 90—92°. The substance is therefore *l*-limonene tetrabromide (Found: Br, 69·9; $[\alpha]_D^{19°}$ − 66·12°. *l*-Limonene tetrabromide, $C_{10}H_{16}Br_4$, requires Br, 70·2% and has $[\alpha]_D^{9°}$ − 73·45°).

Oxidation by Permanganate in Acetone.—Fraction B (700 c.c.) mixed with acetone was treated with powdered potassium permanganate (1200 g.) in quantities of 10 g. at a time. The acetone was then distilled off and the residue steam-distilled, yielding 436 c.c. of *p*-cymene (62·3% of the mixture used) having α − 0·7°. The residual alkaline liquor, combined with the washings of the precipitated manganese dioxide, was concentrated to low bulk (compare *loc. cit.*, p. 1719), shaken with ether and ethyl acetate

to remove a small amount of neutral matter, from which traces of the carbonyl compound $C_9H_{14}O$ were isolated (p. 1658), then acidified and again extracted with ether (i), and ethyl acetate (ii). After removal of acetic acid by heating under reduced pressure, these extracts amounted to (i) 61·3 g. and (ii) 15·6 g. and consisted of oily acids, which could not be induced to crystallise either as such or in the form of derivatives. They were therefore converted into ethyl esters, and these distilled under reduced pressure, giving fraction (a), b. p. 117—170°/11 mm., $[\alpha]_D^{20°} - 4{\cdot}8°$; fraction (b), b. p. 170—215°/11 mm., $[\alpha]_D^{20°} - 4{\cdot}8°$, which from the long range of boiling point were obviously mixtures.

After many attempts to isolate a pure acid from these esters it was found that by hydrolysing them with sodium hydroxide in alcohol, a sodium salt, insoluble in alcohol, was produced, which though hygroscopic could be obtained in a granular condition by filtering rapidly from the excess of alcoholic soda, washing thoroughly with 96% alcohol, and drying in a vacuous desiccator. More of this sodium salt was secured by distilling the solvent from the mother-liquors and boiling the residue with dry alcohol. Finally, the viscous residual mixture of soluble sodium salts was dissolved in water, shaken with ether to remove a small amount of neutral tar that had formed, then acidified, and the liberated acid recovered by extraction with ether. This solvent having been distilled off, the acid was boiled with baryta, the excess of the latter removed by carbon dioxide, the filtrate taken to dryness in a vacuum, and the residue boiled with alcohol, which caused the separation of an insoluble barium salt, a little more of which was obtained by repeating the process. Finally, there was left a comparatively small amount of a mixture of barium salts soluble in alcohol, from which a little more material could be separated by precipitation as the thorium salt, but this method was not pursued further. The insoluble sodium and barium salts, isolated as described above, were purified as far as possible by repeated boiling with 96% alcohol, and then gave the following results on analysis, which showed them to be salts of the same acid. *Sodium* salt. Found: Na, 17·0%. *Barium* salt, Found: Ba, 39·1%. Calc. for $C_9H_{14}O_6Na_2$, Na, 17·4%; calc. for $C_9H_{14}O_6Ba$, Ba, 38·6%. The free acid, regenerated from either the sodium or barium salt, boiled at about 210°/34 mm. and formed a colourless, viscid oil (Found: C, 54·0, 53·9; H, 6·4, 6·8. $C_9H_{14}O_5$ requires C, 53·5; H, 6·9%).

On direct titration with *N*-soda solution no definite end-point could be obtained, but when the acid was boiled with excess of *N*-soda for at least 30 minutes and the excess of alkali titrated

back with *N*-acid satisfactory end-points were reached and the amount of soda used was equivalent on the average to sodium (Na) 22·19%. For conversion of $C_9H_{14}O_5$ into $C_9H_{14}O_6Na_2$ the amount of sodium (Na) required is 22·7%.

The silver salt of the acid is relatively stable at atmospheric temperatures even on exposure to light; it dissolves in boiling water and if the solution is filtered rapidly from the small amount of reduced silver formed, re-deposits the salt on cooling as a colourless granular powder, which, however, cannot be dried for analysis without the application of heat, which leads to reduction; and the results are always from 2 to 4% high in silver. Small amounts of the barium salt have been obtained in crystalline form by the cautious addition of alcohol to a 25% solution of the salt in water, but the crystals are very deliquescent, and it was not found practicable to secure enough crystallised barium salt for examination in this way.

The acid gave no derivative with semicarbazide, hydroxylamine, or phenylhydrazine.

To a solution of 2·6 g. of the sodium salt in 30 c.c. of water 30 c.c. of Beckmann's chromic acid mixture were added and the mixture was left standing with occasional agitation for 4 days. It was then thoroughly extracted with ether, which removed 1·52 g. of oily acids, smelling strongly of acetic acid. This residue was left in a vacuum over caustic potash until the bulk of the acetic acid was removed, and then treated with solution of semicarbazide in alcohol, when in the course of a few hours it deposited a copious crop of crystals of a semicarbazone, m. p. 182°; after recrystallisation from alcohol, this rose to 194° (corr.) and showed no change on further crystallisation and no depression when mixed with lævulic acid semicarbazone. The oxidation products of the $C_9H_{14}O_5$ acid are therefore lævulic and acetic acids, and in view of this and the results recorded above the authors regard this acid as a lactone of the acid $OH{\cdot}CHMe{\cdot}CH_2{\cdot}CH_2{\cdot}CH[CH(OH){\cdot}CO_2H]{\cdot}CH_2{\cdot}CO_2H$ (p. 1650).

The acids regenerated from the barium salts soluble in alcohol referred to above also yield lævulic and acetic acids on oxidation with chromic acid and therefore probably still contain some of the $C_9H_{14}O_5$ lactone acid, which seems to be the principal product of the oxidation of limonene by permanganate in acetone solution.

Oxidation by Permanganate in Water.—Fraction B (100 c.c.) was added in four portions to 1 litre of water containing 94 g. of potassium permanganate, and shaken occasionally till decolorised. The mixture was then steam-distilled to remove unchanged hydrocarbon, and the residual liquor in the distillation flask, with the washings from the precipitated manganese dioxide, thoroughly

extracted with ether, yielding a little cuminaldehyde (derived from *p*-cymene), which was identified by a mixed melting point determination of the semicarbazone (m. p. 210°). The liquor was then concentrated to low bulk, made acid, and shaken with (i) ether and (ii) ethyl acetate. The ethereal extract after removal of the solvent was distilled under reduced pressure, and yielded two fractions, the first a thick oil and the second crystalline, m. p. 159—160°, and consisting of *iso*propenylbenzoic acid, formed by distillation of hydroxy*iso*propylbenzoic acid, which is known as an oxidation product of *p*-cymene under these conditions (Found : C, 73·6; H, 6·4. Calc. for $C_{10}H_{10}O_2$: C, 74·1; H, 6·2%. Found in silver salt : Ag, 40·9. Calc. for $C_{10}H_9O_2Ag$: Ag, 40·15%). The oily fraction gave a semicarbazone, which after recrystallisation melted constantly at 194° and showed no depression of melting point when mixed with lævulic acid semicarbazone (Found : C, 41·9; H, 6·7. Calc. for $C_6H_{11}O_3N_3$: C, 41·6; H, 6·3%). The ethyl acetate extract, on removal of the solvent, deposited a crystalline acid, m. p. 195° (Found : C, 50·2; H, 6·4. $C_8H_{12}O_5$ requires C, 50·85; H, 6·4%). The substance remained unchanged in m. p. after recrystallisation from boiling alcohol and produced no depression when mixed with hydroxyterpenylic acid, $C_8H_{12}O_5$, already known as an oxidation product of *d*-limonene (Godlewski, *J. Russ. Chem. Soc.*, 1899, **31**, 211).

As lævulic acid has not been previously mentioned as formed in the oxidation of limonene by permanganate in water, commercial limonene was oxidised as described above, and yielded hydroxyterpenylic and lævulic acids, but no cuminaldehyde or *iso*propenylbenzoic acid.

From the foregoing results it is clear that fraction B of the chenopodium oil hydrocarbons contains, in addition to *p*-cymene, *l*-limonene.

Nature of Terpene A.

As already stated, it has not been possible to isolate this terpene, or to obtain mixtures containing more than 10 to 12% of it as indicated by the amount of tetrabromide obtainable. For evidence of its constitution reliance has therefore had to be placed on (i) reactions of the only crystalline derivative, the tetrabromide, and (ii) the formation of certain substances when mixtures containing it are oxidised.

Oxidation of the Total Hydrocarbon Fraction by Chromic Acid.—The total hydrocarbon fraction of chenopodium oil was oxidised as already described (*loc. cit.*, p. 1717). After separation by steam distillation of the unattacked hydrocarbons (2150 c.c. from 2500 c.c.) there remained in the distillation flask 70 g. (about 1·5%) of a thick

oil, which, after drying, was distilled under reduced pressure, yielding an oil, b. p. 138—154°/19 mm., and a hard, pitch-like residue, which decomposed on further heating. The oil, after standing in solution in ether over potassium carbonate, was redistilled in two fractions, b. p. 110—120°/15 mm. and 120—136°/15 mm. Both were pale yellow, viscous oils having a faint carvone-like odour; they yielded no solid derivatives with phenylcarbimide or *p*-nitrobenzoyl chloride, but on addition of semicarbazide in aqueous acetic acid solution were converted in the course of 3 days into semi-solid masses, which, when rubbed with alcohol, became crystalline, m. p. 140° (air-dry) and 194° when completely dried at 100°; after recrystallisation from boiling alcohol, they melted at 157° (air-dry) or 204° (dried at 120° in a vacuum), and these melting points were unchanged after a further crystallisation from alcohol. The acetic acid of crystallisation (see below) persists when the air-dry substance is crystallised from boiling alcohol, but if the dried substance is recrystallised from alcohol or boiling water the product obtained melts at 204° and is anhydrous. From all solvents the substance forms rosettes of transparent prisms [Found: loss on drying at 120° in a vacuum, 21·2%. $C_{11}H_{19}O_2N_3,C_2H_4O_2$ requires loss (acetic acid), 21·05%. Found in dried material: C, 58·6, 58·7; H, 8·6, 8·4; N, 19·2. $C_{11}H_{19}O_2N_3$ requires C, 58·6; H, 8·5; N, 18·6%]. The substance is therefore a *semicarbazone* of a product, $C_{10}H_{16}O_2$, probably a *keto-alcohol*. When the semicarbazone is formed in presence of alcohol and acetic acid, or when it is repeatedly boiled with water, there is formed a *base* which has only been isolated as the *acetate*, minute rosettes of needles, m. p. 206°, from water by slow evaporation, and the *picrate*, brilliant yellow needles, m. p. 158°, from acetone or acetone and benzene. This differs from the semicarbazone by the elements of a molecule of water [Found (i) in acetate: C, 57·5, 58·2; H, 8·3, 8·1. $C_{11}H_{17}ON_3,C_2H_4O_2$ requires C, 58·05; H, 7·8%. Found (ii) in picrate: N, 18·6. $C_{11}H_{17}ON_3,C_6H_2(NO_2)_3\cdot OH$ requires N, 19·3%].

It is clear from this that the semicarbazone readily undergoes internal condensation, losing a molecule of water, and on this account it is regarded as having the constitution represented by formula (VI), and the base $C_{11}H_{17}ON_3$ formed from it as having formula (VII).

Only part of the oil reacts with semicarbazide solution and after the whole of the semicarbazone has been separated the mother-liquor on dilution with water yields a thick oil, which can be extracted with ether. This could not be induced to crystallise, nor could it be distilled without some decomposition. It appears,

however, to be a derivative of α-terpinene, since on oxidation with aqueous permanganate it gave a good yield of the mixed *anti*- and *para*-forms of αδ-dihydroxy-α-methyl-δ-*iso*propyladipic acid, m. p. 189°, and showed no depression of melting point on addition of a recrystallised mixture in equal parts of these two forms of this acid (J., 1923, **123**, 1878).

In this oxidation by Beckmann's mixture, α-terpinene is converted into dimethylacetonylacetone, the yield being about 3% of the total hydrocarbon fraction taken. The substance was identified by conversion into the semicarbazide derivative, which melted at 201° and showed no depression of melting point when mixed with the semicarbazide derivative prepared from synthetic dimethylacetonylacetone (Found: C, 59·2; H, 8·9; N, 23·05. Calc. for $C_9H_{15}ON_3$: C, 59·7; H, 8·3; N, 23·2%). Some *p*-tolyl methyl ketone was also formed in the oxidation, and was identified by means of its semicarbazone (Found: C, 62·1; H, 6·6. Calc., C, 62·8; H, 6·8%), m. p. 210°, which showed no depression when the substance was mixed with *p*-tolyl methyl ketone semicarbazone. α-Terpinene, *d*-limonene, and *p*-cymene have all been treated separately with Beckmann's mixture, and their oxidation products are being examined, but none of them yields the substance $C_{10}H_{16}O_2$ described above, and it seems safe to assume that this is derived from terpene *A*.

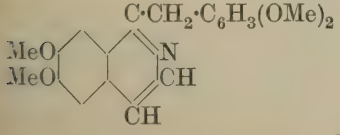
Oxidation of the Total Hydrocarbon Fraction by Permanganate in Acetone.—When the total hydrocarbon fraction is oxidised by permanganate in acetone, the principal products are a mixture of the *para*- and *anti*-forms of αδ-dihydroxy-α-methyl-δ-*iso*propyladipic acids already described by the authors (J., 1923, **123**, 1878) and dimethylacetonylacetone, resulting from the further oxidation of these acids derived from α-terpinene, *p*-tolyl methyl ketone, and a little cuminic acid, both arising from *p*-cymene, and a mixture of optically active oily acids identical with those, described above (p. 1653), derived from *l*-limonene. The only other product was obtained by extracting the concentrated neutral aqueous liquors with ether, which removed a viscous, brown oil too small in amount to permit of direct purification. From this a crystalline semicarbazone was obtained, which on recrystallisation from boiling alcohol formed colourless needles, m. p. 204° (corr.), which became yellow on exposure to light (Found: C, 61·3, 61·5; H, 8·7, 8·15; N, 21·3. $C_{10}H_{17}ON_3$ requires C, 61·5; H, 8·7; N, 21·5%). On hydrolysis, the semicarbazone furnishes an oil smelling like a mixture of menthone and cuminaldehyde, and from this oil the semicarbazone cannot be regenerated. This semicarbazone is optically inactive, and, if it comes from terpene *A*, should be

that of Δ^2-tetrahydro-*p*-tolyl methyl ketone, $C_9H_{14}O$ (VIII), but as the yield of semicarbazone obtained only amounts to 0·24% of the total hydrocarbon fraction used, it has not been possible to accumulate enough for examination in detail.

Tetrabromide of Terpene A.—The preparation and isolation of the tetrabromide has been described already (*loc. cit.*, p. 1717). Of numerous attempts to use this tetrabromide as a means of gaining information regarding the constitution of terpene *A*, only the following have given useful results. 12·5 G. of the tetrabromide were added to a solution of 1·9 g. of sodium in methyl alcohol, and the mixture, after boiling for 7 hours, was steam-distilled, when 4·4 g. of a heavy, colourless oil were obtained, b. p. 115—120°/18 mm., containing 30·2% of bromine ($C_{10}H_{14}Br{\cdot}OMe$ requires Br, 32·6%). This appeared to be a monobromomethyl ether corresponding to the monobromomethyl ether which Wallach obtained from limonene tetrabromide (*Annalen*, 1894, **281**, 127). The removal of the fourth bromine atom by the further use of sodium converted the monobromomethyl ether almost wholly into *p*-cymene. Unlike Wallach's product, it did not after reduction yield a menthenone by oxidation with either chromic acid or permanganate. It was only slowly attacked by either agent, and the products in both cases were *p*-tolyl methyl ketone with a little *p*-toluic acid. In further experiments, silver acetate was used: 5·3 g. of the tetrabromide were shaken with 5·8 g. of silver acetate in 10 c.c. of acetic acid during 8 hours, then made alkaline with sodium carbonate, and shaken with ether, which removed a yellow, viscous oil (3·1 g.). This on solution in light petroleum (b. p. 40—60°) deposited some insoluble tar, and the oil thus purified, after drying over potassium carbonate and removal of the petroleum by distillation and exposure in a vacuum until of constant weight, gave the following results: C, 52·8; H, 6·1; Br, 29·2 ($C_{10}H_{14}Br{\cdot}O{\cdot}CO{\cdot}CH_3$ requires C, 52·6; H, 6·2; Br, 29·3%). The substance is therefore a *bromoacetoxydihydro*-p-*cymene* (II) and this was confirmed by hydrolysing a weighed quantity (0·2175 g.) of the substance in the cold with a known amount of potassium hydroxide in alcohol (30·6 c.c. of *N*/10-KHO), the mixture being allowed to stand for a week, after which the excess of alkali (16·42 c.c. of *N*/10-KHO) was determined by titration with standard nitric acid. The amount of alkali used (14·2 c.c of *N*/10-KHO), after correction for a small amount of bromide (equal to 0·0478 g. Br) formed, was 21·1%, whilst that required for the removal of one acetyl group from $C_{10}H_{14}Br{\cdot}O{\cdot}CO{\cdot}CH_3$ is 20·5%.

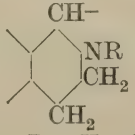
Seven g. of the bromoacetoxy-compound were agitated with 30 c.c. of water to form an emulsion; to this 130 c.c. of Beckmann's

chromic acid mixture were added in three portions at intervals of 1 hour, and the whole was shaken for 8 hours. This was extracted with (1) light petroleum, b. p. 40—60°, and (2) ether, and the extracts were dried over anhydrous sodium sulphate. The petroleum extract (1) left an oily residue (2·9 g.) which was pungent, and had an odour of *p*-tolyl methyl ketone; on treatment with semicarbazide it yielded a semicarbazone which after crystallising twice from boiling alcohol formed colourless, opaque prisms melting constantly at 210° and showing a slight rise in melting point to 211° when mixed with an equal quantity of *p*-tolyl methyl ketone semicarbazone prepared from synthetic material. The mother-liquor from the preparation of the semicarbazone was made alkaline with sodium carbonate and shaken with light petroleum, when it yielded 1·7 g. of an oil containing bromine and apparently consisting largely of unchanged material. The ether extract (2) yielded on re-extraction with sodium carbonate solution and acidification of this (*a*) terephthalic acid, colourless crystals, subliming without melting above 280°, and (*b*) *p*-toluic acid, m. p. 177°, showing no depression when mixed with a pure specimen of *p*-toluic acid.



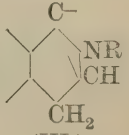
The authors desire to express their cordial thanks to Mr. F. Walton and Mr. S. E. Pusey for much assistance in the experimental work.

WELLCOME CHEMICAL RESEARCH LABORATORIES,
LONDON. [*Received, May 13th*, 1925.]



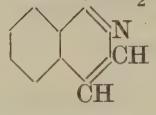
CCXX.—iso*Quinoline Derivatives. Part IX. Preparation and Reduction of* iso*Quinoline and its Derivatives.*

By ROBERT FORSYTH, CHARLES IGNATIUS KELLY, and FRANK LEE PYMAN.

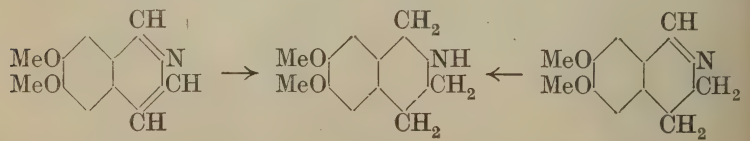


THE reduction of papaverine (I) and *N*-methylpapaverinium salts by means of tin and hydrochloric acid yields not only the expected tetrahydro-derivatives (II), but also, as by-products, the 2 : 4-dihydro-derivatives, pavine and *N*-methylpavine, containing the unique dicyclic system (III) (Pyman, J., 1915, **107**, 176, where earlier references are given). The present inquiry had the object

(I.)



(II.) (R = H or Me)



(III.)

of determining whether the formation of by-products of this type on the reduction of *iso*quinoline, by means of tin and hydrochloric acid, is a general property or not, and necessitated a quantitative study of the reduction of pure materials, for the quantities of these by-products to be expected were only small. Thus, the yields of pavine isolated by different investigators range from 8 to about 25% (Pope and Gibson, J., 1910, **97**, 2207), whilst the yield of *N*-methylpavine was 3% of the theoretical.

The reduction of *iso*quinoline itself was first examined, for uncharacterised by-products of its reduction to tetrahydro*iso*quinoline have been noticed by former investigators, and it was uncertain whether these were of the pavine type or due to impurities in the initial material. Experiments showed that pure *iso*quinoline can be reduced to tetrahydro*iso*quinoline in nearly theoretical (96%) yield. The effect of a 1-benzyl group was next studied, and here 1-benzyl*iso*quinoline methiodide gave 1-benzyl-2-methyltetrahydro*iso*quinoline in a yield of 85% of the theoretical, unaccompanied by any other organic base, the deficit being due to partial decomposition of the material with the formation of ammonia. Similarly, the only product isolated after reduction of 1-benzyl-*iso*quinoline (IV) was 1-*benzyl*-1 : 2 : 3 : 4-*tetrahydro*iso*quinoline* (V). The constitution of this substance was proved by its conversion into 1-benzyl-2-methyltetrahydro*iso*quinoline on methylation.

(IV.)  (V.)

The effect of methoxy-substituents in the *iso*quinoline nucleus was next examined, and here also a negative result was obtained, for 6 : 7-dimethoxy*iso*quinoline (VI) gave 6 : 7-*dimethoxy*-1 : 2 : 3 : 4-*tetrahydro*iso*quinoline* (VII) in a yield of 94% of the theoretical. The identity of the product was established by comparison with the product of reduction of 6 : 7-dimethoxy-3 : 4-dihydro*iso*quinoline (VIII) (Pyman, J., 1909, **95**, 1610). Similarly, the reduction of 6 : 7-*dimethoxy*iso*quinoline methiodide* gave as the sole isolable product 6 : 7-dimethoxy-2-methyltetrahydro*iso*quinoline (Pyman, J., 1909, **95**, 1266).

(VI.) (VII.) (VIII.)

It has thus been shown that neither a 1-benzyl nor 6 : 7-dimethoxy-groups suffice to induce formation of compounds of the pavine type on the reduction of derivatives of *iso*quinoline, and the further investigation of this problem, which is contemplated, will necessitate the preparation and reduction of 1-benzyl-6 : 7-dimethoxy*iso*-quinoline and possibly also of 1-veratryl*iso*quinoline.

Of the *iso*quinoline derivatives required for this work, a part of the *iso*quinoline itself was isolated from coal tar by fractionation and crystallisation of the acid sulphate as described below, the yield being better than that obtained by Harris and Pope (J., 1922, **121**, 1029), using another method. Several methods for the preparation of 1-benzyl*iso*quinoline were examined, and of these the only satisfactory one was that of Decker and Pschorr (*Ber.*, 1904, **37**, 3397) by the action of benzyl magnesium chloride on *N*-methyl*iso*quinolone and distillation of the 1-benzyl*iso*quinoline methiodide produced. The oxidation of 1-benzyl-3 : 4-dihydro-*iso*quinoline (Pictet and Kay, *Ber.*, 1909, **42**, 1973) gave only 3% of 1-benzyl*iso*quinoline, and the dehydration of α-hydroxy-β-phenyl-acetylamino-α-phenylethane (A) by phosphorus pentoxide gave only 4% of 1-benzyl*iso*quinoline. This last result is in accord with the work of Robinson (J., 1909, **95**, 2167), who obtained only a trace of a picrate, suspected of being 1-benzyl*iso*quinoline picrate, in this way, and is at variance with the results of Pictet and Gams (*Ber.*, 1910, **43**, 2386), who obtained a 40% yield. The latter authors, like Robinson, prepared the carbinol (A) by the reduction of ω-phenylacetylaminoacetophenone, but found it to melt at 123°, whereas Robinson found the m. p. 99°. Here, again, our results confirm those of Robinson, the carbinol (A) proving to melt at 99° whether prepared by Robinson's method or by the action of phenyl-acetyl chloride upon β-hydroxy-β-phenylethylamine.

The preparation of 6 : 7-dimethoxy*iso*quinoline was effected essentially by the method of Rügheimer and Schön (*Ber.*, 1909, **42**, 2374), that is, by the action of sulphuric and arsenic acids upon veratrylaminoacetal, but the technique has been improved. Veratrylaminoacetal was prepared by the reduction of *veratrylidene-aminoacetal*, a more convenient method than the action of chloro-acetal upon veratrylamine, the method of the previous authors (*Ber.*, 1908, **41**, 17).

Experimental.

Preparation of iso*Quinoline.*—Three gallons of "crude pyridine bases" (corresponding to 6 tons of coal tar) were dehydrated by shaking three times with aqueous sodium hydroxide (80° Tw.), and the product (10·85 litres) was distilled up to 170° and then fractionated through a 12-pear column. The various fractions,

b. p. 200—280°, were fractionated similarly twice more, when 2·3 litres (2470 g.) of "heavy quinoline bases," b. p. 230—255°, were obtained. This fraction was converted into acid sulphate, and crystallised fractionally from alcohol, when 185 g. of pure *iso*quinoline hydrogen sulphate, m. p. 207·5° (corr.), were obtained. This gave 102 g. of the base, b. p. 242° (corr.) over a range of 0·5°; m. p. 24° (corr.). The yield of *iso*quinoline from the "heavy quinoline bases" is thus about 4%, whereas Harris and Pope (who refer to previous work on the subject, J., 1922, **121**, 1029) obtained only 1·5% by a more laborious method.

Reduction of iso*Quinoline.*—*iso*Quinoline (6·45 g.), alcohol (68 c.c.), hydrochloric acid (100 c.c. conc.), and granulated tin (42 g.) were heated on the water-bath under reflux for 12 hours. After cooling, the separated tin salts were collected (mother-liquor M) and deprived of tin by means of hydrogen sulphide, when, on evaporation, crude tetrahydro*iso*quinoline hydrochloride (8·0 g.; m. p. 195°) was obtained. It was mixed with aqueous sodium hydroxide and distilled into hydrochloric acid, and the distillate gave, on evaporation, pure tetrahydro*iso*quinoline hydrochloride (7·83 g.; m. p. 196—197°. Hoogewerf and van Dorp, *Rec. trav. chim.*, 1885, **4**, 125, give m. p. 195—197°). The residue from the steam-distillation was extracted with chloroform, which removed a base giving a crystalline hydrochloride, the total residue as hydrochloride, m. p. 280—290°, amounting to only 0·05 g. The mother-liquor M gave, after removal of tin, crude tetrahydro*iso*quinoline hydrochloride (0·3 g.; m. p. 190°; m. p. of mixture with the pure salt, 192°). The total yield of tetrahydro*iso*quinoline is thus 96·35% of the theoretical. To establish its purity, 8·0 g. were mixed with carbon disulphide in dry ether, and the precipitated tetrahydro*iso*quinoline tetrahydro*iso*quinolyldithiocarbamate (Bamberger and Dieckmann, *Ber.*, 1893, **26**, 1208) was decomposed with hydrochloric acid, when 7·86 g. of tetrahydro*iso*quinoline hydrochloride of unchanged m. p. were recovered.

1-*Benzyl*iso*quinoline.*—*A.* After Decker and Pschorr (*Ber.*, 1904, **37**, 3397). Five g. of 1-benzyl*iso*quinoline methiodide (from *N*-methyl*iso*quinolone and benzyl magnesium chloride; yield 36% of pure salt, m. p. 248° [corr.]) were heated under 20—30 mm. until all methyl iodide was removed; the residue then distilled at 222° (corr.)/18 mm. Decker and Pschorr give 211—213°/11 mm. The distillate, which crystallised and melted at 55—56° (corr.), was converted into the hydrochloride, and more of this salt was recovered from the distillation residue (yield 3·5 g. = 86%). This salt crystallises from water in colourless, elongated prisms, which contain $2H_2O$ and melt below 100°, but after drying first in a vacuum

and then at 100°, the substance melts at 185—187° (corr.). Decker and Pschorr give m. p. 171—172°; Pictet and Gams, 175° (Found: H_2O, 12·0. Calc. for $2H_2O$, 12·4%. Found, in dried salt: Cl, 13·9. Calc., Cl, 13·9%). The picrate melted at 184° (corr.). Decker and Pschorr give 184—185° (corr.).

B. After Pictet and Kay (*Ber.*, 1909, **42**, 1973). To 1-benzyl-3 : 4-dihydro*iso*quinoline (2 g.; b. p. 196—197°/12 mm.) in glacial acetic acid (100 c.c.) at 100°, potassium permanganate (1 g.) in water (200 c.c.) was added with shaking in 1½ hours, and the mixture was heated for another hour. After basifying, ether removed an oil (0·8 g.) which was converted into the picrate and crystallised fractionally from alcohol, when 0·11 g. of the nearly pure salt was obtained (yield 3%; m. p. 181—182° [corr.]; not depressed after mixture with an authentic specimen). Numerous attempts to improve upon this yield by varying the conditions were unsuccessful. Pictet and Kay do not state their yield, but indicate that it was poor.

C. After Robinson (J., 1909, **95**, 2167) and Pictet and Gams (*Ber.*, 1910, **43**, 2386). ω-Phenylacetylaminoacetophenone (from phenylacetyl chloride, ω-aminoacetophenone hydrochloride, and sodium hydroxide; yield 50%; m. p. 103°) was reduced by Robinson's method and gave α-hydroxy-β-phenylacetylamino-α-phenylethane (yield 73%; m. p. 99° as stated by Robinson). On attempting the reduction under the conditions employed by Pictet and Gams, a poor yield of a crude product, m. p. 73°, was obtained. α-Hydroxy-β-phenylacetylamino-α-phenylethane was also prepared by mixing 2 g. of β-hydroxy-β-phenylethylamine carbonate (Wolfheim, *Ber.*, 1914, **47**, 1440) with phenylacetyl chloride (2·5 g.) and 20% aqueous sodium hydroxide (15 c.c.), and after purification melted at 99°, alone or mixed with the substance made by Robinson's method.

α-Hydroxy-β-phenylacetylamino-α-phenylethane (40 g.; m. p. 99°) in xylene (200 c.c.) was dehydrated by phosphorus pentoxide (200 g.), and the basic products were collected as described by Pictet and Gams, and converted into the hydrochloride, when 1-benzyl*iso*quinoline hydrochloride (1·8 g.; m. p. [dry] 185°; yield 3·9%) was obtained. A specimen of the picrate prepared from this salt had m. p. 184° (corr.), alone or mixed with an authentic specimen.

Reduction of 1-*Benzyl*iso*quinoline.*—1-Benzyl*iso*quinoline hydrochloride (4·0 g.; air-dried), alcohol (20 c.c.), concentrated hydrochloric acid (20 + 10 c.c.) * and tin-foil (10 + 2·5 g.) were digested

* In this and the following reductions additional quantities of hydrochloric acid and tin were added after some hours.

for 21 hours on the water-bath. Water was added, tin removed, and the solution concentrated and mixed with sodium iodide, when pure 1-benzyl-1 : 2 : 3 : 4-tetrahydro*iso*quinoline hydriodide (3·75 g.; anhydrous, m. p. 167—168°) separated. The filtrate was mixed with sodium hydroxide and extracted with ether, 0·2 g. of brown oil being obtained. This was not wholly basic, but gave a turbid solution with hydrochloric acid. After filtration through charcoal and addition of sodium iodide, 0·22 g. of the above iodide, m. p. (crude) 145—155° (not depressed by mixture with the pure salt), was deposited, which after crystallisation from water gave 0·15 g., m. p. 162—165°. The total yield is thus 81% of the theoretical.

1-*Benzyl*-1 : 2 : 3 : 4-*tetrahydro*iso*quinoline hydriodide*, colourless well-formed prisms from water, has m. p. (substance dried at 100°) 167—168·5° (corr.). It is sparingly soluble in cold water (Found : loss at 100°, 5·0. $C_{16}H_{17}N,HI,H_2O$ requires H_2O, 4·9%. Found, in dried salt : C, 54·8; H, 5·1; I, 36·3. $C_{16}H_{17}N,HI$ requires C, 54·7; H, 5·1; I, 36·2%). The *base* (V) was a colourless, viscous oil, which did not crystallise after keeping for 2 days over sulphuric acid in a vacuum. The *picrate* crystallised from alcohol in deep yellow, prismatic needles, m. p. 166—167° (corr.) after drying at 100°.

Methylation.—1-Benzyltetrahydro*iso*quinoline and methyl iodide were heated for a few minutes under reflux, and after removal of uncombined methyl iodide a gummy product remained, doubtless a mixture of the hydriodides of the secondary and tertiary bases with the methiodide of the latter. The bases regenerated from this by means of sodium hydroxide and ether were crystallised fractionally as picrates, when 1-benzyl-2-methyltetrahydro*iso*quinoline picrate separated first. It had m. p. 165—166° (corr.), alone or mixed with a specimen prepared by the reduction of 1-benzyl*iso*quinoline methiodide, and the hydriodides from the two sources also proved to be identical.

Reduction of 1-*Benzyl*iso*quinoline Methiodide.*—The pure methiodide (10 g.; m. p. 248° [corr.]), alcohol (40 c.c.), hydrochloric acid (40 + 20 c.c. conc.), and tin-foil (20 + 5 g.) were heated on a water-bath under reflux for 24 hours. After distilling the alcohol, water was added, when the bulk of the organic tin salts were deposited (mother-liquor L). The gummy deposit was dissolved in water, and deprived of tin by means of hydrogen sulphide. The filtrate was evaporated under diminished pressure to remove excess of hydrochloric acid, and the residue was dissolved in water and mixed with sodium iodide, when pure 1-benzyl-2-methyl-1 : 2 : 3 : 4-tetrahydro*iso*quinoline hydriodide (8·33 g.) was deposited. Before

and after crystallisation from alcohol, it melted at 174—175° (corr.), separating from alcohol in prismatic columns as stated by Freund and Bode (*Ber.*, 1909, **42**, 1746), who give m. p. 175—180°. The picrate crystallised from alcohol in rhombic tablets, m. p. 165—166° (corr.), as stated by these authors. The mother-liquor L was deprived of tin, mixed with the filtrate from the above hydriodide, basified with sodium hydroxide, and extracted with ether, which removed an oily base (0·35 g.). This was converted into the hydriodide (0·4 g.; m. p. 166—170°) and crystallised from alcohol, when 0·25 g. of the pure salt was obtained. The total yield of the pure salt is thus 86% of the theoretical. The liquor from which the base was extracted contained ammonia. A similar result was obtained on repetition of this experiment, an 84% yield of the pure hydriodide being obtained.

6 : 7-*Dimethoxy*iso*quinoline*.—Veratraldehyde (52·4 g.) and aminoacetal (42 g.) were heated for several hours on the water-bath, until the water, which soon separated, had evaporated. The crude product, obtained in theoretical yield, had m. p. 53—58°, and after crystallisation from ether gave *veratrylideneaminoacetal* in nearly colourless, very pale yellow, well-formed plates, m p. 61—62° (corr.) (Found: C, 64·1; H, 8·3. $C_{15}H_{23}O_4N$ requires C, 64·0; H, 8·2%).

Crude veratrylideneaminoacetal (50 g.) in absolute alcohol * (0·5 litre) was reduced by the gradual addition of sodium (50 g.) and more alcohol. After water had been added, ether collected nearly pure veratrylaminoacetal, which, after removal of solvents at 100°/15 mm., amounted to 45 g. and was suitable for use in the next operation without distillation.

Veratrylaminoacetal has b. p. 208° (corr.)/15 mm. (Found: C, 63·4; H, 8·8. $C_{15}H_{25}O_4N$ requires C, 63·6; H, 8·8%). Rügheimer and Schön (*Ber.*, 1909, **42**, 2374), who did not analyse the compound, give b. p. 197°/11 mm.

Arsenic pentoxide (5 g.) was dissolved in warm water (1 c.c.), concentrated sulphuric acid (10 c.c.) added, and the whole cooled in a freezing mixture. Crude veratrylaminoacetal (5 g.) was run in a few drops at a time with thorough rubbing to dissolve the viscous product. A homogeneous solution was obtained in about ¼ hour, and was kept for 1 hour at the ordinary temperature, and then heated for 1 hour at 100°. The products from 10 such experiments were diluted with water (100 c.c.) and mixed with sufficient 20% aqueous sodium hydroxide to neutralise the bulk of the acid. After cooling, an amorphous precipitate was removed by filtration,

* Fusel oil (at 130°) cannot be substituted for absolute alcohol in this case.

and the liquor basified with sodium hydroxide and extracted with chloroform. (Distressing emulsions are obtained if the removal of the amorphous precipitate is omitted.) The chloroform residue was mixed with hydrochloric acid, the solution evaporated to dryness, and the residual hydrochloride crystallised several times from alcohol. From the final mother-liquors, the base was regenerated by sodium hydroxide, and extracted with chloroform. The chloroform residue was extracted twice with hot ether, and the extract converted into hydrochloride and crystallised from alcohol. In this way, veratrylaminoacetal (50 g.) gave 8·5 g. of pure 6 : 7-dimethoxy*iso*quinoline hydrochloride (dried at 100°), that is 21% of the theoretical. Rügheimer and Schön describe the yield as "satisfactory." This salt crystallises from alcohol in nearly colourless needles, containing $3H_2O$, which are lost at 100°; when anhydrous, it melts and effervesces at 221° (corr.). Rügheimer and Schön give 208—210° (decomp.). The base separated from ether in large prisms, m. p. 93° (corr.); Rügheimer and Schön give 93—94°.

6 : 7-*Dimethoxy*iso*quinoline methiodide* is formed when the base is mixed with methyl iodide. It is sparingly soluble even in hot alcohol, from which it separates on cooling in pale buff, glistening, anhydrous needles, m. p. *ca.* 256° (decomp.; corr.) (Found : I, 38·3. $C_{12}H_{14}O_2NI$ requires I, 38·4%).

Reduction of 6 : 7-*Dimethoxy*iso*quinoline*.—The pure base (4·8 g., m. p. 93°), alcohol (20 + 5 c.c.), concentrated hydrochloric acid (20 + 20 c.c.), and tin-foil (20 g.) were digested for 30 hours on the water-bath. The product was dissolved in hot water (0·7 litre) and freed from tin by hydrogen sulphide; on concentration, 5·22 g. of pure 6 : 7-dimethoxytetrahydro*iso*quinoline hydrochloride were obtained (in three crops). The mother-liquor was evaporated to dryness and mixed with alcohol, when 0·2 g. of the same salt, m. p. 260° after sintering from 256°, separated; the mother-liquor from this, when evaporated to dryness and mixed with absolute alcohol, deposited a further 0·05 g. (m. p. 242—245°; mixed with the pure salt, m. p. 252—258°). The total yield (5·47 g.) amounts to 94% of the theoretical. The final mother-liquor gave on evaporation to dryness a gummy residue (0·11 g.), from which no crystalline base or salt could be obtained.

6 : 7-*Dimethoxy*-1 : 2 : 3 : 4-*tetrahydro*iso*quinoline hydrochloride* crystallises from water in colourless quadrilateral plates, m. p. 262° (corr.). It is readily soluble in cold water, and very readily soluble in hot water, but sparingly soluble in cold alcohol (Found : C, 57·8; H, 7·2. $C_{11}H_{15}O_2N,HCl$ requires C, 57·5; H, 7·0%). The *picrate* crystallised from alcohol in broad, yellow needles, m. p. 202—203°

(corr.). The *base* (VII) crystallised from chloroform in colourless plates, which were easily soluble in chloroform, but sparingly soluble in ether. It readily takes up carbon dioxide from the air, and was not obtained free from carbonate (m. p. 80—130°).

6 : 7-Dimethoxytetrahydro*iso*quinoline was also obtained by the reduction of 6 : 7-dimethoxy-3 : 4-dihydro*iso*quinoline with tin and alcoholic hydrochloric acid. The hydrochloride and picrate from this source had the m. p.'s recorded above, alone or mixed with the corresponding salts from the reduction of 6 : 7-dimethoxy*iso*quinoline.

Reduction of 6 : 7-*Dimethoxy*isoquinoline *Methiodide*.—The pure methiodide (10 g.), alcohol (40 c.c.), concentrated hydrochloric acid (40 + 20 c.c.), and tin-foil (20 + 5 g.) were digested for 18 hours on the water-bath, and the product was deprived of tin by means of hydrogen sulphide. The residue remaining after evaporation of the water was dissolved in water and mixed with picric acid (7 g.) in hot water (300 c.c.), when, on cooling, 10·45 g. of 6 : 7-dimethoxy-2-methyl-1 : 2 : 3 : 4-tetrahydro*iso*quinoline picrate, m. p. 158° (corr.), separated. The base (0·25 g.) regenerated from the mother-liquors was converted into picrate and gave 0·35 g. of the above salt, m. p. 152—153°. The total yield is thus 82% of the theoretical. The identity of the salt, for which Pyman (*loc. cit.*) gives m. p. 159—160° (corr.), was confirmed by the preparation from it of the hydrochloride, m. p. (dry) 217—218° (corr.), and base, m. p. 83—84° (corr.) (Pyman gives m. p. 216—217° [corr.] and 83—84° [corr.] respectively), and by comparison of the latter with an authentic specimen prepared by the reduction of 6 : 7-dimethoxy-3 : 4-dihydro*iso*quinoline methiodide (mixed m. p. 83—84° [corr.]).

We desire to thank (1) the Council of the Lord Kitchener National Memorial Fund for the grant of a scholarship which has enabled one of us (C. I. K.) to take part in the investigation, (2) Messrs. Brotherton and Co., Ltd., tar distillers, Leeds, for raw materials and facilities for the isolation of *iso*quinoline, (3) Professor R. Robinson, F.R.S., and Mr. H. S. Land, B.Sc.Tech., for gifts of *iso*quinoline, and (4) the Wellcome Chemical Research Laboratories for a specimen of 6 : 7-dimethoxy-3 : 4-dihydro*iso*quinoline.

CCXXI.—*The Surface Tensions of Aqueous Phenol Solutions. Part II. Activity and Surface Tension.*

By Arthur Kenneth Goard and Eric Keightley Rideal.

The equation of Gibbs determining the surface adsorption of substances in solution ("Equilibrium in Heterogeneous Systems," Scientific Papers, Vol. II) should strictly be written in the form $\Gamma = -d\sigma/d\mu$, where σ = surface tension and $\mu = \mu_0 + RT \log_e a$. Γ is here the excess concentration (positive or negative) of the solute at the surface and a is the mean activity of the solute (compare Lewis and Randall, "Thermodynamics," New York, 1923).

Very little attempt has been made hitherto to apply this equation to actual cases, most workers having dealt with systems in which the activity can be equated approximately to the bulk concentration of the solute. Since it is frequently just in concentrated solutions, where this equality fails to hold, that adsorption phenomena become important, it is highly desirable that the strict form of the Gibbs equation should be more widely adopted. As a simple example of the use of activities, we may take the case of a binary liquid mixture at its critical solution temperature, where a small change in the relative proportions of the components does not affect the surface tension, regardless of the amount of surface adsorption (Lewis and Randall, *op. cit.*, Chap. XXI, Exercise 7). It further follows that in the region of this critical point, unless the adsorption exhibit very sudden and violent changes, the surface tension is largely independent of the relative concentrations of the two components. In Part I of this investigation it was shown that the difference between the surface tensions of the two liquid phases formed by phenol and water was only 0·33 dyne/cm. at 0°, and that this difference diminished continuously up to the critical solution temperature. The surface tensions of the two phases are thus remarkably similar, despite large differences of composition. A generalisation of this kind was stated empirically by Antonov in 1907 (*J. Chim. Phys.*, 1907, **5**, 364); it is now seen to be the natural result of the activity relations displayed by two liquids in the "critical zone."

As an example of the opposite kind, in which the activity of a solute may undergo great alteration without any change of concentration, we may take the "salting out" of organic substances from aqueous solutions by the addition of inorganic salts, *e.g.*, that of phenol by sodium chloride. Various experimenters have shown that the toxicity of phenol in aqueous solution is increased by the addition of salt; their results have been summarised by Lash Miller (*J. Physical Chem.*, 1920, **24**, 562). Berczeller (*Biochem. Z.*,

1914, **66**, 173, 191, 202) showed that this increase was accompanied by a lowering of the surface tension. Miller (*loc. cit.*) suggested that both these phenomena are due to an increase in the chemical potential of the phenol; and Lemon (*J. Physical Chem.*, 1920, **24**, 570) and Laird (*ibid.*, p. 664) showed that approximately the same toxic power was exhibited by all " equivalent " phenol solutions—*i.e.*, solutions of phenol in water containing different amounts of salt, but all in equilibrium with the same solution of phenol in some immiscible solvent (*e.g.*, kerosene).

A more precise investigation of the relation between the surface tensions and activities of such solutions being desirable, the system phenol–sodium chloride–water was chosen for this purpose. To determine the phenol activity in aqueous solutions containing salt, analysis of the vapour proved inadequate, the partial pressure of the phenol being too small to allow of accurate measurement, and a partition method in which amyl alcohol was used as the second solvent failed because the distribution of amyl alcohol itself was affected by the presence of salt. Paraffin oil, however, being nearly insoluble in water, was practically free from this disadvantage.

The concentration of phenol in paraffin in equilibrium with a saturated aqueous solution of the former is small (about 0·2 mole/litre). Unfortunately, from zero concentration up to fifth molar, the activity of phenol in paraffin is not directly proportional to the concentration (see Table I); otherwise, its determination would be very simple. Since phenol associates in water, the curve relating its activity in water to its concentration therein must be *concave* towards the concentration axis (*i.e.*, the activity increases more slowly than the concentration). The experimental curve relating the concentrations of phenol in paraffin in equilibrium to the corresponding concentrations in water was, however, *convex* towards the latter axis, showing, as might indeed have been anticipated, that phenol associates more rapidly in paraffin than in water.

An independent method of determining the phenol activity is therefore necessary in order that the concentrations of phenol in paraffin may be referred to the true activities of the former. From data supplied by Peddle and Turner (J., 1911, **99**, 691), it is possible to calculate the approximate activity of phenol in salt-free solution, up to 0·55*M*, if the effect due to heat of dilution be neglected. By referring these to the values in Table I, using a rough extrapolation to cover the higher phenol activities, we were able to draw a set of curves giving the relation between the concentration of phenol in the aqueous phase and the phenol activity. These curves were now initially concave towards the concentration axis.

Beyond a certain point, however, which corresponded to a 0·4*M*-

solution of phenol in pure water, the curves were inflected, becoming convex. This inflection was undoubtedly due to insufficient correction of the original data; at higher concentrations the effect of heat of dilution probably becomes of importance. Analysis of the freezing-point data by Lewis and Randall's method (constancy of j/m) also indicated that errors in the activity values might be expected to become considerable at concentrations much beyond the above. In particular, the graphical extrapolation necessary over the regions of higher activity is very sensitive to error.

It was decided, therefore, to assume that the activities, as calculated by the freezing-point method, were sensibly correct up to a value of about 0·3 (*i.e.*, that corresponding to a 0·4M-solution of phenol in pure water). Beyond this, the relation between activity and concentration was assumed to be expressed by a graphical extrapolation of each curve, preserving throughout the extrapolated region the curvature of its earlier portion. This procedure was in some measure justified (*a*) by the fact that for the curves relating to the higher salt concentrations the extrapolation was nearly linear, and (*b*) by the observation that if the corrected activities, as obtained separately from each of the curves, were all referred to a common diagram expressing the relation between phenol activity and concentration in paraffin solution, a set of points was obtained which lay, with very small deviations, on a single curve.

Finally, therefore, a smooth curve was drawn through these points, relating the concentration of phenol in paraffin to its corrected activity; and from this curve the values given in column IV of Table I were obtained. The results are shown in Fig. 1; curves I—VI give the activities of phenol in aqueous solutions containing 0, 5, 10, 15, 20, and 25 g. of sodium chloride per 100 c.c. of solution respectively. The nature of the second, graphical, correction of activities is shown in curve V, where the dotted curve indicates the inflection obtained at higher concentrations, using the extrapolation from the freezing-point data of Peddle and Turner.

The experimental procedure adopted to determine the partition of the phenol was as follows: 20 c.c. Portions of a phenol solution of known concentration were placed with 20 c.c. of paraffin oil in glass-stoppered bottles, to which weighed amounts of salt had been added, immersed in a thermostat at 20°. The mixtures were shaken vigorously and repeatedly for some hours, and 10 c.c. of the lower, aqueous, layer were then removed and the phenol content was estimated by Koppeschaar's method, using a standard solution of potassium bromate and bromide. The phenol content of the paraffin phase was estimated by difference, save in the case of those solutions which comprised *three-phase* mixtures: water + phenol +

salt, a phenol-rich phase, and phenol + paraffin. Of these mixtures, which are marked " saturated " in Table I, the aqueous phase was estimated as before; 10 c.c. of the paraffin phase were then removed, and shaken with an equal volume of water. From the amount of phenol passing into the water, it was possible, by means of previous measurements of the partition of phenol in the absence of salt, to estimate the amount of phenol present in the paraffin phase of the original mixture.

TABLE I.

Column I gives the concentration of sodium chloride in moles/litre; column I*a*, the salt concentration in g./100 c.c. of solution.

The Surface Tensions of Aqueous Phenol, and Phenol–Salt, Solutions.

In these experiments the phenol content was estimated by titration, and the surface tensions were determined by the drop-weight method, using the apparatus previously described (Goard and Rideal, this vol., p. 780). The densities of the solutions of sodium chloride were taken from Kohlrausch, the difference of density (which is small) due to the phenol being taken as directly proportional to the phenol concentration.

All measurements were made at 20°. The weight of ten drops

was ascertained, the mean weights given below being calculated from several closely concordant determinations.

Table II.

The first column gives the salt concentration in moles/litre, the second column the concentration in g./100 c.c. of solution.

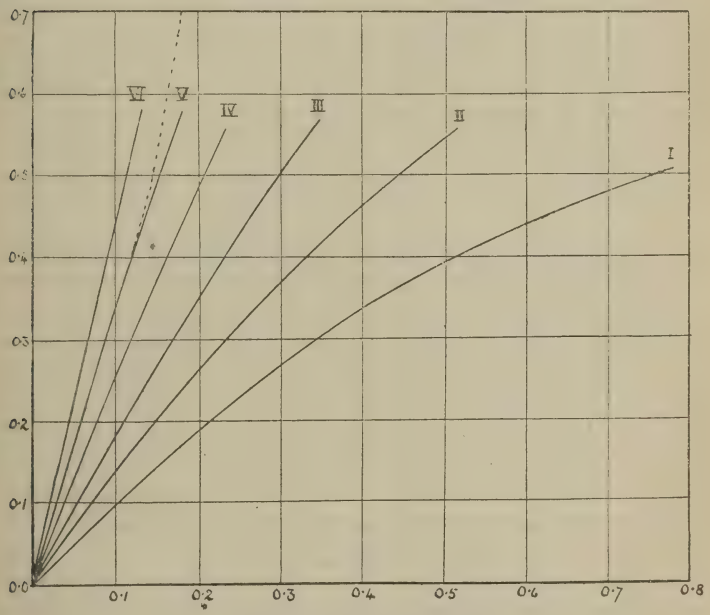
2·22	13		0·5121	1·086	41·59

In Fig. 2, the surface tensions of phenol solutions containing different amounts of salt (obtained by graphical means from Table II) are shown plotted against the logarithm of the corresponding phenol activities. Curves I—VI represent solutions containing 0, 5, 10 . . . 25 g. of salt per 100 c.c., respectively (corresponding thus to curves I—VI in Fig. I).



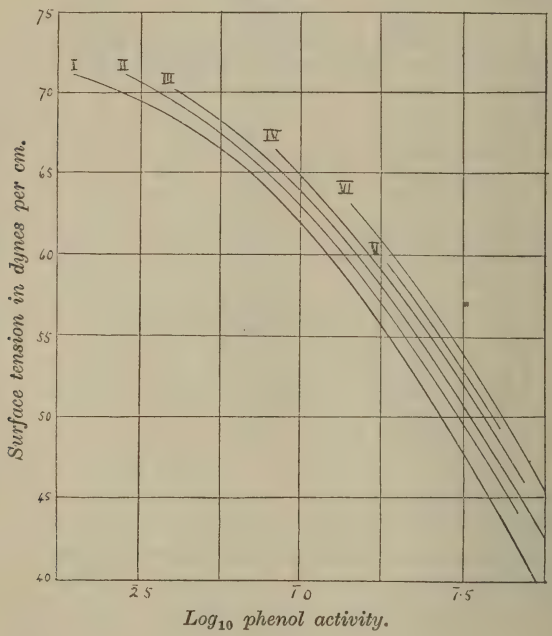
Considering first curve I, it will be observed that, as the activity of the phenol increases, the slope of the curve also increases, at first rapidly, then much more slowly, up to the point of saturation. The whole curve, in fact, strongly resembles those reproduced by Harkins for aqueous solutions of the lower fatty acids ("Surface Energy in Colloidal Systems," Chap. VI, Vol. I of "Colloidal Behaviour." Bogue, New York, 1924).

The maximum value of the adsorption, Γ, found by drawing a tangent to the curve at its steepest point, and taking the mean of several such determinations, is $69{\cdot}2 \pm 1 \times 10^{-11}$ g.-mol. per sq. cm. If we follow Langmuir (*J. Amer. Chem. Soc.*, 1917, **39**, 1848) in assuming that the surface layer is comprised in a unimolecular film, the area, A, occupied by a single molecule at the surface is

given by $A = 1/\Gamma N$, whence $A = 23{\cdot}8 \pm 0{\cdot}5 \times 10^{-16}$ sq. cm. The value found by Adam (*Proc. Roy. Soc.*, 1923, *A*, **103**, 676) in the cases of *p*-hexadecyl- and *p*-octadecyl-phenol was also 23·8 Å.U. This, he considers, represents the area of cross-section of the benzene nucleus. The agreement here can scarcely be accidental; it indicates that the molecules of ordinary phenol form a unimolecular film at the surface, the hydroxyl groups being drawn inwards, leaving the plane of the benzene nucleus at right angles to the surface.

FIG. 1.

Activity of phenol in aqueous solution.



Mole of phenol per litre.

The thickness of the adsorbed layer can only be calculated by assuming a value for the density, which is probably nearly that of pure phenol. The density of solid phenol at 33° is 1·06; that of the phenol-rich phase formed at 20° is 1·05. The thickness of the adsorbed layer, taking the latter figure, is 6·4 Å.U. The probable length of the benzene ring is given by Adam as about 6 Å.U.

These values differ considerably from those given by Langmuir (*loc. cit.*), who, from data furnished by Morgan and Egloff (*J. Amer. Chem. Soc.*, 1916, **38**, 555, 844), deduces that the phenol molecule, of mean area 34 Å.U., lies flat on the surface of the solution. This difference is principally due to the fact that Langmuir assumed the

phenol activity to be throughout proportional to the concentration. If the present values for the surface tensions be plotted against the logarithms of the *concentrations*, the maximum apparent value of Γ is reached in the middle of the curve, at a concentration of phenol of about 0·2 mole/litre, after which there is a decrease of slope, and consequently a decrease in the apparent value of the adsorption, due to the fact that no allowance has been made for association of the phenol.

FIG. 2.

Considering now the curves formed by solutions of phenol containing salt, we see that they lie parallel to curve I, and have the same slope at corresponding activities. It follows that the amount of phenol adsorbed at the surface of equi-active phenol solutions is independent of the concentration of salt in the solution. The curves are, however, not coincident, showing that the salt has an effect on the actual value of the surface tension. The extent of the displacement of the curves shows this effect to be nearly the same as that of salt on pure water. At higher concentrations, however, the effect of salt on the phenol solutions diminishes, the curves for 15, 20, and 25% of salt being closer together than those for 0, 5, and 10%. With pure water, on the other hand, the effect increases as the salt solution becomes more concentrated.

Discussion of Results.

The results described in this paper do not seem to support the now well-known theory of surface tension proposed by Langmuir (*loc. cit.*) and Harkins (*op. cit.*), which maintains (1) that the surfaces of liquids containing asymmetric molecules consist of a unimolecular film of these molecules, oriented in such a way that their more active portions are drawn inwards, and (2) that " the surface energy of a liquid is thus not a property of the group molecules, but depends only on the least active portions of the molecules, and the manner in which these are able to arrange themselves in the surface layer " (Langmuir, *loc. cit.*). We have seen that there is good reason to suppose that the adsorbed layer at the surface of aqueous phenol solutions, at least when these approach saturation, consists of a unimolecular film of oriented phenol molecules. This is in accordance with the views of Langmuir; but further consideration must lead us to hesitate before ascribing, as this theory postulates, the actual surface tensions of the solutions entirely to the effect of the stray fields of force surrounding the outer layers of atoms.

Langmuir supposes the surface tension of an aqueous salt solution to consist of a unimolecular layer of oriented water molecules; but if these oriented molecules, by virtue of their stray fields, are alone responsible for the elevation of the surface tension, it is difficult to conceive that their effect should be largely unaltered by the presence at the surface of a closely packed layer of phenol molecules. Yet we have seen this to be the case. It would seem that, besides the effect of the surface film, it is necessary to take into account what may be called the " foundation " of the film. This is further indicated by the form of the curves obtained if the surface tensions given in Table II are plotted against salt concentration. The lowering of surface tension is at first nearly linear; with increasing salt concentration, the rate of fall increases somewhat up to a point of inflection, shortly after which a second phase separates; the surface tension varies very little beyond this point. Close inspection of the curves shows that there is no marked discontinuity at the " salting-out " point; for some little distance before the point is actually reached the rate of fall of surface tension diminishes, indicating possibly a thickening of the surface film of phenol molecules. Even here, however, the effect of the salt persists; since the actual value of the surface tension at different salting-out points varies with the salt concentration.

We must conclude, therefore, that although the presence of a unimolecular film of oriented phenol molecules at the surface is probably the chief factor in determining the surface tension,

the molecules at greater depths have also an influence upon it. Recent work by Iredale (*Phil. Mag.*, 1923, **45**, 1088; 1924, **48**, 177), Wilson (*Physical Rev.*, 1920, **16**, 8), and Terzaghi (*ibid.*, p. 54) indicates that molecular forces may be active over ranges considerably exceeding the length of a single molecule. A complete theory of surface tension should cover both the surface film and the "foundation" upon which that film rests.

CCXXII.—*Bromination of Acyl Derivatives of Phenylhydrazine. Preparation of 2 : 4-Dibromophenylhydrazine.*

By JAMES ERNEST HUMPHRIES and ROY EVANS.

BROMINATION, even with excess of the halogen, of the acetyl and benzoyl derivatives of phenylhydrazine in cold chloroform or carbon tetrachloride does not produce diazonium salts (compare Michaelis, *Ber.*, 1893, **26**, 2190; Vaubel, *J. pr. Chem.*, 1894, **49**, 540; 1897, **55**, 220). The formation of diazonium salt in Michaelis's experiment appears to have been due to the action of the bromine on phenylhydrazine formed from its acetyl derivative by hydrolysis by the hydrochloric acid used as solvent.

In our experiments, no evidence was obtained of the existence of *N*-bromo-compounds, proved by Chattaway (J., 1908, **93**, 852) to be formed in the bromination of phenylhydrazine.

The experiments were carried out at $-5°$ to $-10°$. After the initial experiments chloroform was used as solvent, since the acyl derivatives are more soluble in it than in carbon tetrachloride. The brominated phenylhydrazines produced were identified by conversion into the bromophenylhydrazones of benzophenone or benzaldehyde. Tests for diazonium compounds were carried out with an alkaline solution of β-naphthol.

Acetylphenylhydrazine. (1) Bromine (1 mol.) was added gradually to the solution, which became red and turbid. *Acetyl-p-bromophenylhydrazine hydrobromide* slowly separated as a white, crystalline solid, m. p. 132° (decomp.) (Found: total Br, 51·5; HBr, by titration with baryta, 26·4. $C_8H_9ON_2Br,HBr$ requires total Br, 51·6; HBr, 26·1%). The compound dissolved immediately in alcohol and from the solution acetyl-*p*-bromophenylhydrazine, m. p. 164°, was soon deposited (Found: Br, 34·7. Calc., Br, 34·9%).

(2) A solution of 12 g. (1 mol.) of acetylphenylhydrazine in 400 c.c. of chloroform was cooled to 0°, slowly treated with 8·2 c.c. (2 mols.) of bromine, and kept for 12 hours at the ordinary temperature, when the heavy, red oil that had separated solidified (from more dilute solutions it separated in crystals). The crystalline mass, which was washed with chloroform, was *acetyl*-2 : 4-*dibromophenylhydrazine hydrobromide*, m. p. 146° (decomp.); it decomposed in the air, giving off hydrogen bromide (Found: total Br, 61·85; HBr, 20·9. $C_8H_8ON_2Br_2$,HBr requires total Br, 61·7; HBr, 20·8%). The compound was dissolved in cold alcohol and water added to the solution, when acetyl-2 : 4-dibromophenylhydrazine, m. p. 146°, was formed in theoretical yield (24—25 g.) (Found: Br, 51·7. Calc., Br, 51·9%). The hydrochloride of the hydrazine was easily obtained by warming the acetyl derivative with concentrated hydrochloric acid.

Benzoylphenylhydrazine. The solution turned red and turbid when the bromine (2 mols.) was added and after a short time white needles of 2 : 4-dibromophenylhydrazine hydrobromide separated (Found: Br, 68·9. Calc., Br, 69·2%).

THE UNIVERSITY, ABERDEEN. [*Received, May 21st*, 1925.]

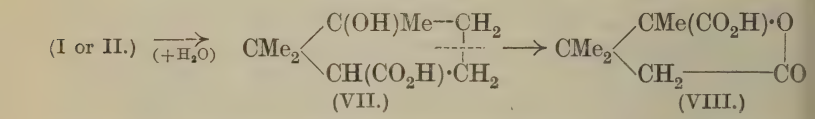
CCXXIII.—*The Structure of α-Campholytic Acid. A Correction.*

By JUAN PEDIGE CHARLES CHANDRASENA, CHRISTOPHER KELK INGOLD, and JOCELYN FIELD THORPE.

IN a previous paper (J., 1922, **121**, 1542) it was pointed out that the existing evidence of the structure of campholytic acid is equivocal: it could be used just as easily to support the bridged-ring constitution (I) as the accepted unsaturated structure (II). The possibility of a tautomeric form having structure (I) had not previously been considered, but it was suggested that the time had arrived to do so in view of the proved tautomerism between (III) and (IV) (compare Parts I and II of the same series).

(I.) $CMe_2<\begin{matrix}CMe\text{——}CH_2\\ |\quad\quad |\\ C(CO_2H)\cdot CH_2\end{matrix}$ ⇌ $CMe_2<\begin{matrix}CMe\text{═══}CH\\ |\quad\quad |\\ CH(CO_2H)\cdot CH_2\end{matrix}$ (II.)

(III.) $CMe_2<\begin{matrix}C(CO_2H)\cdot CH_2\\ |\quad\quad |\\ CH\text{——}CO\end{matrix}$. ⇌ $CMe_2<\begin{matrix}C(CO_2H)\text{:}CH\\ |\quad\quad |\\ CH_2\text{——}CO\end{matrix}$ (IV.)



The object of the paper was, therefore, to advance unequivocal evidence favouring formula (I), and it was suggested that the oxid-

ation of campholytic acid to the lactonic acid (VI) might be regarded in that light:

(I.) (V.) (VI.)

The lactone (VI) has the same m. p. and almost the same properties as the isomeric lactone (VIII), which, of course, might arise from *either* (I) *or* (II), through (VII):

(I or II.) (VII.) (VIII.)

The lactone actually obtained, however, is not (VI), as was at first supposed, but (VIII); and so, again, the evidence of structure is ambiguous.

Structure (VI) was incorrectly assigned to the lactonic acid on the grounds of its identity with a specimen prepared from trimethylglutaric acid by Pandya and Thorpe (J., 1923, **123**, 2865), who, being misled by an erroneous statement of Balbiano (now corrected: this vol., p. 1072), wrongly regarded the substance as possessing formula (VI). The authors desire to express their regret that this mistake should have arisen.

CCXXIV.—*The Formation and Stability of* spiro-*Compounds. Part XII. Further Evidence for the Multiplanar Configuration of the* cyclo*Heptane Ring.*

By JOHN WILLIAM BAKER.

BAKER and INGOLD showed (J., 1923, **123**, 122) that the original hypothesis of Beasley, Ingold, and Thorpe (J., 1915, **107**, 1080) fails, when applied to the *cyclo*heptane ring, in a manner suggesting that this ring, when once formed, is nearly strainless and therefore possesses multiplanar configuration.

To obtain confirmatory evidence, the action of hydrolysing agents on the dibromo-ester (I) and the methoxy-ring acid (II) has been investigated with the object of preparing either or both of the acids of types (III) or (IV).

(I.) (II.)

(III.) (IV.)

The relative stability of these acids (III) and (IV) forms an important criterion respecting the condition of strain in the *cyclo*heptane ring, for whilst in the dimethyl ($R_2 = Me_2$, angle 109·5°) and *cyclo*pentane series ($R_2 = C_4H_8>$, angle 108°) the open-chain keto-form is the stable modification, in the *cyclo*hexane series ($R_2 = C_5H_{10}>$, angle 120°) the strain in the three-membered *spiro*-ring is so far relieved that the hydroxy-ring acid becomes the stable isomeride; in intermediate cases, $R_2 = Et_2$ and Pr^{α}_2, a tautomeric equilibrium exists between the keto- and hydroxy-ring forms. If, therefore, the *cyclo*heptane ring is uniplanar as used to be supposed (angle 128·6°), its hydroxy*cyclo*propane compound of type (III) should be even more stable than the *cyclo*hexane analogue. If, on the other hand, the seven-membered ring is multiplanar, and therefore strainless or nearly so, it should resemble more closely its *cyclo*pentane analogue and the keto-acid (type IV) should be the stable modification.

The results obtained clearly indicate that the *cyclo*heptane ring is strainless, or nearly so,* for the open-chain keto-acid was the more stable isomeride, the hydroxy-ring acid (which was isolated) passing into the keto-acid under the conditions in which this reversible isomeric change has been observed in other cases.

On hydrolysis of the dibromo-ester (I) with boiling methyl-alcoholic potassium hydroxide the methoxy-ring acid (II), analogous in all respects to the corresponding *cyclo*hexane compound, was obtained. On hydrolysis with hydrobromic acid this methoxy-ring acid gave a large yield of a liquid acid and a very small yield of a solid acid which, although insufficient was obtained for analysis, was identified as *cyclo*heptane*spirocyclo*propane-1 : 2-dicarboxylic acid (V), the hydrobromic acid evidently having acted partly as a reducing agent.

(V.) (VI.)

The liquid acid, which was purified through its silver salt, proved to be the hydrated form (VI) of the keto-acid, for it readily

* Other investigators have reached the same conclusions on quite different grounds (compare Meerwein and his collaborators, *J. pr. Chem.*, 1922, **104**, 161, 289; Dickens, Horton, and Thorpe, J., 1924, **125**, 1830).

yielded a semicarbazido-acid on treatment with semicarbazide acetate.*

Hydrolysis of the dibromo-ester (I) with boiling 64% aqueous potassium hydroxide yielded (*a*) a small amount (about 1%) of the hydroxy-ring acid, (*b*) a large proportion of the above-mentioned hydrated keto-acid, and (*c*) a liquid lactonic by-product which, owing to an insufficiency of material, could not definitely be identified.

From these experiments, it appears that, in the presence of hot concentrated alkalis, a tautomeric equilibrium, greatly favouring the open-chain form, exists between the hydroxy-ring acid and the keto-acid.

Thus the *cyclo*heptane compounds resemble closely their *cyclo*pentane analogues, which contain a practically strain-free ring, and therefore it may be asserted with considerable confidence that the *cyclo*heptane ring also is nearly strainless as suggested in the earlier communication (*loc. cit.*).

It seems curious that the *cyclo*heptane ring should be multiplanar whilst the *cyclo*hexane ring shows no evidence of strainless configuration until joined to another ring in some such combination as is represented in decahydronaphthalene. This, however, can be accounted for if we assume with Mohr (*J. pr. Chem.*, 1918, **98**, 352) that these rings undergo vibrational interchange between the strainless and uniplanar phases, and further postulate that the uniplanar phase, which is more highly strained in the *cyclo*heptane than in the *cyclo*hexane series, is, for that reason, of much smaller duration in the former than in the latter type of ring.

Experimental.

The ethyl $\alpha\alpha'$-dibromo*cyclo*heptane-1 : 1-diacetate used was prepared as described by Baker and Ingold (*loc. cit.*). Since it cannot be distilled without passing into the bromolactone, the undistilled product was employed.

Hydrolysis of the Dibromo-ester (I).—(a) *With methyl-alcoholic potassium hydroxide.* cyclo*Heptane*spiro-1-*methoxy*cyclo*propane*-1 : 2-*dicarboxylic acid.* The dibromo-ester (5 g.) was added as rapidly as was consistent with safety to a boiling solution of potassium hydroxide (10 g.) in 30 c.c. of methyl alcohol, and boiling

* Incidentally an observation was made which probably explains the frequent failure to prepare semicarbazones of the ketoglutaric acids previously investigated. The *cyclo*heptane semicarbazido-acid is a stronger acid than acetic acid and under the ordinary conditions of semicarbazone formation takes sodium from the sodium acetate employed. Its mono- and di-sodium salts are sufficiently sparingly soluble to separate from the solution, but it may well be that in lower series such salts are too soluble to do likewise.

continued under reflux for a further 20 minutes. After evaporation of the alcohol, the residue was repeatedly extracted with ether, whence the methoxy-ring acid was obtained as a gum which slowly solidified. On crystallisation from ether–ligroin (b. p. 40—60°), it was obtained in large rosettes, m. p. 165° (Found: C, 58·7; H, 7·4; *M*, by titration, 121·3. $C_{12}H_{18}O_5$ requires C, 59·4; H, 7·5%; *M*, 121·1).

(b) *With* 64% *aqueous potassium hydroxide.* The dibromo-ester (5 g.) was added as rapidly as was consistent with safety to 45 c.c. of boiling 64% potash solution, and boiling continued for 20 minutes. The residue obtained from the ethereal extract of the cooled, diluted, and acidified product was a gum which was repeatedly extracted with warm water. The aqueous extract on evaporation left an almost colourless gum, from which a minute quantity of the hydroxy-ring acid (III) was slowly deposited as a white, crystalline solid (mixed m. p. determination).

The liquid fraction of the soluble portion, treated with semicarbazide hydrochloride in a saturated solution of sodium acetate, slowly deposited the white *disodium* salt of the semicarbazido-acid, which was drained on porous tile and crystallised from methyl alcohol–ethyl acetate, from which it separated as a crystalline powder, decomp. 240° (Found: Na, 14·3. $C_{12}H_{17}O_5N_3Na_2$ requires Na, 14·0%). Another portion of the gum was dissolved in dilute ammonia and the *silver* salt precipitated by the addition of silver nitrate to the neutral solution (Found: Ag, 46·8. $C_{11}H_{16}O_6Ag_2$ requires Ag, 46·9%).

The portion insoluble in water formed no semicarbazone derivative and from its general characteristics appeared to be the same hydroxy-lactone obtained when the bromo-lactone was hydrolysed with concentrated potash solution (Baker and Ingold, *loc. cit.*).

Hydrolysis of the Methoxy-ring Acid with Hydrobromic Acid.—*αα′-Dihydroxy*cyclo*heptane*-1 : 1-*diacetic acid* (VI). The methoxy-ring acid (0·75 g.) was heated under reflux with 7·5 c.c. of hydrobromic acid (*d* 1·49) for 2 hours, the hydrobromic acid evaporated off on the steam-bath, and the residue extracted with ether. The gum obtained from the ethereal extract deposited, after long standing, a small quantity of a crystalline acid, m. p. 215°, which depressed the m. p. of the hydroxy-ring acid but not that of the *cyclo*heptane *spiro*acid (V).

The portion which would not solidify, consisting of the hydrated form of the keto-acid, was dissolved in dilute ammonia, silver nitrate solution added to the neutral solution, and the precipitated *silver* salt (Found: Ag, 46·7. $C_{11}H_{16}O_6Ag_2$ requires Ag, 46·9%) washed successively with water, alcohol, and ether. The acid was

regenerated by warming the silver salt with hydrochloric acid and extracting with pure ether. On treatment with a solution of semicarbazide acetate, it deposited the white, crystalline *monosodium* salt of the semicarbazido-acid, which, treated like the disodium salt, was obtained as a white, crystalline powder, decomp. 235° [Found : C, 47·2 (corrected for the percentage of carbon which remained unburnt as sodium carbonate); H, 5·85; Na, 7·4. $C_{12}H_{18}O_5N_3Na$ requires C, 47·0; H, 5·9; Na, 7·5%].

A Correction.—The acid X (this vol., p. 987), described as a *bicyclo*heptane derivative, has since been found to be a lactonic acid derived from this by hydrolytic fission of the three-membered ring. The mechanism of the reaction is being further investigated.

The author desires to express his gratitude to Professor C. K. Ingold, F.R.S., for his kindly interest and advice during the progress of this investigation, and to the Research Fund Committee of the Chemical Society for a grant by which most of the expenses incurred in this research were met.

THE UNIVERSITY, LEEDS. [*Received, May 27th,* 1925.]

CCXXV.—*Tridentate Groups in Complexes of Tetrahedral and Octahedral Symmetry.*

By J. D. MAIN SMITH.

UNTIL 1912, the property of rotating the plane of propagation of polarised light had been invariably ascribed to the presence of " asymmetric atoms " in the molecules of compounds. In every case, each such characteristic atom was discernible as in direct association with four different atoms or atomic groups arranged tetrahedrally about the active atom. In 1911, Werner showed that optically active compounds could contain an " asymmetric atom " with which six atoms or atomic groups were octahedrally associated. His demonstration in 1912 of the existence of optically active compounds containing a cobalt atom octahedrally associated with three identical groups of atoms (chelate ethylenediamine molecules) led him to abandon the conception that optical activity is due to the presence of " asymmetric *atoms* " and to attribute optical activity to *molecular* asymmetry. Subsequent chemical evidence points strictly to the existence in optically active compounds generally, not of asymmetric atoms, but of asymmetric molecules, and, in the light of recent knowledge of the structure of atoms, it appears probable that every atom, at least so far as the outer structure is

concerned, possesses at least one plane of symmetry. Nevertheless, it is possible to discern in the molecule of every known optically *active* compound a central or nuclear atom about which the *asymmetry* of the molecule is focussed. This nuclear atom is the so-called asymmetric atom. In the case of optically *inactive* compounds, it is similarly possible to discern a central or nuclear atom about which the *symmetry* of the molecule is focussed. This atom, almost invariably that directly combined with the largest number of atoms or atomic groups, is the nuclear atom of Werner's co-ordination theory.

For the purposes of classification and nomenclature of chemical compounds it is necessary to select certain atoms in molecules as points of reference to which all other atoms in the molecule may be regarded as related. As the spatial relationships of atoms in molecules can be ascertained almost solely from considerations of symmetry, it is necessary to select the nuclear atom of a co-ordination complex as the point of reference, and to regard separately each atom directly attached thereto. An atom directly attached to a nuclear atom may itself be multivalent and may become the end member of an atomic group which may be considered as an entity or radical directly attached to the nuclear atom. Obviously such an atomic group may be attached directly to the nuclear atom by means of more than one atom, and atomic groups may thus be classified as unitary, chelate, and tridentate, respectively, according as they contain one, two, and three atoms directly attached to the nuclear atom.

The term "chelate group," used by Professor G. T. Morgan to indicate its claw-like attachment to a nuclear atom to form a cyclic system of linked atoms, may logically be extended to any atomic group which combines with a single atom to form a cyclic system, but it is convenient to restrict its use to those groups which yield heterocyclic systems when combined with nuclear atoms, usually metallic atoms.

Tridentate groups may be regarded as comprising three fused chelate groups and may be symbolised as ABC to indicate the three comprised chelate groups AB, AC, BC. Tridentate groups may be classified according to the number of different chelate groups comprised, and can be of only three types symbolised by AAA, AAB, and ABC, the first comprising three similar chelate groups, the second two similar chelate groups, and the third three different chelate groups.

Tridentate groups have long been known in organic chemistry, but invariably associated with so-called tetrahedral atoms. Removal of one of the median carbon atoms of naphthalene, for example,

leaves a typical tridentate group. Tridentate groups in inorganic chemistry were first identified by Werner in association with an octahedral nuclear atom, or more properly, with a nuclear atom having the co-ordination number six. The group $(NH_3)_3Co(OH)_3$, for example, was proved to be capable of uniting with another nuclear cobalt atom, both having the co-ordination number six, as in the complex ion

$$(NH_3)_3Co\overset{OH}{\underset{OH}{}}Co(NH_3)_3,$$

in which each $(NH_3)_3Co(OH)_3$ group is a tridentate group to the other Co atom. Prior to 1924, all the tridentate groups identified were found in complexes containing at least two octahedral nuclear atoms, as in the foregoing example. In that year, Pope and Mann (*Compt. rend.*, 1924, **178**, 2085) proved that $\alpha\beta\gamma$-triaminopropane was a group capable of triple attachment to a single metallic atom having the co-ordination number six, the cobaltic and rhodium compounds containing only two molecules of the tri-acidic base per metallic atom.

In view of the interest attaching to such compounds containing tridentate groups in uni-nuclear octahedral complexes, the results of the examination some years ago of the possibilities of tetrahedral and octahedral isomerism, due to association of tridentate groups with a single nuclear atom, are now published. A complete examination of the possibilities of tetrahedral and octahedral isomerism in complexes containing single atoms or unitary groups and also those containing chelate groups has already been published ("Chemistry and Atomic Structure," 1924, ch. VII). The following tables are based on the system of symbolisation there presented, with the necessary modifications for tridentate groups.

Only one main type of **tetrahedral** complex containing tridentate groups is possible, and consists of one tridentate group (symbolised by three capitals) and one unitary group (symbolised by lower-case letters). As shown above, only three variants of tridentate groups are possible, symbolised by AAA, AAB, and ABC, to indicate the various possible combinations of three fused chelate groups. This single type of tetrahedral complex is thus divisible into only three classes, (i) AAAb, (ii) AABc, and (iii) ABCd. The first class consists of a single optically inactive form, and the second and third each of two optically active (enantiomorphous) isomerides.

Three main types of **octahedral** complexes containing tridentate groups are possible, the first containing three single atoms or three unitary groups, the second containing one chelate group (indicated by two capitals) and one single atom or unitary group, and the third

containing two tridentate groups. Three single atoms or three unitary groups considered together can have only three variants, symbolised by aaa, aab, and abc. There can thus be no more than nine variants of one tridentate group with three unitary groups, and no more than nine variants of two tridentate groups. These two sets each of nine classes are shown in Table 1. As chelate groups can be of no more than two variants, symbolised by AA and AB, there can be no more than six variants of one tridentate group with one chelate group and one unitary group. These six classes are also shown in Table 1. The octahedral configuration containing tridentate groups can thus give rise to no more than three main types comprising 24 separate classes.

The various possible isomeric forms of any one class are differentiated into *cis*- and *trans*-forms according to whether the tridentate group is attached to three adjacent points forming a triangle on an imaginary octahedron about the nuclear atom or to three points two of which are octahedrally polar. In the *cis*-configuration the nuclear atom lies outside and in the *trans*-configuration within the plane containing the tridentate group.

With one exception, every optically inactive form containing a tridentate group contains at least one plane of symmetry. The exception is in the case of the inactive *cis*-form of the combination ABC ABC, which contains a centre of symmetry. This configuration is unique in that it is the sole inactive form of the 430 octahedral forms so far examined (75 with only unitary groups, 206 with chelate groups, and 149 with tridentate groups) which does not contain a plane of symmetry.

The following tables relate only to complexes which contain one nuclear atom, but the correct number of isomerides even for binuclear cases may be simply deduced by aid of the tables. If a tridentate group, or the chelate group, or a unitary group contain a nuclear atom so that the group as a whole is asymmetric, *i.e.*, not superposable on its mirror-image, every form shown in the tables as optically inactive will be optically active and an enantiomorphous form will be possible. The number representing the inactive forms is thus simply doubled and added to the number of active forms. Only one other special case need be considered. If in the combination ABC DEF, the tridentate groups are each asymmetric and in addition are mirror-images of one another, the number of possible optically active *cis*-forms will be reduced by two and one optically inactive form will take their place and will, like the inactive *cis*-combination ABC ABC, contain a centre of symmetry.

To illustrate the use of the tables in the determination of the number of possible isomeric forms of uni-nuclear complexes con-

taining tridentate groups, the compounds containing triaminopropane may be taken. This tridentate group comprises three chelate groups, of which two are similar, and the symbol for the group is thus AAB. The compounds prepared contained two tridentate groups per metallic atom, and thus belong to type 3,

class (v), AAB AAB. Reference to Table IV shows that this class represents four isomeric forms, two optically active (enantiomorphous, *cis*-forms, one inactive *cis*-form, and one inactive *trans*-form. Pope and Mann's compounds may thus have been one or both of the inactive forms, the mixture (racemoid) of active forms, or a mixture of the racemoid forms with either or both of the inactive forms.

The results of the examination of the types, classes, and isomeric forms of tetrahedral and octahedral complexes containing a group contributing four to the co-ordination number of a nuclear atom will be communicated later, conclusive evidence having been obtained in these laboratories of the existence of a quadridentate group in both octahedral and tetrahedral complexes.

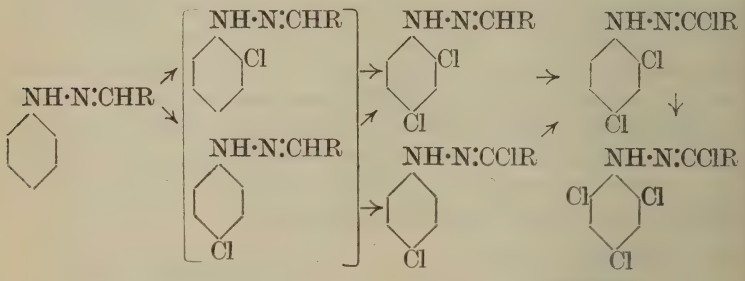
CCXXVI.—*The Action of Halogens upon* m- *and* p-*Nitrobenzaldehydephenylhydrazones.*

By FREDERICK DANIEL CHATTAWAY and ARTHUR JOHN WALKER.

THE action of chlorine upon some arylhydrazones has been shown (Bülow, *Ber.*, 1918, **51**, 399) to result in the complete disruption of the hydrazone molecule and the formation of a diazonium chloride. This result might have been expected, since it had already been shown (Chattaway, J., 1908, **93**, 852; 1909, **95**, 958, 1065) that diazonium chlorides are produced quantitatively by the action of chlorine on arylhydrazines.



The stable nature of the nitrobenzaldehydephenylhydrazones renders it possible to follow more closely the action of chlorine upon them, since no appreciable breaking down of the molecule takes place during chlorination at the ordinary temperature.

When chlorine is passed in excess into a fine suspension in chloroform of *m*- or *p*-nitrobenzaldehydephenylhydrazone, the final product in each case is a tetra-substituted hydrazone, containing chlorine in the 2 : 4 : 6-positions of the hydrazine residue and also in the ω-position of the aldehyde residue :

$$C_6H_2Cl_3{\cdot}NH{\cdot}N{:}CCl{\cdot}C_6H_4{\cdot}NO_2.$$

If the chlorination be effected slowly, at various stages compounds can be isolated, the constitutions of which show that substitution in the two parts of the hydrazone molecule follows a similar course to that taken when acetanilide and benzaldehyde, respectively, are chlorinated.

Substitution in the ω-position of the aldehyde residue probably occurs to some extent from the first, but becomes more and more predominant as halogen enters the hydrazine nucleus. The main course of the substitution may be represented as follows, compounds not actually isolated being written in brackets (R = $C_6H_4{\cdot}NO_2$) :

As might be expected, the situation of the nitro-group in the aldehyde residue somewhat affects the course of the reaction, the chlorine entering the ω-position more easily when the nitro-group occupies the para-position.

As in the chlorination of the acetarylamides, the chlorine probably first replaces the hydrogen of the imino-group, and becomes transferred to the nucleus by a process of intramolecular rearrangement. These transformations must take place with great ease, for the product of the action of an excess of hypochlorous acid upon *m*-nitrobenzaldehydephenylhydrazone in the presence of potassium bicarbonate gives all the reactions of a nitrogen chloride and is very probably a mixture of ω-*chloro*-m-*nitrobenzaldehydechloroimino*-o- and -p-*chlorophenylhydrazones*, since on warming with hydrochloric acid it yields ω-*chloro*-m-*nitrobenzaldehyde*-2 : 4-*dichlorophenylhydrazone*.

All the ω-chloro-*m*- and -*p*-nitrobenzaldehydechlorophenylhydrazones, when heated with sodium acetate and acetic acid, are converted quantitatively into α-*acetyl*-β-*nitrobenzoylchlorophenyl*-

hydrazines identical with the compounds obtained by acetylating the corresponding nitrobenzoylchlorophenylhydrazines; *e.g.*,

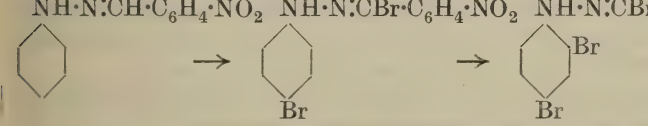
$$C_6H_3Cl_2\cdot NH\cdot N{:}CCl\cdot C_6H_4\cdot NO_2 \xrightarrow{CH_3\cdot CO_2Na} C_6H_3Cl_2\cdot NAc\cdot NH\cdot CO\cdot C_6H_4\cdot NO_2.$$

The α-acetyl-β-nitrobenzoyl-*p*- and -2:4-dichlorophenylhydrazines, when heated with concentrated hydrochloric acid, are readily and completely hydrolysed into acetic acid, *m*- or *p*-nitrobenzoic acid, and the corresponding *p*- or 2 : 4-dichlorophenylhydrazine; *e.g.*,

$$C_6H_3Cl_2\cdot NAc\cdot NH\cdot CO\cdot C_6H_4\cdot NO_2 \xrightarrow{H_2O} CH_3\cdot CO_2H + C_6H_3Cl_2\cdot NH\cdot NH_2 + NO_2\cdot C_6H_4\cdot CO_2H.$$

Under similar conditions the corresponding α-acetyl-*m*- or -*p*-nitrobenzoyl-2 : 4 : 6-trichlorophenylhydrazine is not hydrolysed completely as might be expected, but yields *m*- or *p*-nitrobenzoic acid, and α-acetyl-2 : 4 : 6-trichlorophenylhydrazine, which is not easily broken down further; *e.g.*,

$$C_6H_2Cl_3\cdot NAc\cdot NH\cdot CO\cdot C_6H_4\cdot NO_2 \xrightarrow{H_2O} C_6H_2Cl_3\cdot NAc\cdot NH_2 + NO_2\cdot C_6H_4\cdot CO_2H.$$



It seems probable that the firm attachment of the acetyl group in these compounds is to be attributed to the steric effect of the two *o*-substituted halogen atoms.

All ω-chloro-*m*- and -*p*-nitrobenzaldehydephenylhydrazones react with ammonia, forming *hydrazidines* by the replacement of the ω-chlorine atom by the amino-group; *e.g.*,

$$C_6H_2Cl_3\cdot NH\cdot N{:}CCl\cdot C_6H_4\cdot NO_2 \xrightarrow{NH_3} C_6H_2Cl_3\cdot NH\cdot N{:}C(NH_2)\cdot C_6H_4\cdot NO_2.$$

These are yellow or deep red basic compounds which all form colourless, well-crystallised hydrochlorides.

The action of bromine is similar to that of chlorine, although less energetic, direct substitution only leading to the introduction of two halogen atoms into the hydrazine residue, thus :

ω-*Bromo*-m- and -p-*nitrobenzaldehyde*-2 : 4 : 6-*tribromophenylhydrazones* are, however, easily obtained by the direct bromination of *m*- and *p*-nitrobenzaldehyde-2 : 4 : 6-tribromophenylhydrazones.

The behaviour of the ω-bromo-*m*- and -*p*-nitrobenzaldehyde-bromophenylhydrazones towards acetic acid and sodium acetate, and of the α-acetyl-β-nitrobenzoylbromophenylhydrazines towards hydrochloric acid, is exactly like that of the corresponding chloro-compounds.

The direct chlorination or bromination of any of the *m*- or *p*-nitrobenzaldehyde halogen-substituted phenylhydrazones naturally leads to the formation of an ω-substituted derivative; *e.g.*,

$$C_6H_4Cl\cdot NH\cdot N{:}CH\cdot C_6H_4\cdot NO_2 \xrightarrow{Br} C_6H_4Cl\cdot NH\cdot N{:}CBr\cdot C_6H_4\cdot NO_2.$$

The ω-bromo-*m*- and -*p*-nitrobenzaldehydebromophenylhydrazones react with ammonia, forming *hydrazidines*, which are mostly deep red, basic compounds, which yield colourless salts.

Experimental.

Action of Chlorine upon m-*Nitrobenzaldehydephenylhydrazone.*

Unless effected cautiously, chlorination of *m*-nitrobenzaldehydephenylhydrazone resulted only in the separation of the final product, ω-*chloro*-m-*nitrobenzaldehyde*-2 : 4 : 6-*trichlorophenylhydrazone*. When carried out slowly, at intermediate stages m-*nitrobenzaldehyde*-2 : 4-*dichlorophenylhydrazone* and ω-*chloro*-m-*nitrobenzaldehyde*-2 : 4-*dichlorophenylhydrazone* separated from the solution. A smaller quantity of ω-chloro-*m*-nitrobenzaldehyde-*p*-chlorophenylhydrazone was also obtained.

ω-*Chloro*-m-*nitrobenzaldehyde*-2 : 4 : 6-*trichlorophenylhydrazone*, $C_6H_2Cl_3\cdot NH\cdot N{:}CCl\cdot C_6H_4\cdot NO_2$. Chlorine was passed to saturation into a cooled suspension of 5 g. of *m*-nitrobenzaldehydephenylhydrazone in 30 c.c. of chloroform, the dark solution which was first formed finally lightening in colour, and depositing the ω-*chloro*-m-*nitrobenzaldehyde*-2 : 4 : 6-*trichlorophenylhydrazone* as a grey, crystalline mass. This separated from acetic acid, in which it was only moderately soluble, in fine, colourless, hair-like needles, m. p. 157° (yield 5 g.) (Found: Cl, 37·6. $C_{13}H_7O_2N_3Cl_4$ requires Cl, 37·4%).

The same compound separated when chlorine was passed into a suspension of *m*-nitrobenzaldehyde-2 : 4 : 6-trichlorophenylhydrazone in chloroform. A small quantity of the substance, when boiled with an alkaline solution of potassium permanganate, yielded *m*-nitrobenzoic acid, m. p. 140°, thus showing the absence of halogen in the aldehyde nucleus.

Isolation of m-*nitrobenzaldehyde*-2 : 4-*dichlorophenylhydrazone and* ω-*chloro*-m-*nitrobenzaldehyde*-p-*chlorophenylhydrazone*,

$C_6H_3Cl_2\cdot NH\cdot N{:}CH\cdot C_6H_4\cdot NO_2$ and $C_6H_4Cl\cdot NH\cdot N{:}CCl\cdot C_6H_4\cdot NO_2$. Chlorine was cautiously passed into a suspension of *m*-nitrobenzaldehydephenylhydrazone (5 g.) in chloroform (30 c.c.) until the solution formed darkened and set to a solid brown mass, probably containing unstable compounds of the hydrazones with hydrogen chloride. On the addition of an equal volume of alcohol, it changed to a clean yellow, crystalline mass of *m*-nitrobenzaldehyde-2 : 4-dichlorophenylhydrazone, m. p. 211° after recrystallisation from acetic

acid. The chloroform and alcohol mother-liquor slowly deposited crystals containing *ω-chloro*-m-*nitrobenzaldehyde*-p-*chlorophenylhydrazone*. After two recrystallisations from acetic acid this melted at 130°, but since further purification in this way was difficult, it was dissolved in boiling alcohol, a few c.c. of concentrated ammonia solution were added, the solution was acidified with concentrated hydrochloric acid, diluted with hot water, filtered, and made alkaline with ammonia; the *m*-nitrobenzaldehyde-*p*-chlorophenylhydrazidine which separated crystallised from alcohol in deep red needles, m. p. 150°, identical with the hydrazidine obtained from ω-bromo-*m*-nitrobenzaldehyde-*p*-chlorophenylhydrazone (p. 1694).

Isolation of ω-chloro-m-*nitrobenzaldehyde*-2 : 4-*dichlorophenylhydrazone*, $C_6H_3Cl_2\cdot NH\cdot N{:}CCl\cdot C_6H_4\cdot NO_2$. In another experiment, the passage of chlorine was cautiously continued until the brown precipitate containing *m*-nitrobenzaldehyde-2 : 4-dichlorophenylhydrazone (above) just redissolved. The solution on standing, or on the addition of an equal volume of alcohol, yielded pale yellow crystals of *ω-chloro*-m-*nitrobenzaldehyde*-2 : 4-*dichlorophenylhydrazone*. This crystallised from acetic acid, in which it was moderately soluble, in long, pale yellow needles, m. p. 158° (yield 4 g.) (Found : Cl, 31·0. $C_{13}H_8O_2N_3Cl_3$ requires Cl, 30·9%).

The constitution of the compound was confirmed as follows : A mixture of 2 g. of β-*m*-nitrobenzoyl-2 : 4-dichlorophenylhydrazine and 3 g. (2 mols.) of phosphorus pentachloride was maintained for a few minutes at 190°, and the cooled product treated with water and extracted with ether. To the residue after evaporation were added a few c.c. of alcohol; the yellow solid which separated, m. p. 158° after recrystallisation from acetic acid, was identical with the chlorination product described above.

Action of Chlorine upon p-*Nitrobenzaldehydephenylhydrazone.*

ω-Chloro-p-*nitrobenzaldehyde*-2 : 4 : 6-*trichlorophenylhydrazone*. A cooled suspension of 5 g. of *p*-nitrobenzaldehydephenylhydrazone in 100 c.c. of chloroform was saturated with chlorine. The crystalline mass of *ω-chloro*-p-*nitrobenzaldehyde*-2 : 4 : 6-*trichlorophenylhydrazone* obtained separated from acetic acid, in which it was sparingly soluble, in fine, pale yellow needles, m. p. 164° (yield 6 g.) (Found : Cl, 37·5. $C_{13}H_7O_2N_3Cl_4$ requires Cl, 37·4%).

The same compound was obtained by the chlorination under similar conditions of *p*-nitrobenzaldehyde-2 : 4 : 6-trichlorophenylhydrazone.

When boiled with an alkaline solution of potassium permanganate, it yielded *p*-nitrobenzoic acid, m. p. 238°.

Isolation of intermediate products in the chlorination of p-*nitro-*

benzaldehydephenylhydrazone. These products can be obtained with much greater ease than the analogous compounds formed in the chlorination of *m*-nitrobenzaldehydephenylhydrazone, the main products, *ω-chloro*-p-*nitrobenzaldehyde*-p-*chlorophenylhydrazone* and *ω-chloro*-p-*nitrobenzaldehyde*-2 : 4-*dichlorophenylhydrazone*, separating in good quantity at different stages of the reaction.

ω-Chloro-p-*nitrobenzaldehyde*-p-*chlorophenylhydrazone.* Chlorine was cautiously passed into a fine suspension in chloroform (5 g. in 100 c.c.) of *p*-nitrobenzaldehydephenylhydrazone, until the red solution first formed just became brown. Orange crystals of *ω-chloro*-p-*nitrobenzaldehyde*-p-*chlorophenylhydrazone* separated slowly, and a further quantity on addition of alcohol. It crystallised from acetic acid, in which it was moderately soluble, in orange needles m. p. 213° (yield 3 g.) (Found: Cl, 23·0. $C_{13}H_9O_2N_3Cl_2$ requires Cl, 22·9%). The same compound separated when *p*-nitrobenzaldehyde-*p*-chlorophenylhydrazone was similarly chlorinated. On boiling with alkaline permanganate solution, it yielded *p*-nitrobenzoic acid, m. p. 238°.

ω-Chloro-p-*nitrobenzaldehyde*-2 : 4-*dichlorophenylhydrazone.* The cautious passage of chlorine was continued beyond the stage described above, until the orange crystals of ω-chloro-*p*-nitrobenzaldehyde-*p*-chlorophenylhydrazone just redissolved. The solution almost immediately set to a mass of bright yellow crystals of *ω-chloro*-p-*nitrobenzaldehyde*-2 : 4-*dichlorophenylhydrazone.* This crystallised from acetic acid, in which it was sparingly soluble, in long, bright yellow, hair-like needles, m. p. 199° (yield 6 g.) (Found: Cl, 31·2. $C_{13}H_8O_2N_3Cl_3$ requires Cl, 30·9%).

The same compound separated when *p*-nitrobenzaldehyde-2 : 4-dichlorophenylhydrazone was similarly chlorinated.

Conversion of ω-Chlorohydrazones into α-Acetyl-β-nitrobenzoylphenylhydrazines.—When the ω-chloro-*m*- and -*p*-nitrobenzaldehyde-chlorophenylhydrazones are boiled for 2 hours with an excess of anhydrous sodium acetate and acetic acid, they are quantitatively converted into the corresponding α-acetyl-β-nitrobenzoylchlorophenylhydrazines, which separate as solids when the acetic acid solutions are poured into water. They are best recrystallised from alcohol, in which the *p*-chloro-derivatives are easily soluble and the di- and tri-chloro-derivatives moderately easily soluble. These α-acetyl-β-nitrobenzoylchlorophenylhydrazines are readily hydrolysed when heated with a mixture of alcohol and hydrochloric acid, yielding ethyl acetate, the corresponding nitrobenzoic acid, and the hydrochloride of the corresponding hydrazine, a procedure which provides the easiest method of determining their constitution, and consequently that of the original ω-chlorohydrazones.

α-*Acetyl*-β-m-*nitrobenzoyl*-2 : 4-*dichlorophenylhydrazine*,

$$C_6H_3Cl_2\cdot NAc\cdot NH\cdot CO\cdot C_6H_4\cdot NO_2,$$

was obtained as described above from ω-chloro-*m*-nitrobenzaldehyde-2 : 4-dichlorophenylhydrazone, and also directly from β-*m*-nitrobenzoyl-2 : 4-dichlorophenylhydrazine by boiling for a few minutes with acetyl chloride. It forms colourless plates, m. p. 155—156° (Found : Cl, 19·3. $C_{15}H_{11}O_4N_3Cl_2$ requires Cl, 19·3%).

The substance (1 g.) was boiled for 3 hours with 50 c.c. of alcohol and 20 c.c. of hydrochloric acid. The crystals of 2 : 4-dichlorophenylhydrazine hydrochloride that separated on cooling were identified by conversion into *o*-nitrobenzaldehyde-2 : 4-dichlorophenylhydrazone, m. p. 192·5°. The mother-liquor was neutralised and alcohol and ethyl acetate were distilled off. On acidifying the residue and cooling, crystals of *m*-nitrobenzoic acid, m. p. 140°, separated.

α-*Acetyl*-β-p-*nitrobenzoyl*-p-*chlorophenylhydrazine*, obtained similarly, forms long prisms with domed ends, m. p. 167° (Found : Cl, 10·7. $C_{15}H_{12}O_4N_3Cl$ requires Cl, 10·6%). When boiled with alcohol and hydrochloric acid it yielded acetic acid, *p*-nitrobenzoic acid, and *p*-chlorophenylhydrazine.

α-*Acetyl*-β-p-*nitrobenzoyl*-2 : 4-*dichlorophenylhydrazine* crystallises in long, colourless, six-sided plates, m. p. 158° (Found : Cl, 19·4. $C_{15}H_{11}O_4N_3Cl_2$ requires Cl, 19·3%). When boiled with a mixture of hydrochloric acid and alcohol it yielded acetic acid, *p*-nitrobenzoic acid, and 2 : 4-dichlorophenylhydrazine.

α-*Acetyl*-β-m-*nitrobenzoyl*-2 : 4 : 6-*trichlorophenylhydrazine* was prepared as described above from ω-chloro-*m*-nitrobenzaldehyde-2 : 4 : 6-trichlorophenylhydrazone, and also directly from β-*m*-nitrobenzoyl-2 : 4 : 6-trichlorophenylhydrazine by boiling for a few minutes with acetyl chloride. It crystallises in small, colourless prisms, m. p. 143° (Found : Cl, 26·3. $C_{15}H_{10}O_4N_3Cl_3$ requires Cl, 26·4%).

Hydrolysis of α-*Acetyl*-β-m-*nitrobenzoyl*-2 : 4 : 6-*trichlorophenylhydrazine to* m-*Nitrobenzoic Acid and* α-*Acetyl*-2 : 4 : 6-*trichlorophenylhydrazine*.—α-Acetyl-β-*m*-nitrobenzoyl-2 : 4 : 6-trichlorophenylhydrazine (4 g.) was boiled for 3 hours with 30 c.c. of alcohol and 20 c.c. of hydrochloric acid. On making alkaline with sodium carbonate and diluting with water, a colourless, oily liquid separated, which was removed. From the aqueous layer, on acidification, *m*-nitrobenzoic acid crystallised. The oily liquid did not crystallise alone or in contact with solvents. To its solution in warm alcohol *m*-nitrobenzaldehyde (2 parts) was added; on cooling, acetyl-*m*-nitrobenzaldehyde-2 : 4 : 6-trichlorophenylhydrazone,

$$C_6H_2Cl_3\cdot NAc\cdot N{:}CH\cdot C_6H_4\cdot NO_2,$$

separated in colourless, rectangular plates, m. p. 204°, identical with

the substance obtained by the acetylation of *m*-nitrobenzaldehyde-2 : 4 : 6-trichlorophenylhydrazone. The yield was 70%, and the original oily liquid from the hydrolysis must therefore have been mainly α-acetyl-2 : 4 : 6-trichlorophenylhydrazine, $C_6H_2Cl_3$·NAc·NH_2.

α-*Acetyl*-β-p-*nitrobenzoyl*-2 : 4 : 6-*trichlorophenylhydrazine* was prepared as above from ω-chloro-*p*-nitrobenzaldehyde-2 : 4 : 6-trichlorophenylhydrazone, and also directly by boiling *p*-nitrobenzoyl-2 : 4 : 6-trichlorophenylhydrazine for a few minutes with acetyl chloride. It forms flat, colourless needles, m. p. 121° (decomp.) (Found : Cl, 26·4. $C_{15}H_{10}O_4N_3Cl_3$ requires Cl, 26·5%). When boiled with hydrochloric acid and alcohol, it behaves like the corresponding *m*-nitrobenzoyl derivative, yielding α-acetyl-2 : 4 : 6-trichlorophenylhydrazine as a colourless oil, and *p*-nitrobenzoic acid.

Conversion of ω-Chlorohydrazones into Hydrazidines.—In each case the ω-chloro-compound was boiled with alcohol and a slight excess of concentrated aqueous ammonia until the original solid had completely dissolved. The hydrazidine formed separated either during the reaction or on subsequent cooling. These hydrazidines are strongly coloured compounds which combine with hydrochloric acid (1 mol.) to form colourless salts that crystallise well when solutions of the bases in hot dilute hydrochloric acid are allowed to cool.

m-*Nitrobenzaldehyde*-p-*chlorophenylhydrazidine*,

$$C_6H_4Cl{\cdot}NH{\cdot}N{:}C(NH_2){\cdot}C_6H_4{\cdot}NO_2,$$

is very soluble in alcohol, from which it separates in deep red needles, m. p. 150° (Found : Cl, 12·3. $C_{13}H_{11}O_2N_4Cl$ requires Cl, 12·2%).

m-*Nitrobenzaldehyde*-2 : 4-*dichlorophenylhydrazidine*,

$$C_6H_3Cl_2{\cdot}NH{\cdot}N{:}C(NH_2){\cdot}C_6H_4{\cdot}NO_2,$$

crystallises from alcohol, in which it is moderately easily soluble, in thin, irregular, orange plates, m. p. 154° (Found : Cl, 21·9. $C_{13}H_{10}O_2N_4Cl_2$ requires Cl, 21·75%). The *hydrochloride* is easily soluble in alcohol, less easily soluble in water. It separates from a mixture of these solvents in clusters of colourless needles, m. p. 220° (decomp.).

m-*Nitrobenzaldehyde*-2 : 4 : 6-*trichlorophenylhydrazidine* is sparingly soluble in alcohol, separating in fine, yellow leaflets, m. p. 194° (Found : Cl, 29·9. $C_{13}H_9O_2N_4Cl_3$ requires Cl, 29·6%). The *hydrochloride* forms colourless plates, m. p. 230° (decomp.), sparingly soluble in water and more soluble in alcohol.

p-*Nitrobenzaldehyde*-2 : 4 : 6-*trichlorophenylhydrazidine* crystallises from alcohol, in which it is moderately easily soluble, in dark red needles, m. p. 157° (Found : Cl, 29·8%). The *hydrochloride*, which is sparingly soluble in water, forms colourless, compact prisms, m. p. 260° (decomp.).

Action of Bromine upon m- *and* p-*Nitrobenzaldehydephenylhydrazones.*—The bromination of the nitrobenzaldehydephenylhydrazones was studied by Ciusa and Vecchiotti (*Gazzetta*, 1916, **46**, i, 240), who obtained the final products and, in the case of the *m*- and *p*-nitrobenzaldehydehydrazones, correctly regarded them as ω-bromonitrobenzaldehyde-2 : 4-dibromophenylhydrazones. They did not isolate the intermediate ω-bromonitrobenzaldehyde-*p*-bromophenylhydrazones.

ω-*Bromo*-m-*nitrobenzaldehyde*-p-*bromophenylhydrazone*,

$$C_6H_4Br{\cdot}NH{\cdot}N{:}CBr{\cdot}C_6H_4{\cdot}NO_2.$$

To a suspension of 5 g. (1 mol.) of *m*-nitrobenzaldehydephenylhydrazone in 100 c.c. of acetic acid was added a solution of 6 g. of bromine (slightly less than 2 mols.) in acetic acid. As the hydrazone dissolved, a yellow precipitate of the dibromo-compound separated, which crystallised from acetic acid, in which it was moderately easily soluble, in glistening, yellow plates, m. p. 146·5° (yield 6 g.). The use of less bromine caused the separation of the same compound in smaller amount, whilst the use of exactly 2 mols. of bromine led to the formation of small quantities of the tribromo-compound (Found : Br, 40·3. $C_{13}H_9O_2N_3Br_2$ requires Br, 40·1%). The same compound was also obtained by similarly brominating *m*-nitrobenzaldehyde-*p*-bromophenylhydrazone.

ω-*Bromo*-m-*nitrobenzaldehyde*-2 : 4-*dibromophenylhydrazone*. In a second experiment a larger quantity of bromine, 10 g. (3 mols.), was added, the ω-bromo-*m*-nitrobenzaldehyde-2 : 4-dibromophenylhydrazone finally separating as a thick, crystalline mass. It crystallised from acetic acid in bright yellow needles, m. p. 179° (yield 7 g.) (Found : Br, 50·4%). The same compound was obtained by similarly brominating *m*-nitrobenzaldehyde-2 : 4-dibromophenylhydrazone. When boiled with alkaline permanganate solution, it yielded *m*-nitrobenzoic acid, m. p. 140°.

The following ω-bromo-hydrazones were similarly prepared by the addition of bromine (1 mol.) to a suspension of the appropriate *m*-nitrobenzaldehydephenylhydrazone :

ω-*Bromo*-m-*nitrobenzaldehyde*-2 : 4 : 6-*tribromophenylhydrazone* crystallises in long, colourless, hair-like needles, m. p. 173°, sparingly soluble in acetic acid and alcohol (Found : Br, 57·7. $C_{13}H_7O_2N_3Br_4$ requires Br, 57·5%).

ω-*Bromo*-m-*nitrobenzaldehyde*-p-*chlorophenylhydrazone* crystallises from acetic acid, in which it is moderately easily soluble, in bright yellow, rectangular plates, m. p. 133° (Found : Cl + Br, 32·6. $C_{13}H_9O_2N_3ClBr$ requires Cl + Br, 32·6%).

ω-*Bromo*-p-*nitrobenzaldehyde*-p-*bromophenylhydrazone*,

$$C_6H_4Br{\cdot}NH{\cdot}N{:}CBr{\cdot}C_6H_4{\cdot}NO_2,$$

was prepared by the two methods described in the case of the isomeric *m*-nitro-derivative. It crystallises from acetic acid, in which it is moderately easily soluble, in light orange leaflets, m. p. 224° (Found: Br, 40·0%).

ω-*Bromo*-p-*nitrobenzaldehyde*-2 : 4-*dibromophenylhydrazone* separated when a solution of bromine (10 g.; 3 mols.) was added to a suspension in acetic acid of 5 g. of *p*-nitrobenzaldehydephenylhydrazone (1 mol.), or when bromine (1 mol.) was added to *p*-nitrobenzaldehyde-2 : 4-dibromophenylhydrazone (1 mol.). It crystallises from acetic acid, in which it is sparingly soluble, in long, deep yellow needles, m. p. 214° (Found: Br, 50·2. $C_{13}H_8O_2N_3Br_3$ requires Br, 50·2%). When boiled with alkaline permanganate, the compound yielded *p*-nitrobenzoic acid, m. p. 238°.

By boiling the ω-bromohydrazones with sodium acetate in acetic acid α-acetyl-β-nitrobenzoylbromophenylhydrazines were obtained. These were recrystallised from alcohol, in which the monobromo-derivatives are more easily soluble than the dibromo-derivatives.

α-*Acetyl*-β-m-*nitrobenzoyl*-p-*bromophenylhydrazine*,

$$C_6H_4Br\cdot NAc\cdot NH\cdot CO\cdot C_6H_4\cdot NO_2,$$

was obtained from ω-bromo-*m*-nitrobenzaldehyde-*p*-bromophenylhydrazone as a colourless, amorphous solid which could not be made to crystallise. When boiled in alcohol with hydrochloric acid, it yielded acetic acid, *p*-bromophenylhydrazine, and *m*-nitrobenzoic acid.

α-*Acetyl*-β-m-*nitrobenzoyl*-2 : 4-*dibromophenylhydrazine* was obtained from ω-bromo-*m*-nitrobenzaldehyde-2 : 4-dibromophenylhydrazone, and also from β-*m*-nitrobenzoyl-2 : 4-dibromophenylhydrazine, by boiling with acetyl chloride. It forms colourless, compact prisms, m. p. 169° (Found: Br, 35·1. $C_{15}H_{11}O_4N_3Br_2$ requires Br, 35·0%). When boiled with alcohol and hydrochloric acid, it yielded acetic acid, 2 : 4-dibromophenylhydrazine, and *m*-nitrobenzoic acid.

α-*Acetyl*-β-m-*nitrobenzoyl*-2 : 4 : 6-*tribromophenylhydrazine* crystallises from acetic acid, in which it is moderately easily soluble, in fine, colourless prisms, m. p. 180° (Found: Br, 44·7. $C_{15}H_{10}O_4N_3Br_3$ requires Br, 44·8%). On boiling for 3 hours with hydrochloric acid and alcohol, it yielded *m*-nitrobenzoic acid and a colourless, oily liquid. This formed a crystalline hydrazone (m. p. 230°) with *m*-nitrobenzaldehyde, identical with acetyl-*m*-nitrobenzaldehyde-2 : 4 : 6-tribromophenylhydrazone,

$$C_6H_2Br_3\cdot NAc\cdot N{:}CH\cdot C_6H_4\cdot NO_2,$$

obtained by the acetylation of *m*-nitrobenzaldehyde-2 : 4 : 6-tribromophenylhydrazone. The original oily liquid must therefore have been α-acetyl-2 : 4 : 6-tribromophenylhydrazine.

α-*Acetyl*-β-p-*nitrobenzoyl*-p-*bromophenylhydrazine* crystallises in colourless prisms, m. p. 169—170° (Found : Br, 21·25. $C_{15}H_{12}O_4N_3Br$ requires Br, 21·2%). When boiled with alcohol and hydrochloric acid, it yielded acetic acid, *p*-nitrobenzoic acid, and *p*-bromophenylhydrazine.

α-*Acetyl*-β-p-*nitrobenzoyl*-2 : 4-*dibromophenylhydrazine* forms stout, colourless octahedral crystals, m. p. 201—202° (Found : Br, 35·2. $C_{15}H_{11}O_4N_3Br_2$ requires Br, 35·0%). When boiled with hydrochloric acid and alcohol, it yielded acetic acid, *p*-nitrobenzoic acid, and 2 : 4-dibromophenylhydrazine. The same compound was prepared by boiling β-*p*-nitrobenzoyl-2 : 4-dibromophenylhydrazine with acetyl chloride for a few minutes.

The following hydrazidines were prepared from the corresponding ω-bromohydrazones by warming them with alcoholic ammonia.

m-*Nitrobenzaldehyde*-p-*bromophenylhydrazidine*,

$$C_6H_4Br\cdot NH\cdot N{:}C(NH_2)\cdot C_6H_4\cdot NO_2,$$

separates from alcohol, in which it is moderately easily soluble, in fine, dark red plates, m. p. 145° (decomp.). The *hydrochloride* crystallises in colourless plates, m. p. 200° (decomp.).

m-*Nitrobenzaldehyde*-2 : 4-*dibromophenylhydrazidine* separates from alcohol, in which it is very sparingly soluble, in small, dark red plates, m. p. 182° (decomp.) (Found : Br, 38·8. $C_{13}H_{10}O_2N_4Br_2$ requires Br, 38·6%). The *hydrochloride* forms colourless leaflets, m. p. 225° (decomp.).

p-*Nitrobenzaldehyde*-p-*bromophenylhydrazidine* crystallises from alcohol, in which it is moderately easily soluble, in almost black needles, m. p. 155° (decomp.) (Found : Br, 24·0. $C_{13}H_{11}O_2N_4Br$ requires Br, 23·9%). Its *hydrochloride* crystallises in colourless plates, m. p. 210° (decomp.).

p-*Nitrobenzaldehyde*-2 : 4-*dibromophenylhydrazidine* crystallises from alcohol, in which it is moderately easily soluble, in dark bronze-red needles, m. p. 175° (Found : Br, 38·7. $C_{13}H_{10}O_2N_4Br_2$ requires Br, 38·6%). The *hydrochloride* forms colourless, compact, rhombic plates, m. p. 200° (decomp.).

The following is a brief description of the hydrazones and hydrazines employed in confirming the structure of the α-acetylphenylhydrazines :

Acetyl-m-*nitrobenzaldehyde*-2 : 4 : 6-*trichlorophenylhydrazone*, prepared by boiling *m*-nitrobenzaldehyde-2 : 4 : 6-trichlorophenylhydrazone for a short time with acetic anhydride, separates from alcohol, in which it is moderately easily soluble, in colourless, rectangular plates, m. p. 204° (Found : Cl, 27·4. $C_{15}H_{10}O_3N_3Cl_3$ requires Cl, 27·5%).

Acetyl-m-*nitrobenzaldehyde*-2 : 4 : 6-*tribromophenylhydrazone*, pre-

pared in a similar manner, crystallises from acetic acid, in which it is moderately easily soluble, in thick, colourless tablets, m. p. 230° (Found : Br, 46·0. $C_{15}H_{10}O_3N_3Br_3$ requires Br, 46·1%).

The following nitrobenzoylphenylhydrazines, prepared directly by the Schotten-Baumann method, were all crystallised from alcohol, in which they are moderately easily soluble.

β-m-*Nitrobenzoyl*-2 : 4 : 6-*trichlorophenylhydrazine ;* long, six-sided needles, m. p. 205° (Found : Cl, 29·6. $C_{13}H_8O_3N_3Cl_3$ requires Cl, 29·5%).

β-p-*Nitrobenzoyl*-2 : 4 : 6-*trichlorophenylhydrazine ;* stout, colourless plates, m. p. 203° (Found : Cl, 29·7. $C_{13}H_8O_3N_3Cl_3$ requires Cl, 29·5%).

β-m-*Nitrobenzoyl*-2 : 4-*dichlorophenylhydrazine ;* elongated, colourless plates, m. p. 196°.

β-m-*Nitrobenzoyl*-2 : 4-*dibromophenylhydrazine ;* colourless needles, m. p. 210° (Found : Br, 38·8. $C_{13}H_9O_3N_3Br_2$ requires Br, 38·5%).

β-p-*Nitrobenzoyl*-2 : 4-*dibromophenylhydrazine ;* pale yellow needles, m. p. 227°.

THE QUEEN'S COLLEGE, OXFORD. [*Received, March 18th,* 1925.]

CCXXVII.—*The Tautomerism of Dyads. Part IV. New Evidence of the Tautomeric Mobility of Oximes.*

By JOHN PREEDY GRIFFITHS and CHRISTOPHER KELK INGOLD.

THE purpose of this paper is to place dyad migration in oximes on a secure experimental basis such as has been provided in the cases of hydrogen cyanide, acetylene, and some monosubstitution products of the latter (E. H. Ingold, J., 1922, **121**, 1604; 1924, **125**, 1528; this vol., p. 1199), and to emphasise the suggestion, already made or foreshadowed by others (notably Brady and Dunn, J., 1916, **109**, 659; 1924, **125**, 291) that tautomerism of the dyad type, superimposed on the stereochemical theory of Hantzsch and Werner, constitutes the explanation of the isomerism and reactions of oximes.

$$[H]C{:}N \rightleftharpoons C{:}NH \qquad [H]C{:}\overset{|}{C} \rightleftharpoons C{:}\overset{|}{C}[H]$$

$$\text{(I.)}\quad [H]\overset{||}{N}{:}O \rightleftharpoons \overset{||}{N}{\cdot}O[H]\quad \text{(II.)} \qquad . \quad . \quad . \quad \text{(A)}$$

Whilst the retention of Hantzsch and Werner's stereochemical hypothesis is, for strong reasons, necessary to explain the isomerism of the oximes themselves, a structural addition to the theory is

just as imperatively required to account for their ethers (*Ann. Report*, 1924, p. 111).

(III.) $\begin{matrix} R\cdot C\cdot R' \\ \| \\ Alk\cdot N:O \end{matrix}$ (N-Ethers: *syn*- and *anti*-forms.)

$\begin{matrix} R\cdot C\cdot R' \\ \| \\ N\cdot OAlk. \end{matrix}$ (IV.) (O-Ethers: *syn*- and *anti*-forms.)

Formula (IV) for the O-ethers has long been generally approved, and, in view of evidence recently accumulated,* and of analogy with azoxy- and aliphatic diazo-compounds, no apology is necessary for using the "nitrone" formula (III), rather than the older *iso*oxime formula $\begin{matrix} RR'C—NAlk \\ \diagdown O \diagup \end{matrix}$, for the N-ethers.†

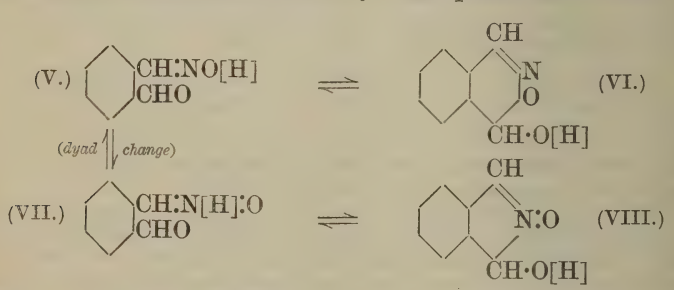
The study of tautomerism in numerous other cases has shown that the isolation of isomeric alkyl derivatives may be taken as an indication of the possibility of tautomeric interchange between parent hydrogen compounds of corresponding constitution. If, therefore, the structures given to the oxime-ethers (III) and (IV) be accepted, a *prima facie* case in favour of tautomerism of the dyad type between corresponding parent forms (I and II) is established (equation A).‡

Physical methods, which have the advantage of avoiding all the unknown disturbances attending the use of a chemical reagent, were applied to the problem; but, probably owing to the mobility of the oxime system, success was not achieved. Another method

* Thus towards diphenylketen, an almost universal reagent for double linkings, both the double bonds act separately (Staudinger and Miescher, *Helv. Chim. Acta*, 1919, **2**, 554):

$$>C:N:O \longrightarrow >C:N\begin{matrix}\diagup CPh_2 \\ \diagdown CO \\ \quad O\end{matrix} \longrightarrow CPh_2\begin{matrix}\diagup CO \\ \diagdown N \\ >C \quad O\end{matrix}\begin{matrix}\diagup CPh_2 \\ \diagdown CO.\end{matrix}$$

Many other examples might be given. Sugden's work (this vol., p. 1177) supplies strong confirmation from the physical side.

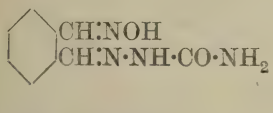


† If the nitrone structure be adopted, the existence of *syn*- and *anti*-N-ethers does not require an *ad hoc* extension of the Hantzsch-Werner hypothesis: it follows automatically from the optical resolution of amine-oxides, $R_1R_2R_3N:O$, just as the geometrical isomerism of ethylenes follows from the optical activity of methanes of the type $R_1R_2R_3R_4C$.

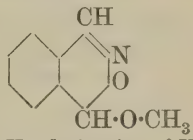
‡ It is not intended to preclude the intervention of the ring-form $\begin{matrix} >C—NR \\ \diagdown O \diagup \end{matrix}$ in certain decompositions, and, as an intermediate, in a few methods of formation of N-ethers and of oximes. Similarly, one cannot dismiss the nitroso-isomeride $>CH\cdot N:O$, which often constitutes an intermediate stage in reactions leading to oximes. All the available evidence shows, however, that these structures represent comparatively unstable oxime-forms, and may be looked upon as constituting minor ramifications of the tautomeric system, the main reversible reaction in which is, as will be shown, that represented by equation A.

of investigation was therefore sought, which, whilst still avoiding so far as possible, the complications arising from the use o reagents, would clearly and certainly distinguish between the tw expected forms and detect any equilibrium between them.

The object in view was ultimately attained by utilising th special properties of phthalaldehydemonoxime. This substance ordinarily represented by (V), contains all the essential feature which give ring-chain tautomeric character to a sugar, th residues –CH:O and –OH being present in such relative position that they can interact with the formation of an " oxide " rin and a " glucoside-yielding " hydroxyl group. If, therefore, th structure –CH:NOH, present in (V), be really one of the tauto meric forms of the oxime group, we should expect, just as in th case of a sugar, to be able to crystallise the cyclic tautomeric forn (VI). This individual, moreover, although a tautomeric substance should be sufficiently well differentiated chemically from any othe possible isomeride as to leave no doubt about its constitution, an therefore none about the particular oxime structure from whic it is derived.



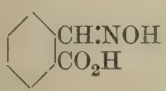
On the other hand, if an isomeride of the constitution (VII should also be present in any considerable quantity, the fact shoul be rendered evident by the tendency, possessed by this individua also, to pass into, and crystallise in the form of, its ring tautomeride (VIII). This structure, based on the *iso*indole ring system, als is strikingly differentiated from any other possible isomeride :



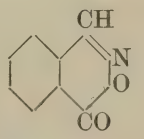
Thus the chemical differences to be expected from the simple dyad change (V) $\rightleftharpoons$ (VII) become magnified by the production, through ring closure, of the more distinctive structures (VI) and (VIII). At the same time, the mobile dyad equilibrium becomes partly " set " through association with the slower ring-chain changes. These are just the conditions which are required to render the dyad change open to experimental confirmation.

All these theoretical anticipations have been realised experimentally.

The ring form (VI), which was isolated in the crystalline condition, exhibited clear evidence of its constitution and of its structural analogy with the reducing sugars; it showed the usual aldehydic reactions (of the open-chain form V), yielding, for instance, the *semicarbazone* (IX), and also united readily with methyl alcohol, giving a *methyl* derivative *devoid of aldehydic properties*. This must therefore be derived from (VI) by the replacement of the bracketed hydrogen atom, and all its reactions, for instance, the ease with which it is hydrolysed back to the parent substance by a small quantity of mineral acid, emphasise its resemblance to a glucoside and leave no doubt as to the correctness of formula (X).



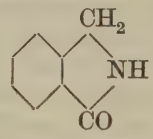
(IX; derivative of V.)



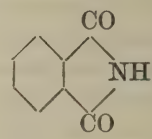
(X; derivative of VI.)

It is clear, therefore, that in solutions of the substance under discussion we have the ring-chain tautomeric system (V) $\rightleftharpoons$ (VI).

A closer study proved, moreover, that the principal phase in solution, as well as the solid substance itself, is represented by the ring-formula (VI). Thus, in contrast to the completeness and rapidity with which the "glucosidic" methyl derivative (X) is formed from freshly-prepared solutions of the parent, the aldehydic reactions of the latter, *e.g.*, the formation of the semicarbazone (IX), are noticeably sluggish: a solution of (VI), treated after some time with semicarbazide acetate, deposits a small quantity of the semicarbazone, but the complete precipitation of this substance requires a considerable period; and if a freshly-prepared solution of (VI) is used, no initial deposition is observed. It is noteworthy also that, although the main product of the oxidation of (VI) by cold neutral permanganate is *o*-carboxybenzaldoxime anhydride (XII), evidently derived directly from the ring compound, a small amount of the oxime-acid (XI), the normal product of oxidation of (V), is formed simultaneously. Observations of this kind make it quite evident that, as with sugars, the ring phase is the more stable one.

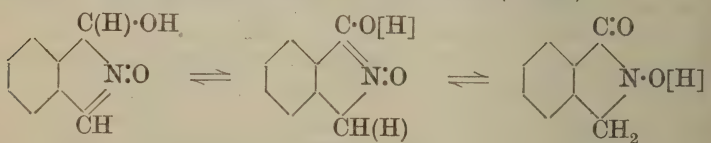


(XI; by-product.)



(XII; main product.)

Evidence of the existence of a second oxime structure (VII) was obtained by the isolation of a second ring-compound (VIII), which

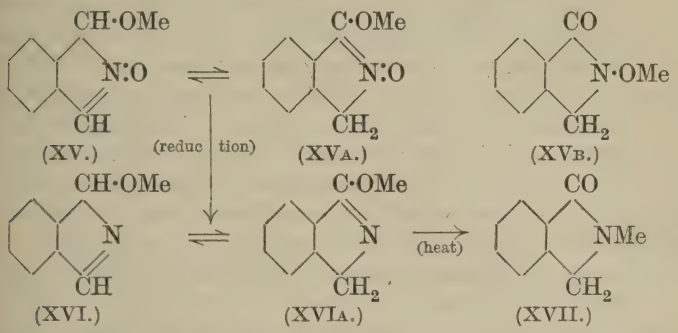


resembled the first in certain respects (for instance, in the absence from its methylation product of all aldehydic properties), but differed markedly from it in others. The key to its constitution was found in the fact that on reduction it gave phthalimidine (XIII), thus revealing the presence of the heterocyclic nucleus on which the anticipated formula (VIII) is based.

(XIII.) 

 (XIV.)

On oxidation phthalimide (XIV) was obtained.



Closer examination showed, however, that the substance is not adequately represented by formula (VIII) alone, but that it is capable of reacting in several forms. This is to be expected. Obviously a substance of formula (VIII) would be susceptible to the type of triad change which is apparently common to all compounds containing an unsaturated five-membered ring fused to the benzene nucleus, as in indene, benzimineazole, and aziminobenzene (Ingold and Piggott, J., 1922, **121**, 2381). The second individual involved in this kind of tautomeric interchange would have formula (VIIIA). This, however, contains a system of the type known to undergo the "tetrad" change into an *N*-hydroxy-isomeride (Bamberger, *Annalen*, 1920, **420**, 137), and it should therefore pass reversibly into an individual of the formula (VIIIB).

(VIII.) (VIIIA.) (VIIIB.)

There is experimental evidence favouring all these formulæ. First, whilst any of the three forms might yield phthalimidine on reduction, only (VIII) can adequately account for aldehydic reactions depending on the opening of the heterocyclic ring. In addition, however, the compound forms a yellow sodium salt and an intensely coloured iron salt; and (VIII) cannot account for this, although either of (VIIIA) and (VIIIB) can do so. Finally, the compound forms two isomeric *methyl* derivatives. One of these, the main product, is obviously an *N*-methoxy-compound, derived from (VIIIB), for, unlike its isomeride, it cannot be reduced to a phthalimidine without previous hydrolysis; this methyl derivative is therefore represented by formula (XVB). The second methyl derivative (by-product) is a *C*-methoxy-compound, derived from

either (VIII) or (VIIIA), as is proved by the fact that it yields *O-methylphthalimidine* (XVI or XVIA) on reduction; the by-product must therefore be represented either by (XV) or by (XVA), or, more probably, by both.

O-Methylphthalimidine readily passes into *N*-methylphthalimidine (XVII), a type of isomeric change which is not uncommon and has for long been exemplified by the transformation of cyanuric into *iso*cyanuric esters on heating.

Further details with regard to the cyclic and aldehydic reactions of the compounds (VI) and (VIII), and the conditions of their interconversion, will be found in the experimental portion of this paper; but the summary already given will be sufficient indication as to the manner in which the isolation and study of these compounds establishes the fundamental dyad change of the oxime group.

EXPERIMENTAL.

Phthalaldehyde was prepared by hydrolysing with aqueous alcoholic potassium oxalate the ωωω′ω′-tetrabromoxylene obtained by brominating boiling *o*-xylene (Thiele and Gunther, *Annalen*, 1906, **347**, 107).

1-*Hydroxy*-2 : 3-*benzoxazine* (VI).—Phthalaldehyde (13·4 g.), dissolved in 30 c.c. of methyl alcohol, was gradually mixed in the cold with an aqueous solution (200 c.c.) of hydroxylamine prepared from 6·9 g. of hydroxylamine hydrochloride and 5·4 g. of anhydrous sodium carbonate. After a few minutes, the solution was extracted with much ether, and the extract washed with water, dried with calcium chloride by shaking, concentrated, and seeded with a crystal of hydroxybenzoxazine obtained from a previous experiment, when the substance crystallised (70% yield). A further quantity could be obtained from the ethereal mother-liquor, which also contained, however, some of the isomeric hydroxy*iso*indole oxide. Extraction of the aqueous mother-liquor with ethyl acetate yielded

a further quantity of the latter substance. If, however, at an stage of these extractions the aqueous solution was set aside fo a time, the unextracted material became converted into the methoxy benzoxazine described below.

On one or two occasions the preparation of hydroxybenzoxazin by the process described above failed for reasons that we have no been able to discover, almost the sole product being hydroxy*iso* indole oxide. Other cases of failure, resulting in the productio of the methoxy-compound, were traced to undue delay in pro ceeding with the extraction or removing the methyl alcohol fron the ethereal extract. On the other hand, during the preliminary experiments the desired hydroxybenzoxazine could sometimes b produced under quite a variety of conditions (see p. 1705).

1-*Hydroxy*-2 : 3-*benzoxazine* separates from ether–ligroin in prisms m. p. 114—115° (Found: C, 64·5; H, 4·7; N, 9·5. $C_8H_7O_2N$ requires C, 64·4; H, 4·7; N, 9·4%). It is very soluble in ethy acetate, easily soluble in chloroform or ether, but almost insoluble in ligroin. It reduces Fehling's solution. Its action towards methy and ethyl alcohols, oxidising agents, and other ketone reagents is described below. Attempts were made to reduce it both in acid and in alkaline solution under various conditions, including those described on pp. 1706–7, but without success, deeply coloured amorphous products being obtained which could not be purified No phthalimidine was obtained.

1-*Methoxy*-2 : 3-*benzoxazine* (X).—This may be obtained (*a*) by leaving phthalaldehyde in contact with hydroxylamine (1 mol.) in 30% methyl alcohol, when the compound crystallises; (*b*) from hydroxybenzoxazine by boiling with methyl alcohol, preferably in the presence of a trace of hydrochloric acid; (*c*) from hydroxy-*iso*indole oxide by digesting for several days with faintly acidified aqueous methyl alcohol, and then diluting. It separates from ether in glistening plates, m. p. 77° (Found: C, 66·3; H, 5·6; N, 8·7. $C_9H_9O_2N$ requires C, 66·3; H, 5·5; N, 8·6%). It is hydrolysed with great ease with dilute hydrochloric acid, giving hydroxy-benzoxazine.

1-*Ethoxy*-2 : 3-*benzoxazine* was prepared like the methoxy-compound, ethyl alcohol being used in place of methyl alcohol. It was obtained crystalline, but, as it tended to separate as an oil from all solvents in which it was not extremely soluble, it was not purified for analysis.

Phthalaldehyde-1-*oxime*-2-*semicarbazone* (IX).—The formation of this substance from hydroxybenzoxazine was studied in some detail and the main results have already been described (p. 1701). The semicarbazone itself can be purified in small quantities by rapid

crystallisation from ethyl acetate, from which a microcrystalline powder separates, m. p. 235° (decomp.) (Found: C, 52·7; H, 5·0. $C_9H_{10}O_2N_4$ requires C, 52·4; H, 4·9%).

Phthalaldehyde-1-*oxime*-2-p-*nitrophenylhydrazone*, prepared from hydroxybenzoxazine like the corresponding semicarbazone, and also from hydroxy*iso*indole oxide by digesting with *p*-nitrophenylhydrazine in acetic acid solution, separated from ethyl acetate in small, yellow prisms, m. p. 175° (decomp.) (Found: C, 59·0; H, 4·4. $C_{14}H_{12}O_3N_4$ requires C, 59·2; H, 4·2%).

Oxidation of 1-*Hydroxy*-2 : 3-*benzoxazine: Formation of* o-*Carboxybenzaldoxime and its Anhydride* (XI and XII).—The hydroxybenzoxazine, dissolved in pure ether, was shaken with successive small quantities of 1% potassium permanganate solution (in all, equiv. to 1 atom of oxygen) containing an excess of magnesium sulphate, the mixture was filtered, extracted with ether, and the aqueous solution acidified and again extracted. *o*-Carboxybenzaldoxime anhydride was recovered from the first extract and was identified by its m. p. (186°) and by its conversion into phthalimide on heating. The small amount of *o*-carboxybenzaldoxime obtained from the second extract was identified by its m. p. (120°) and by converting it into the anhydride.

1(*or* 3)-*Hydroxy*iso*indole*-2-*oxide* (N-*Hydroxyphthalimidine*) (VIII, etc.).—It is difficult to give precise directions for the preparation of this substance, for not only was it frequently obtained as almost the sole product on repeating as exactly as possible an experiment which had previously yielded hydroxybenzoxazine, but, on other occasions, attempts to repeat a successful preparation of hydroxy*iso*indole oxide gave hydroxybenzoxazine instead. It is believed that accidental seeding is, at any rate partly, responsible for these erratic results. Two circumstances, however, appear definitely to increase the chances of producing hydroxy*iso*indole oxide, namely, (*a*) the presence of alkalis, (*b*) a high temperature. Condition (*a*) can readily be understood, since hydroxy*iso*indole oxide yields a rather stable sodium salt, the formation of which would disturb any equilibrium involving hydroxy*iso*indole oxide, in such a way as to favour the ultimate isolation of this substance at the expense of hydroxybenzoxazine. Condition (*b*) is explicable if, in the dyad equilibrium between (V) and (VII) (p. 1700), a rise of temperature favours the (usually) less permanent form (namely, VII) just as in the cases of hydrogen cyanide and acetylene. The following typical experiments illustrate the employment of these two methods.

(i) The procedure leading to the formation of hydroxybenzoxazine (p. 1703) was repeated, excepting that 6·5 g. of anhydrous sodium

carbonate were employed instead of 5·4 g., the solution being neutralised before the extraction, which was carried out with chloroform in place of ether.

(ii) The procedure detailed on p. 1703 was followed with the exception that all solutions were previously heated at 60°, and mixed at this temperature. The extraction was carried out with ethyl acetate instead of ether, the extract being washed with water and roughly dried by sodium sulphate before evaporation.

The same substance can also be prepared by allowing hydroxybenzoxazine to remain dissolved in solvents (other than alcohols or ketones), or by digesting it with dilute aqueous sodium carbonate and acidifying. 1-Hydroxy*iso*indole-2-oxide separates from chloroform in well-defined prisms, m. p. 181° (Found : C, 64·3; H, 4·8; N, 9·4. $C_8H_7O_2N$ requires C, 64·4; H, 4·7; N, 9·4%). It is readily soluble in chloroform or ethyl acetate, sparingly soluble in ether, and nearly insoluble in water or ligroin. It is soluble in dilute mineral acids, giving colourless solutions, and it is also dissolved by aqueous sodium carbonate (or sodium hydroxide), giving a yellow solution containing a sodium salt, which is precipitated as a yellow powder when an ethyl acetate solution of the hydroxy-compound is mixed with ethereal-alcoholic sodium ethoxide. Ferric chloride gives an intense violet colour, the reaction constituting a delicate test for the substance in dilute solution. It also readily reduces Fehling's solution on warming, and, on digesting with an acetic acid solution of *p*-nitrophenylhydrazine acetate, gives the hydrazone above mentioned. Its action towards oxidising and reducing agents and its behaviour on methylation are described below.

Reduction of 1-*Hydroxy*iso*indole-2-oxide to Phthalimidine* (XIII).—(i) The substance (1 g.), dissolved in 3 c.c. of methyl alcohol, was treated gradually at 50—60° with 32 g. of 3% sodium amalgam, the solution being kept only faintly alkaline by successive additions of glacial acetic acid. After removal of the mercurial layer, the liquid was evaporated to dryness in a vacuum, and the solid residue extracted with warm ethyl acetate, from which crystals of nearly pure phthalimidine separated (m. p. 145—149°). On crystallisation from benzene, it had the correct m. p. (150—151°), and it was then definitely identified by analysis (Found : C, 71·9; H, 5·5. Calc., C, 72·2; H, 5·5%), and by conversion into its nitroso-derivative (m. p. 156°).

(ii) The hydroxy*iso*indole oxide was dissolved in dilute acetic acid and treated with an excess of zinc dust, added sufficiently rapidly to bring the solution to its boiling point towards the end of the process. An excess of ammonia was then added and the

solution extracted with ether, when an almost quantitative yield of phthalimidine was obtained.

(iii) Hydroxy*iso*indole oxide was dissolved in dilute acetic acid and treated with sodium amalgam in the cold, glacial acetic acid being added as required to keep the solution acid. The mercury was separated, an excess of sodium hydroxide added, and the phthalimidine extracted with ether (yield nearly quantitative).

Oxidation of 1-*Hydroxy*iso*indole*-2-*oxide to Benzaldoxime*-o-*carboxylic Acid* (XI) *and Phthalimide.*—This oxidation was carried out like that described on p. 1705 excepting that ethyl alcohol was used in place of ether and that no magnesium sulphate was added. No product was obtained on extracting the filtered solution with ether, but on acidifying and again extracting, a mixture of phthalimide and benzaldoxime-*o*-carboxylic acid was obtained, from which the former was readily separated owing to its smaller solubility in water.

N-*Methoxyphthalimidine* (IXB).—The hydroxy*iso*indole oxide was dissolved in methyl alcohol and treated with the theoretical quantity of methyl-alcoholic sodium methoxide, and then with twice the theoretical amount of methyl iodide. After heating on the water-bath for ½ hour, the excess of methyl iodide and the methyl alcohol were evaporated and the residue was mixed with water and extracted with ether, from which, on evaporation, long needles were obtained, m. p. 74° after crystallisation from ether–ligroin (a mixture with the isomeric methoxy-compound of m. p. 77° melted at 45°) (Found: C, 66·1; H, 5·6. $C_9H_9O_2N$ requires C, 66·3; H, 5·5%). The substance is readily soluble in benzene, ethyl acetate, chloroform, or ether, moderately soluble in ligroin, and insoluble in water. It does not dissolve in alkalis, gives no colour with ferric chloride, does not reduce Fehling's solution, and gives no condensation products with semicarbazide or the arylhydrazines.

Reduction of N-*Methoxyphthalimidine to Phthalimidine.*—Attempts to reduce this substance in neutral solution with zinc dust, ammonium chloride and aqueous methyl alcohol, or in water or dilute acetic acid with sodium amalgam, resulted in the recovery of unchanged material. Reduction took place, however, with tin and hydrochloric acid, and, on pouring the solution into an excess of alkali and extracting with ether, phthalimidine was obtained.

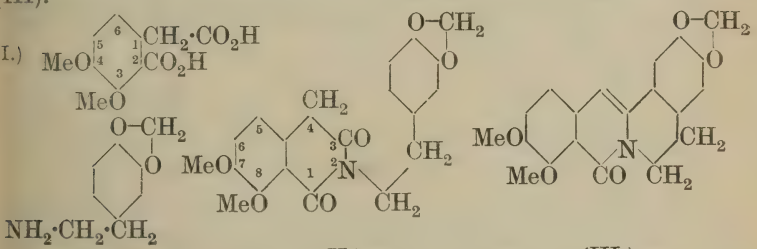
Oxidation of N-*Methoxyphthalimidine to Hydroxy*iso*indole Oxide and Phthalimide.*—The oxidation was carried out in neutral solution by permanganate in presence of magnesium sulphate as described on p. 1705, excepting that sufficient permanganate solution was used to supply three atoms of oxygen. On extraction with ether, a mixture of hydroxy*iso*indole oxide and phthalimide was obtained,

which were separated from each other by fractional crystallisation from ethyl acetate and identified by direct comparison with authentic specimens.

1(*or* 3)-*Methoxy*isoindole-2-*oxide* (IX or IXa) was obtained from the ultimate ether and ether–ligroin residues obtained in the methylation experiment described on p. 1707. The residues from several such experiments were evaporated and then extracted repeatedly with hot ligroin (b. p. 60—70°). On cooling in a freezing mixture, small prisms separated, m. p. 52—53° after softening at 48°, and from the oily residue obtained by evaporation of the ligroin a further quantity of the same substance was isolated by seeding (Found : C, 66·0; H, 5·7. $C_9H_9O_2N$ requires C, 66·3; H, 5·5%). It is readily soluble in all organic solvents, even ligroin, but insoluble in water. It is also insoluble in sodium carbonate solution, but readily soluble in dilute acids. It does not give a colour with ferric chloride, does not reduce Fehling's solution, and gives no condensation products with semicarbazide or the aryl-hydrazines.

*Reduction of Methoxy*isoindole-2-*oxide to* o-*Methylphthalimidine* (XV or XVa).—The substance was treated with successive quantities of zinc dust in a boiling aqueous methyl-alcoholic solution of ammonium chloride, and the filtered solution was evaporated to remove methyl alcohol and extracted with ether. The residue from the ether yielded crystals, which, after draining, melted at about 40°, but owing to their tendency to liquefy under all solvents in which they were not extremely soluble, they were not recrystallised (Found : C, 73·0; H, 6·4. C_9H_9ON requires C, 73·4; H, 6·1%). The constitution of the substance was established by the observations (i) that, on boiling with concentrated hydrochloric acid, it yields phthalimidine, (ii) that, on heating in an open tube until visible decomposition commences, *N*-methylphthalimidine (XVI) is produced. The latter substance was isolated by crystallisation from ether and identified by direct comparison with a specimen prepared by the reduction of *N*-methylphthalimide.

*Oxidation of Methoxy*isoindole-2-*oxide to Phthalimide.*—This oxidation was carried out like that described on p. 1705, using, however, sufficient permanganate to supply rather more than four atoms of oxygen. On working up the product, phthalimide was obtained and identified in the usual way.



The authors desire to thank the Chemical Society for a grant with the aid of which the expenses of this investigation have been met.

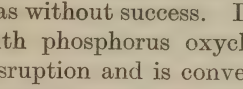
CCXXVIII.—*Synthetical Experiments in the* iso-*Quinoline Group. Part V. Synthesis of Substances allied to Oxyberberine.*

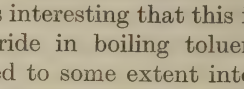
By Robert Downs Haworth, William Henry Perkin, jun., and Herbert Sheppard Pink.

During the course of these synthetical experiments in the group of the berberine alkaloids, it was thought probable that 3 : 4-dimethoxyhomophthalic acid (I) would condense with homopiperonylamine (Ia) with the formation of 2-*homopiperonyl*-7 : 8-*dimethoxyhomophthalimide* (II) and that this substance, under the influence of a suitable dehydrating agent, might yield oxyberberine (III).



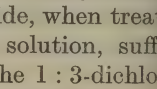
(I.) (Ia.) (II.) (III.)

This plan is independent of, but on similar lines to, the successful synthesis of oxyberberine by Perkin, Ray, and Robinson (this vol., p. 740) and as we have now succeeded with its aid in preparing several substances allied to oxyberberine, there can be little doubt that, when it is extended, it will ultimately lead to the synthesis not only of oxyberberine but also of oxypalmatine and allied substances and therefore indirectly to the synthesis of the corresponding alkaloids. The 3 : 4-dimethoxyhomophthalic acid required for the suggested synthesis was unknown and, while we were working out a method for its preparation, we decided to carry out a preliminary investigation with homophthalic acid itself and with 4 : 5-dimethoxyhomophthalic acid, both of which were available.



Homophthalic acid may be made from phthalide and potassium cyanide (Wislicenus, *Annalen*, 1886, **233**, 102), a method which, owing to the difficulty in controlling the temperature of interaction, can only be used on a small scale. It may also be prepared by the action of phosphorus pentachloride on 2-*iso*nitroso-1-hydrindone, as described by Perkin and Robinson (J., 1907, **91**, 1073), but the best method is that recommended by Ingold and Piggott (J., 1923, **123**, 1483), namely, from 1-hydrindone by oxidation.

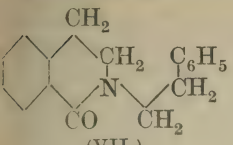
Homophthalic acid condenses readily with β-phenylethylamine

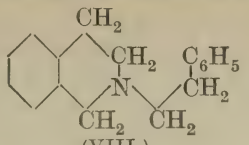


to give 2-β-*phenylethylhomophthalimide* (IV), which dissolves i alkali to a yellow solution with a green fluorescence and condens with aldehydes at the $-CH_2 \cdot CO-$ group. When treated with methy iodide and sodium hydroxide, it yields the 4 : 4-*dimethyl* derivativ (V) and all attempts to obtain the monomethyl derivative, whic would have been useful in the synthesis of substances of the coryd aline type, were unfortunately unsuccessful. A series of experi ments, made with the object of converting this imide into th parent of oxyberberine (X, oxyprotoberberine, compare this vol. p. 1462) by the action of dehydrating agents such as hydroge chloride, thionyl chloride, phosphorus pentoxide or oxychloride was without success. It is interesting that this imide, when treate with phosphorus oxychloride in boiling toluene solution, suffer disruption and is converted to some extent into the 1 : 3-dichloro *iso*quinoline (VI) described by Gabriel (*Ber.*, 1886, **19**, 1655).

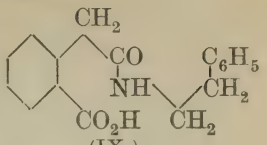
(IV.)

(V.)



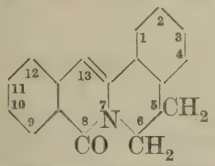


(VI.)

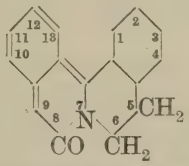


The stability of the imide (IV) to dehydrating agents is probably due to the carbonyl group in the 1-position in the *iso*quinoline ring and attempts were made to reduce this group without reducing the carbonyl group in the 3-position. It was found that zinc dust and sodium amalgam have no action on alkaline solutions of the imide under mild conditions and that, under vigorous conditions, it slowly undergoes hydrolysis. The imide may, however, be reduced electrolytically to a mixture of 2-β-*phenylethyl*-3 : 4-*dihydro*-1-iso*quinolone* (VII) and 2-β-*phenylethyl*-1 : 2 : 3 : 4-*tetrahydro*iso-*quinoline* (VIII). The former is insoluble in alkali, does not condense with aldehydes or suffer internal condensation when it is treated with phosphorus oxychloride, and cannot therefore be the isomeric 3-*iso*quinolone. It is clearly the carbonyl group in the 3-position in the imide which is the more readily reducible and, so far, it has not been found possible to leave this intact and reduce the group in the 1-position. Experiments are, however, in progress with the object of preparing the 3-keto-derivative synthetically.

When the imide (IV) is heated for several hours with sodium hydroxide, the yellow colour gradually disappears and an N-β-*phenylethylhomophthalamic acid* is produced which probably has structure (IX), but direct evidence of this view of its constitution is not yet available (compare, however, Gabriel and Posner, *Ber.*, 1894, **27**, 2504).

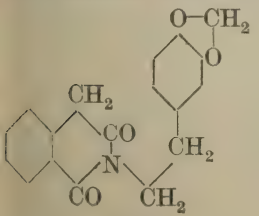


Further experiments on this point are in progress.

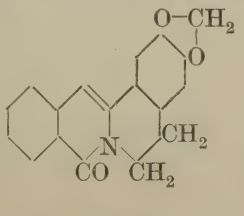


(VII.)

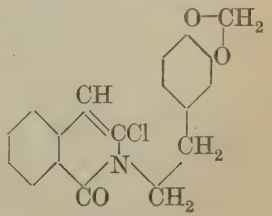
(VIII.)



(IX.)

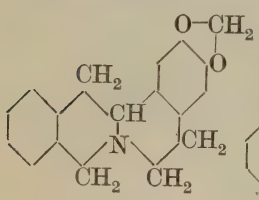


The *methyl* ester of the acid (IX) yields, on treatment with phosphorus oxychloride, a small quantity of a substance (m. p. 234°) which has the composition, $C_{17}H_{13}ON$, of oxyprotoberberine (X). The bright yellow colour of this substance is, however, not in accord with this structure and we are of the opinion that it is the *oxy*iso*protoberberine* of the formula (XI; compare XVIII), but the detailed investigation of this substance was rendered difficult on account of the small yield obtained.



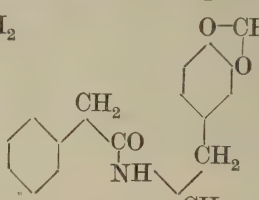
(X.) 

(XI.)



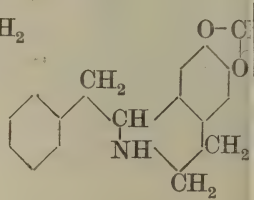
It is well known that derivatives of *iso*quinoline are formed with difficulty from unsubstituted β-phenylethylamine derivatives and that ring closure is much facilitated by the introduction of methoxy- or methylenedioxy-groups. With the view of obtaining increased yields of substances similar to those just described, a series of experiments was next carried out using homopiperonylamine (Ia) in the place of β-phenylethylamine, and 2-*homopiperonylhomophthalimide* (XII) was readily obtained by condensing this with homophthalic acid. It is curious that this imide could not be converted into a substance of the oxyberberine type (XIII) by the action of dehydrating agents and also that, while the imide (IV) yields 1 : 3-dichloro*iso*quinoline (VI) on treatment with phosphorus oxychloride, the imide (XII) does not suffer disruption under these conditions but is converted into 3-*chloro*-2-*homopiperonyl*-1-iso*quinolone* (XIV). Attempts to convert this chloro-derivative into the substance (XIII) by treatment with copper powder and quinoline were unsuccessful.

(XII.)



(XIII.)

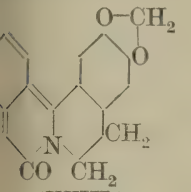
(XIV.)

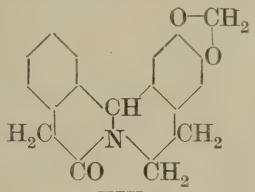


The imide (XII) is converted into the corresponding N-β-*hom*
piperonylhomophthalamic acid (compare IX) on warming with alk
and the investigation of the action of phosphorus oxychloride on
methyl ester of this acid has given interesting results. Two s
stances, *A* and *B*, are produced and of these, *A* (m. p. 180°)
colourless, feebly basic substance, has all the properties to
expected of 2 : 3-*methylenedioxyoxyprotoberberine* (XIII). It m
be reduced electrolytically to the corresponding 2 : 3-*methyle*
dioxytetrahydroprotoberberine (XV, m. p. 129°).

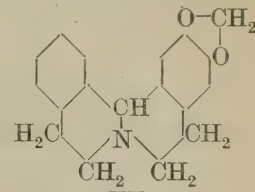
(XV.)

(XVI.)



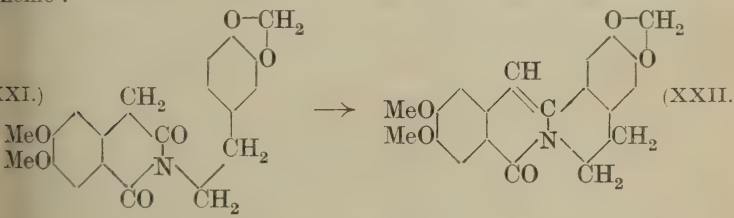


(XVII.)



The correctness of the expression (XIII) for the substance *A* receiv
confirmation from the following independent synthetical expe
ments. *N*-Phenylacetylhomopiperonylamine (XVI), prepared
the method described by Decker (*Annalen*, 1913, **395**, 294), w
converted, by treatment with phosphorus oxychloride, into 6 :
methylenedioxy-1-*benzyl*-3 : 4-*dihydro*isoquinoline, and this reduc
to 1-*benzyl*nor*hydrohydrastinine* (XVII). This base, owing doubtle
to the absence of methoxy-groups in the ring, does not condense wi
formaldehyde and hydrochloric acid, and heating with formaldehy
and formic acid in a sealed tube leads exclusively to the formation
the N-*methyl* derivative (benzylhydrohydrastinine, p. 1721). Whe
however, the *N*-formyl derivative of the base (XVII) is treated wi
phosphorus oxychloride, it yields 2 : 3-*methylenedioxydihydroprotobe*
berine and this, on reduction, is converted into the tetrahydr
derivative, which melts at 129° and is identical with the substan
(XV) produced by the reduction of *A*. Consequently, *A* mu
have the constitution (XIII).* The second substance, *B*, produce
by the action of phosphorus oxychloride on the methyl ester
N-β-homopiperonylhomophthalamic acid (see above), has properti
similar to those of oxy*iso*protoberberine (XI) and it is suggeste
that it is 2 : 3-*methylenedioxyoxy*iso*protoberberine* (XVIII). It is

* If further evidence is required, it is supplied by the fact that 2 :
methylenedioxytetrahydroprotoberberine, on treatment with iodine followe
by silver chloride, yields the corresponding protoberberinium chloride, whic
is decomposed by alkalis, in the same manner as ordinary berberinium chlorid
yielding 2 : 3-methylenedioxydihydroprotoberberine and 2 : 3-methylened
oxyoxyprotoberberine, the latter being identical with *A* (compare p. 1723).



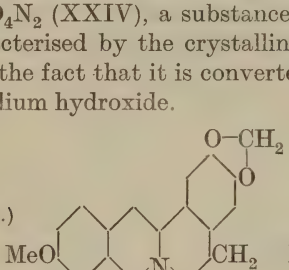
arlet, crystalline substance (m. p. 225°), dissolving with difficulty hydrolytic solvents, from which it separates in the hydrated form orange needles which lose weight at 100° and are converted into ie scarlet, anhydrous substance. On electrolytic reduction, the arlet substance is first converted into the colourless 2 : 3-*methylene*-*oxyoxydihydro*iso*protoberberine* (XIX) and then into 2 : 3-*methylene*-*oxytetrahydro*iso*protoberberine* (XX) isomeric with the substance XV).

(XVIII.)

(XIX.)

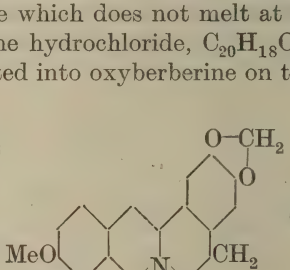
(XX.)

Synthesis of Oxy-ψ-berberine (compare Haworth, Perkin, and ankin, J., 1924, **125**, 1691).—This synthesis, indicated by the heme :



(XXI.) (XXII.)

as carried out in the following manner. 2-*Homopiperonyl*-6 : 7-*methoxyhomophthalimide* (XXI), prepared from 4 : 5-dimethoxy-omophthalic acid and homopiperonylamine, was converted, by ydrolysis with alkali, into the corresponding amic acid (compare X). When the *methyl* ester of this acid was treated with phos-horus oxychloride, it gave a 70% yield of a substance melting at 8° which was identical with the oxy-ψ-berberine described by aworth, Perkin, and Rankin. It is interesting that no isomeride this substance could be detected in the product of the interaction the methyl ester with phosphorus oxychloride. The imide XXI), on treatment with phosphorus oxychloride, behaves similarly 2-homopiperonylhomophthalimide (XII), yielding 3-*chloro*-2-*mopiperonyl*-6 : 7-*dimethoxy*-1-iso*quinolone* (compare XIV).



At the commencement of this research it became necessary to termine whether substances of the oxyberberine type are stable wards phosphorus oxychloride, that is to say, whether they are pable of formation in the presence of this reagent. Experiment owed that oxyberberine is readily acted on by phosphorus oxy-

chloride, two substances being formed, namely, methyl*nor*ox berberine (Faltis, *Monatsh.*, 1910, **31**, 573; Bland, Perkin, a Robinson, J., 1912, **101**, 262; compare this vol., p. 744) and chloro-derivative which clearly has the constitution (XXII because, when treated with ammonia, it yields *iminoberer* $C_{20}H_{18}O_4N_2$ (XXIV), a substance which does not melt at 280° a is characterised by the crystalline hydrochloride, $C_{20}H_{18}O_4N_2,H($ and by the fact that it is converted into oxyberberine on treatme with sodium hydroxide.

(XXIII.)

(XXIV.)

During the synthesis of oxy-ψ-berberine described above, crystalline chloro-derivative was also obtained in small quanti which, since it yielded oxy-ψ-berberine on treatment with sodiu hydroxide, was clearly the derivative corresponding to (XXIII).

Experimental.

β-*Phenylethylamine*.—β-Phenylpropionamide was prepared the following method, which gives good results and does not seem have been previously described. β-Phenylpropionyl chloride (p pared by boiling phenylpropionic acid with a slight excess of thion chloride and distilling the product under reduced pressure), d solved in dry benzene, is saturated with dry ammonia, and t mixture of ammonium chloride and the amide recrystallised fro hot water with the aid of animal charcoal. The amide separat in colourless leaflets (m. p. 105°) and is sufficiently pure for co version into β-phenylethylamine by means of sodium hypochlori (Decker, *Annalen*, 1913, **395**, 291).

β-3 : 4-*Dimethoxyphenylpropionic Acid*.—Veratraldehyde (100 g malonic acid (130 g.), and piperidine (5 c.c.) were heated in pyridi solution (250 c.c.) for 1½ hours on the steam-bath, during whi rapid elimination of carbon dioxide took place, and the reaction w completed by boiling for 10 minutes. The product, on pouring in excess of dilute hydrochloric acid, gave an almost quantitati yield of 3 : 4-dimethoxycinnamic acid, which was reduced to 3 : dimethoxyphenylpropionic acid by sodium amalgam under t conditions described by Perkin and Robinson (J., 1907, 9 1079).

2-β-*Phenylethylhomophthalimide* (IV).—β-Phenylethylamine ydrochloride (15·6 g.) is dissolved in water, the base liberated with otassium hydroxide, extracted with benzene, dried over potassium ydroxide, mixed with homophthalic acid (18 g.), and heated in an il-bath at 180° for 3 hours. The product is dissolved in boiling lcohol and cooled, when the *imide* (IV) separates in almost colour-ss prisms (19 g.) and is sufficiently pure for most purposes. After second crystallisation from alcohol, it was obtained in colourless risms, m. p. 128—129° (Found: C, 77·0; H, 5·8. $C_{17}H_{15}O_2N$ equires C, 77·0; H, 5·7%).

2-β-Phenylethylhomophthalimide (IV) is insoluble in water, paringly soluble in ether, and readily soluble in hot alcohol or cetic acid. It dissolves in sodium hydroxide to a yellow solution ith a green fluorescence and is reprecipitated by saturation with arbon dioxide. If, however, the alkaline solution is warmed for veral hours, the colour disappears and the imide is no longer recipitated by carbon dioxide.

The imide (1 g.) was heated in a sealed tube with phosphorus xychloride (3 c.c.) at 140—150° for 3 hours, the excess of oxy-hloride removed by distillation under reduced pressure, the residue ixed with sodium hydroxide, and the solid collected. This ubstance crystallised from methyl alcohol containing animal harcoal in colourless needles (m. p. 123°) and was evidently identical ith the 1 : 3-dichloro*iso*quinoline (VI) obtained by Gabriel (*loc. cit.*) Found: C, 54·8; H, 2·6. Calc., C, 54·5; H, 2·5%).

2-β-*Phenylethyl*-4 : 4-*dimethylhomophthalimide* (V).—2-β-Phenyl-hylhomophthalimide (2 g.) was dissolved in a solution of sodium ·35 g.) in alcohol (7 c.c.) and water (10·5 c.c.), methyl iodide (3 g.) dded, and the mixture gently boiled until the green fluorescence ad disappeared. Some of the alcohol was removed by distillation, he residue mixed with water, the precipitated oil extracted with her, the extract dried over anhydrous magnesium sulphate, aporated, and the oil distilled under 10 mm., when a colourless stillate was obtained which solidified on prolonged rubbing ith petroleum (Found: C, 77·7; H, 6·5. $C_{19}H_{19}O_2N$ requires 77·8; H, 6·5%). This dimethyl derivative crystallises from queous alcohol in colourless needles (m. p. 60—61°) and is readily luble in ether, but sparingly soluble in petroleum and insoluble sodium hydroxide. That the methyl groups in (V) are both tached to carbon is shown by the fact that no methyl iodide is tained when the substance is boiled with hydriodic acid.

2-β-*Phenylethyl*-3 : 4-*dihydro*-1-iso*quinolone* (VII). 2-β-Phenyl-hylhomophthalimide (2 g.), dissolved in a mixture of alcohol 0 c.c.) and concentrated sulphuric acid (40 c.c.), was placed in the

cathode compartment of an electrolytic cell, the cathode of which consisted of a piece of lead (150 sq. cm. surface) and the anode of a sheet of lead surrounded by sulphuric acid (20%). After a current of 5 amperes had been passed for 16 hours, the solution was diluted with water, extracted with chloroform, the extract dried over potassium carbonate, the solvent removed, and the residue crystallised from ether–petroleum (b. p. 40—60°), separating in colourless needles, m. p. 77—78° (Found: C, 81·3; H, 7·0. $C_{17}H_{17}ON$ requires C, 81·3; H, 6·8%). 2-β-*Phenylethyldihydroisoquinolone* is very soluble in organic solvents with the exception of petroleum, insoluble in dilute acids or alkalis, and will not condense with aldehydes in the presence of sodium ethoxide or piperidine.

2-β-*Phenylethyl*-1 : 2 : 3 : 4-*tetrahydroisoquinoline* (VIII).—The acid mother liquors from the preparation of the *iso*quinolone (see above) were made strongly alkaline with sodium hydroxide, extracted with chloroform, the extract dried over potassium carbonate, and the chloroform removed, when a basic oil remained which did not crystallise. This dissolved completely in dilute hydrochloric acid and, on concentrating, the *hydrochloride* crystallised; it separated from alcohol–ether in long, colourless needles, m. p. 227—229° (Found: C, 74·8; H, 7·4. $C_{17}H_{19}N,HCl$ requires C, 74·6; H, 7·3%).

N-β-*Phenylethylhomophthalamic Acid* (IX).—2-β-Phenylethyl homophthalimide (1·3 g.) was heated with *N*-sodium hydroxide (10 c.c.) for 12 hours on the steam-bath, when the imide dissolved and the yellow colour of the solution gradually disappeared. After cooling, the unchanged imide was precipitated by carbon dioxide and the filtrate acidified with concentrated hydrochloric acid; the straw-coloured gum, which soon hardened, crystallised from benzene in colourless needles, m. p. 122—123° (Found: C, 72·2; H, 5·9 $C_{17}H_{17}O_3N$ requires C, 72·1; H, 6·0%). This acid is readily soluble in alcohol, ether, or benzene, sparingly soluble in water or petroleum and dissolves in sodium bicarbonate with effervescence.

The *methyl* ester. When a methyl-alcoholic solution of the acid is saturated with dry hydrogen chloride, only a small yield of the methyl ester is obtained, the main product being the imide (IV), but the methyl ester may be obtained in a yield of 60% in the following way. The amic acid (2·8 g.), dissolved in a solution of sodium carbonate (0·53 g.) in water (50 c.c.), is mixed with a strong solution of silver nitrate (1·7 g.) and, after remaining for 2 hours in the dark, the silver salt is collected and thoroughly dried in a vacuum desiccator over sulphuric acid. The powdered salt, suspended in dry ether, is boiled under reflux with methyl iodide (2 g.) for 8 hours, and the solution is filtered and concentrated

when the *methyl* ester separates in colourless prisms, m. p. 74—75° (Found : C, 72·9 ; H, 6·5. $C_{18}H_{19}O_3N$ requires C, 72·7 ; H, 6·4%).

*Oxy*iso*protoberberine* (XI).—The above methyl ester (1 g.) was boiled with phosphorus oxychloride (2 c.c.) and toluene (5 c.c.) for an hour, hydrogen chloride being evolved and a brown gum separating. The product was diluted with petroleum (b. p. 40—60° ; 100 c.c.), the clear liquid, which contained considerable quantities of the imide (IV), decanted, the brown gum dissolved in alcohol, mixed with sodium hydroxide, and the dark insoluble substance collected. It separated from glacial acetic acid in yellow needles, m. p. 234° (Found : C, 83·3 ; H, 5·2. $C_{17}H_{13}ON$ requires C, 82·6 ; H, 5·3%). *Oxy*iso*protoberberine* is a weak base, dissolving in strong acids and being reprecipitated on dilution with water. It is sparingly soluble in organic solvents and its solutions in alcohol and glacial acetic acid exhibit an intense green fluorescence. The yield of this substance under the most favourable conditions is very small and in many experiments it could not be isolated at all.

2-*Homopiperonylhomophthalimide* (XII).—Homopiperonylamine was heated with homophthalic acid under conditions similar to those already described in the preparation of the imide (IV ; p. 1715). The product separates from alcohol or glacial acetic acid in colourless needles, m. p. 156—157°, is insoluble in water, but dissolves in warm potassium hydroxide to a yellow solution with a green fluorescence which becomes gradually colourless on boiling (Found : C, 69·9 ; H, 4·8. $C_{18}H_{15}O_4N$ requires C, 69·9 ; H, 4·8%).

2-*Homopiperonyl*-4 : 4-*dimethylhomophthalimide* (compare V) was prepared as described on p. 1715 and on pouring into water, a crystalline precipitate separated which crystallised from methyl alcohol, in which it was sparingly soluble, in long, pale yellow, rectangular prisms, m. p. 126—127°. It is insoluble in aqueous alkali and could not be hydrolysed to the corresponding homophthalamic acid (Found : C, 71·3 ; H, 5·8. $C_{20}H_{19}O_4N$ requires C, 71·2 ; H, 5·6%).

3-*Chloro*-2-*homopiperonyl*-1-iso*quinolone* (XIV).—The imide (XII, 1 g.) was boiled with a mixture of phosphorus oxychloride (3 c.c.) and toluene (10 c.c.) for 6 hours, during which hydrogen chloride was evolved, and, on cooling, a brown syrup separated. After dilution with petroleum (b. p. 40—60°), the clear liquid (which contained unchanged imide and some chloro-derivative) was decanted and the residual oil dissolved in a little alcohol. Sodium hydroxide was then added to remove unchanged imide, and the insoluble solid collected and recrystallised from methyl alcohol, from which it separated in short needles, m. p. 128—129° (Found : C, 66·4 ; H, 4·3. $C_{18}H_{14}O_3NCl$ requires C, 66·1 ; H, 4·3%). When

this chloro-derivative was heated with copper powder in boili quinoline solution and the quinoline removed by dilute hydrochlor acid, no trace of a condensation product could be isolated.

N-*Homopiperonylhomophthalamic Acid* (compare IX).—This ac was obtained from the imide (XII) by heating with *N*-sodiu hydroxide (2 mols.) for 12 hours on the steam-bath. After saturatio with carbon dioxide to remove unchanged imide, the filtered sol tion was acidified with concentrated hydrochloric acid, when yellow gum separated which soon hardened, and crystallised fro dilute acetic acid (1 : 1) in needles, m. p. 158—159° (Found : C, 66· H, 5·0. $C_{18}H_{17}O_5N$ requires C, 66·0; H, 5·2%). The *methyl* est was prepared by the esterification of the acid with methyl alcoh and hydrogen chloride and also by the action of methyl iodide o the silver salt (compare p. 1716). It crystallises with difficulty a then separates from ether in long, colourless needles, m. p. 95—9 (Found : C, 67·1; H, 5·6. $C_{19}H_{19}O_5N$ requires C, 66·9; H, 5·5%

The *amide* was prepared by dissolving the ester in ten times i weight of methyl alcohol and saturating with dry ammonia. Th solution turned green and white needles of the imide (XII) separate on diluting the filtrate with water, the amide was deposited as crystalline mass, which separated from dilute methyl alcohol needles, m. p. 216° (Found : N, 8·7. $C_{18}H_{18}O_4N_2$ requires 8·6%).

2 : 3-*Methylenedioxyoxyprotoberberine* (XIII).—The above meth ester (3 g.), phosphorus oxychloride (6 c.c.), and toluene (15 c.c were boiled for an hour, cooled, diluted with petroleum (b. p. 40- 60°), and the solvents (which contained the imide XII and some the chloro-derivative XIV) decanted from the gum. The latt was extracted with boiling dilute hydrochloric acid, the insolub portion dissolved in hot methyl alcohol and cooled, when a ma of almost colourless needles separated; a further quantity separate in fine needles on concentrating the acid extract, the filtrate fro which contained the substance XVIII (see below). 2 : 3-*Methylen dioxyoxyprotoberberine* separates from methyl alcohol in colourle needles, m. p. 180°, and is sparingly soluble in ether, benzene, cold alcohol, but readily soluble in hot alcohol or glacial acetic aci It dissolves in concentrated mineral acids, but is reprecipitated dilution with water (Found : C, 74·3; H, 4·6. $C_{18}H_{13}O_3N$ requir C, 74·2; H, 4·5%).

2 : 3-*Methylenedioxytetrahydroprotoberberine* (XV).—The su stance XIII (1·5 g.), dissolved in alcohol (60 c.c.) and concentrate sulphuric acid (40 c.c.), was subjected to a current of 5 amperes f 20 hours in the cell described on p. 1716. The mixture was poure into water and extracted with chloroform, when some unchange

XIII separated. The acid filtrate from this was made strongly alkaline with ammonia, extracted with chloroform, the extract dried over potassium carbonate, and the solvent removed, when a brown, syrupy base remained which yielded a sparingly soluble *hydrochloride*, crystallising from water in prisms, m. p. 270° (decomp.). The *base*, liberated from the hydrochloride by sodium hydroxide, separated from methyl alcohol in colourless needles, m. p. 128—129° (Found : C, 77·2; H, 6·1. $C_{18}H_{17}O_2N$ requires C, 77·4; H, 6·1%). The *picrate*, prepared in alcoholic solution, crystallises from alcohol in yellow needles, m. p. 208—210° (decomp.).

2 : 3-*Methylenedioxyoxy*iso*protoberberine* (XVIII).—This highly coloured substance is contained in the acid mother-liquors obtained during the preparation of the substance XIII (see above). The liquors were evaporated and the residue was dissolved in glacial acetic acid containing a little acetic anhydride, when, after some time, a crystalline mass separated which was collected and boiled with water. The substance crystallises from dilute acetic acid in long, orange needles, which lose weight and become scarlet on drying on the steam-bath (compare p. 1713) ; m. p. 225—226° (Found : C, 74·5, 74·2 ; H, 4·8, 4·6. $C_{18}H_{13}O_3N$ requires C, 74·2 ; H, 4·5%). This substance is very sparingly soluble in alcohol, ether, or benzene, readily soluble in glacial acetic acid, and slightly soluble in water to a yellow solution. It is soluble in hot mineral acids, separating on cooling in orange needles which become scarlet on heating. The *acetate* separates from glacial acetic acid in pale yellow needles, m. p. 250° (decomp.), and is rapidly dissociated by water.

2 : 3-*Methylenedioxyoxydihydro*iso*protoberberine* (XIX).—This substance was obtained when 2 : 3-methylenedioxyoxy*iso*protoberberine (XVIII) (1 g.), dissolved in a mixture of alcohol (60 c.c.) and concentrated sulphuric acid (40 c.c.), was reduced with a current of 5 amperes in the cell described on p. 1716. The original orange solution became almost colourless and, after pouring into water, this was extracted with chloroform (B), the extract dried over potassium carbonate, and the solvent removed, when a brown syrup remained which crystallised from alcohol in nodules, m. p. 196—197°, and from dilute acetic acid in needles, m. p. 203—204° (Found : C, 73·7 ; H, 5·2. $C_{18}H_{15}O_3N$ requires C, 73·7 ; H, 5·1%). This dihydro-derivative is sparingly soluble in the usual organic solvents, dissolves in concentrated mineral acids, and is reprecipitated by water.

2 : 3-*Methylenedioxytetrahydro*iso*protoberberine* (XX).—The aqueous mother-liquors (B) from the chloroform extraction (see above) were made alkaline with ammonia and again extracted with chloroform, when a small amount of a basic substance was isolated. The yield of this substance was increased by continuing the above

reduction for 48 hours. The base is a syrup very soluble in organic solvents and has not been obtained in the crystalline state.

The *hydrochloride* is sparingly soluble and crystallises from dilute hydrochloric acid in small prisms decomposing at 260°. The *picrate*, prepared in methyl-alcoholic solution, crystallises from much methyl alcohol in long, yellow needles, m. p. 216—217° (Found: N, 11·2. $C_{24}H_{20}O_9N_4$ requires N, 11·0%).

2-*Homopiperonyl*-6 : 7-*dimethoxyhomophthalimide* (XXI).—This substance was prepared from homopiperonylamine and 4 : 5-dimethoxyhomophthalic acid as described on p. 1715 (Found: C, 65·0; H, 5·2. $C_{20}H_{19}O_6N$ requires C, 65·0; H, 5·1%). It is sparingly soluble in alcohol and crystallises from glacial acetic acid in pale yellow needles, m. p. 178—179°. It dissolves in warm sodium hydroxide to a yellow solution with a green fluorescence and is reprecipitated by carbon dioxide. The *dimethyl* derivative (compare V) was obtained by treating the imide with methyl iodide in alkaline solution under the conditions described on p. 1715. On pouring into water, a white solid separated which crystallised from methyl alcohol in colourless prisms, m. p. 151° (Found: C, 66·8; H, 5·9. $C_{22}H_{23}O_6N$ requires C, 66·5; H, 5·8%).

3-*Chloro*-2-*homopiperonyl*-6 : 7-*dimethoxy*-1-iso*quinolone* (compare XIV).—The above imide (1 g.) was heated with phosphorus oxychloride (2 c.c.) and toluene (5 c.c.) for 2 hours, during which hydrogen chloride was eliminated. Petroleum (b. p. 40—60°) was then added and, after standing for some time, the clear solution was decanted, the residue dissolved in alcohol, unchanged imide removed by treatment with sodium hydroxide, and the solid crystallised from glacial acetic acid, from which it separated in yellow needles, m. p. 163—164° (Found: C, 61·7; H, 4·7. $C_{20}H_{18}O_5NCl$ requires C, 61·9; H, 4·7%).

N-*Homopiperonyl*-4 : 5-*dimethoxyhomophthalamic Acid* (compare IX).—This was prepared by warming the imide with *N*-sodium hydroxide (2 mols.) for 12 hours on the steam-bath. On acidifying with concentrated hydrochloric acid, a grey, granular mass separated which crystallised from dilute acetic acid in needles, m. p. 181—182° (Found: C, 62·1; H, 5·5. $C_{20}H_{21}O_7N$ requires C, 62·0; H, 5·4%). The *methyl* ester, prepared by the two methods employed in the earlier cases (p. 1718), is sparingly soluble in ether and moderately soluble in methyl alcohol, from which it crystallises in colourless prisms, m. p. 136° (Found: C, 62·5; H, 5·6. $C_{21}H_{23}O_7N$ requires C, 62·8; H, 5·7%).

Oxy-ψ-berberine (XXII).—The above methyl ester (2 g.), phosphorus oxychloride (6 c.c.), and dry toluene (10 c.c.) were boiled for an hour, cooled, and diluted with petroleum (100 c.c.; b. p.

40—60°), and the clear solution decanted. The residue was washed with petroleum, digested with sodium hydroxide for 2 hours on the steam-bath, and the brittle solid boiled with a little alcoholic sodium hydroxide, collected, and crystallised from aqueous acetic acid, from which the substance separated in colourless needles, m. p. 267—268° (not depressed on admixture with a specimen of oxy-ψ-berberine prepared by Haworth, Perkin, and Rankin; *loc. cit.*). In several experiments a salt of the dichloro-derivative (compare XXIII) separated towards the end of the reaction as an orange-crystalline solid, which crystallised from methyl alcohol in orange-yellow needles, m. p. 204—205° (decomp.). It was soluble in water and, on treatment with sodium hydroxide and subsequent crystallisation from dilute acetic acid, gave oxy-ψ-berberine.

*Benzyl*nor*hydrohydrastinine* (XVII).—*N*-Phenylacetylhomopiperonylamine (XVI) (10 g.) was dissolved in toluene (50 c.c.) and boiled for 1½ hours with phosphorus oxychloride (20 c.c.). The solution was cooled, diluted with petroleum (b. p. 40—60°), the clear liquid decanted, the residual syrup dissolved in hot alcohol, acidified with sulphuric acid, and heated on the steam-bath with zinc dust until the intense blue fluorescence had disappeared. The solution was filtered hot, the zinc residues were thoroughly extracted with boiling water, and the base was liberated from the united filtrates by the addition of ammonia and extracted with benzene. The benzene extract was washed with water, dried over potassium hydroxide, and the benzene removed, when the residual syrup solidified to a pasty mass.

Benzyl*nor*hydrohydrastinine dissolves in the usual organic solvents with the exception of petroleum and crystallises from ether–petroleum in prisms, m. p. 64—66°. The *hydrochloride* separates from water in colourless, rectangular plates, m. p. 110°, and is sparingly soluble in water or alcohol and particularly sparingly soluble in dilute hydrochloric acid. The *picrate*, prepared in methyl-alcoholic solution, crystallises from methyl alcohol in short, thick prisms, m. p. 184—185° (Found: C, 55·3; H, 4·1. $C_{23}H_{20}O_9N_4$ requires C, 55·6; H, 4·0%). When the base was heated in methyl-alcoholic solution with formalin and diluted with water, an oil separated which was heated with hydrochloric acid, but no substance of the tetrahydroberberine type could be detected and the product contained large quantities of unchanged benzyl*nor*hydrohydrastinine hydrochloride.

Benzylhydrohydrastinine (p. 1712).—Benzyl*nor*hydrohydrastinine (XVII) (0·5 g.) was heated with water (5 c.c.), formic acid (1·2 c.c.), and formalin (1 g.) in a sealed tube for 8 hours at 180°. The product was diluted with water, made alkaline with sodium hydroxide, and

the solution decanted from the syrupy base. This was washed with water, and dissolved in hot dilute hydrochloric acid, when the *hydrochloride* of benzylhydrohydrastinine separated in colourless prisms, m. p. 174—175° (decomp.) (Found: C, 67·6; H, 6·2. $C_{18}H_{20}O_2NCl$ requires C, 68·0; H, 6·3%). The base, liberated from the hydrochloride, was a syrup which was not obtained in the crystalline state.

2 : 3 - *Methylenedioxydihydroprotoberberine*. — Benzyl*nor*hydrohydrastinine (5·4 g.) and anhydrous formic acid (1 g.) were heated in an oil-bath at 200° for 4 hours, the product dissolved in toluene (25 c.c.), and boiled with phosphorus oxychloride (10 c.c.) for 1½ hours. Light petroleum was added, the clear liquid decanted, the residue boiled with dilute hydrochloric acid and animal charcoal, filtered, and the filtrate concentrated, when clusters of yellow prisms of the hydrochloride separated. This was collected, dissolved in water, and the base liberated by sodium hydroxide as a pale yellow solid, which crystallised from ethyl alcohol in clusters of yellow needles, m. p. 128—129° (Found: C, 77·7; H, 5·5. $C_{18}H_{15}O_2N$ requires C, 77·9; H, 5·4%). The *hydrochloride* crystallises from dilute hydrochloric acid, in which it is sparingly soluble, in yellow prisms, m. p. 250°. The *picrate* separates from much alcohol or ethyl acetate in long, orange needles, m. p. 254—255°.

2 : 3-*Methylenedioxytetrahydroprotoberberine* (XV) was obtained by reducing the dihydro-derivative just described with zinc dust and sulphuric acid until the solution became colourless. The hot liquid was filtered, the filtrate decomposed by ammonia, the sticky base washed with water and crystallised from methyl alcohol, from which it separated in almost colourless needles, m. p. 128—129°. This base is identical with the substance resulting from the electrolytic reduction of 2 : 3-methylenedioxyoxyprotoberberine (XIII), since no depression in melting point was observed on mixing specimens which had been prepared by the two different methods.

The 2:3-*Methylenedioxyprotoberberinium Salts*.—The tetrahydro base (XV), dissolved in alcohol, was oxidised by means of iodine in the presence of sodium acetate, when a yellow, crystalline precipitate separated, and, after concentrating, the precipitate was collected, suspended in water, and sulphur dioxide passed. The *iodide* obtained, crystallised from much water in long, pale yellow needles which did not melt at 300° (Found: C, 53·8; H, 3·5. $C_{18}H_{14}O_2NI$ requires C, 53·6; H, 3·5%). The corresponding *chloride* was obtained by digesting the iodide with silver chloride in aqueous suspension for some hours, filtering, and concentrating the filtrate, when the chloride separated as bright yellow needles which did not melt at 250°. When this chloride was heated for ½ hour with 50%

potassium hydroxide, a semi-solid mass separated which hardened on cooling. It was collected, ground, and extracted with hot, very dilute hydrochloric acid. The acid solution, make alkaline with ammonia, yielded a base which crystallised from alcohol in clusters of pale yellow needles, m. p. 128—129°, and proved to be identical with the 2 : 3-methylenedioxydihydroprotoberberine which had been previously obtained (p. 1722) by another process. The substance insoluble in the dilute hydrochloric acid was crystallised from dilute acetic acid, when colourless needles were obtained which melted at 180° and were identical with the 2 : 3-methylenedioxyoxyprotoberberine (XIII) described on p. 1718.

The Action of Phosphorus Oxychloride on Oxyberberine.—Oxyberberine (10 g.) was boiled with phosphorus oxychloride (50 c.c.) for 6 hours, during which the solution became deep orange and a bulky precipitate separated; the excess of oxychloride was then removed by distillation and the solid heated with dilute hydrochloric acid and filtered. The residue crystallised from glacial acetic acid in small, colourless needles, m. p. 245°, and was identical with a specimen of methyl*nor*oxyberberine which had been prepared from oxyberberine by heating with hydrochloric acid in a sealed tube (compare p. 1713). The orange-coloured acid filtrate was decomposed with a large excess of concentrated ammonia, and the *iminoberberine* (XXIV) crystallised from much alcohol, from which it separated in small, pale yellow needles which did not melt at 280° (Found : C, 68·1; H, 5·0. $C_{20}H_{18}O_4N_2$ requires C, 68·6; H, 5·2%). It is sparingly soluble in organic solvents and, on warming with sodium hydroxide, ammonia is evolved and oxyberberine separates. The *hydrochloride* was prepared by dissolving the base in warm dilute hydrochloric acid and allowing to cool slowly, when orange plates separated which did not melt at 280° (Found : C, 61·6; H, 4·9; N, 7·0. $C_{20}H_{19}O_4N_2Cl$ requires C, 62·2; H, 5·0; N, 7·2%). This hydrochloride dissociates slowly in contact with moisture and is rapidly changed to oxyberberine on treatment with sodium hydroxide.

Our thanks are due to the Commissioners of the 1851 Exhibition for a Scholarship (R. D. H.), to the Salters' Institute of Industrial Chemistry for a Fellowship (H. S. P.), and to the Research Fund Committees of the Royal Society and Chemical Society for grants which have defrayed much of the expense of this investigation. We are indebted to Mr. Fred Hall for carrying out most of the analyses required during the course of this investigation.

OXFORD.

[*Received, May 30th,* 1925.]

CCXXIX.—*Researches on Sulphuryl Chloride. Part III. The Influence of Catalysts on the Chlorination of Toluene.*

By Oswald Silberrad, Chas. A. Silberrad, and Beatrice Parke

The present investigation on the chlorination of toluene was undertaken with the object of increasing our knowledge of the influence of catalysts on the chlorinating properties of sulphuryl chloride hitherto confined to the effect of the better known carriers on the chlorination of benzene (Silberrad, J., 1921, **119**, 2029; 1922, **121** 1015).

Previous investigators have recorded that no action occurs between toluene and sulphuryl chloride below 115° (Dubois, *Bull. Acad. Roy. Belg.*, 1872, 42), but that at that temperature benzyl chloride and chlorotoluene are slowly formed. Tohl and Eberhardt (*Ber.*, 1893, **26**, 2940), working at 160°, also obtained a mixture of these compounds, whilst Wohl (D.R.-PP. 1467/1902, 160102/1902 and 162394/1903) patented the manufacture of benzyl chloride (and its homologues) by heating toluene (and its homologues) with sulphuryl chloride to temperatures not exceeding 130°, the yield claimed in the absence of light being 50% on the toluene used. Tohl and Eberhardt (*loc. cit.*) also observed that iodine (at 160°) exercised no retarding influence on the formation of benzyl chloride, and Witte (*Pharm. Rec.* of New York, 1889, Dec. 16), Tohl and Eberhardt (*Ber.*, 1893, **26**, 2943), and Böeseken (*Rec. trav. chim.*, 1911, **30**, 381) obtained *o*- and *p*-toluenesulphonyl chloride as the chief product of treating toluene with sulphuryl chloride in the presence of aluminium chloride.

Apart from the simultaneous formation of chlorotoluene and benzyl chloride the present investigation has not confirmed these observations. The two ingredients react to a noticeable extent far below 115° in the absence of either light or catalysts, whilst iodine exercises a marked effect at 70° both by inhibiting side-chain substitution and by accelerating the formation of chlorotoluene. As regards the influence of aluminium chloride, toluenesulphonyl chloride or chlorotoluene can be produced at will according as the conditions selected are conducive to the Friedel and Crafts reaction or to chlorination; the former conditions appear to have been those selected by the above cited previous workers and the latter come within the present investigation (compare No. 3).

The catalysts examined may conveniently be divided into groups: those which either inhibit chlorination or alter its course without inducing any appreciable acceleration, and those which accelerate

substitution. Of the first series, phosphorus pentachloride is the most remarkable; it appears to prevent ring substitution altogether without, however, materially influencing the quantity of benzyl chloride produced in a given time.* Manganese chloride and arsenic also exhibit this peculiarity, though to a lesser extent, whilst the latter also accelerates side-chain substitution. All the other catalysts examined accelerate ring substitution and, with the exception of sulphur † and bromine, at the expense of the benzyl chloride produced, the yield of the latter compound being reduced to zero in the case of iron, aluminium, antimony, bismuth and tellurium.

Further, the catalytic activity of the elements of the same group, with the exception of bromine, is a function of the atomic weight, increasing with this apparently up to a maximum, as illustrated by bismuth (see table on p. 1726). In this respect, therefore, the elements examined behave in the same manner as halogen carriers in direct chlorination (Willgerodt, *J. pr. Chem.*, 1886, **33**, 264), from which it would appear that they operate as chlorine carriers rather than as dissociation catalysts. The only exception to Willgerodt's rule is furnished by bromine, which is much more active than iodine in spite of their relative atomic weights. It is suggested that this abnormality is due to the transient formation of sulphuryl bromide, concerning the existence of which there has been so much controversy (Odling, *Quart. J. Chem. Soc.*, 1854, **7**, 2; *Jahresbericht*, 1854, 308; *Handbuch Deutsch von Oppenheim*, 1865, **1**, 169; also Sestini, *Bull. Soc. chim.*, 1868, **10**, 226; Gustavson, *Ber.*, 1873, **6**, 9; Melsens, *Compt. rend.*, 1873, **76**, 92). This suggestion is borne out by the fact that bromine shows this abnormal activity only if previously dissolved in and added with the sulphuryl chloride and not when admixed with the hydrocarbon (Nos. 14 and 15), whereas with iodine, which admittedly shows no tendency to form sulphuryl iodide (compare Sestini, *loc. cit.*; Odling, *loc. cit.*), it makes but little difference whether it be added to the hydrocarbon or to the sulphuryl chloride (Nos. 16 and 17).

Not only is the intensity of the action a function of the atomic weight, but also the nature of the chlorination effected (see table); thus, the elements of the same group show a decreasing tendency to induce side-chain substitution with increasing atomic weight, but an increasing tendency to accelerate ring substitution. In all cases where the catalyst showed a marked influence the reaction was accompanied by the formation of strongly coloured inter-

* Erdmann (*Annalen*, 1893, **272**, 149), working with chlorine, found that phosphorus pentachloride accelerated side-chain substitution.

† This observation is in accord with Beck's work on the direct chlorination of toluene in the presence of sulphur (*Ber.*, 1892, **25**, 2445).

mediate products the constitution of which is evidently similar to those previously observed in the case of benzene, thus again contributing strong evidence in favour of the additive theory of chlorination (Silberrad, *loc. cit.*).

Experimental.

For the sake of brevity the method of procedure adopted is described in general terms and the quantitative results are summarised at the end of the paper, only peculiarities specific to each catalyst being described under that head. Unless stated otherwise, no coloration developed.

The apparatus and the method used were similar to those described by one of us (Silberrad, J., 1921, **119**, 2031), save that the mixture was boiled for 8 hours and light was found to produce so marked an effect on the results that its influence was rigidly excluded. The hydrocarbon (79 c.c. of toluene) was treated with 10% excess of sulphuryl chloride (66 c.c.) in the presence of the desired catalyst. The product was boiled with 250 c.c. of water * and steam-distilled, and the distillate dried and fractionated. The fraction boiling below 180° was freed from traces of dichloro-compounds by redistillation, and its composition then calculated from its density and the quantity of benzyl chloride present, estimated by boiling a weighed quantity with excess of solid silver nitrate and sufficient alcohol to form a boiling saturated solution (compare Schultze, *Ber.*, 1884, **17**, 1675; Cohen, Dawson, Blockey, and Woodmansey, J., 1910,

* Without this preliminary treatment sulphuryl chloride when present in any quantity passed over undecomposed on steam distillation.

97, 1625); a less concentrated solution of silver nitrate is liable to give inaccurate and erratic results.

No. 1. *Catalyst nil.*—The boiling ingredients slowly evolved sulphur dioxide and hydrogen chloride: the reaction was evidently not completed during the experiment (8 hours).

No. 2. *Catalyst Gold Chloride.*—Gold is apparently not attacked by sulphuryl chloride below about 150° (North, *Bull. Soc. chim.*, 1911, **9**, 646). It was therefore introduced as the anhydrous trichloride (1·3 g.). The velocity of chlorination was thereby raised about 30% without, however, appreciably altering the nature or relative proportion of the products. The reacting mixture assumed an amber tint.

No. 3. *Catalyst Aluminium Chloride* (*anhydrous*).—Aluminium chloride combines with sulphuryl chloride in the absence of moisture to form aluminium chlorosulphoxide, which acts as a powerful dissociation catalyst (Adrianowsky, *Ber.*, 1879, **12**, 688; Ruff, *Ber.*, 1902, **35**, 4453; *Chem. Ztg.*, 1906, **30**, 1225; Rohland, *Chem. Ztg.*, 1906, **30**, 1173; Silberrad, J., 1921, **119**, 2031). The anhydrous compound was therefore used, 14 g. being added to the toluene and the required quantity of sulphuryl chloride run into the mixture previously raised to 70°. A vigorous evolution of sulphur dioxide and hydrogen chloride took place at once and the reaction was completed in 2½ hours. The acceleration effected by this catalyst therefore amounted to approximately 1600%. The product, which was at first deep purple and finally dark vandyke-brown, had the characteristic odour of toluenesulphonyl chloride. The quantity was, however, small, chlorination being almost the only reaction under the above conditions.

No. 4. *Catalyst Carbon.*—Carbon is not attacked by sulphuryl chloride (Heinemann and Köchlin, *Ber.*, 1882, **15**, 1736; *Jahresbericht*, 1882, 234); any influence this substance might exercise was therefore likely to be physical rather than chemical. Finely-ground (200-mesh) wood charcoal was used (0·7 g.). A slight increase in the amount of nuclear substitution appeared to be induced.

No. 5. *Catalyst Stannic Chloride.*—Tin is only slowly attacked by sulphuryl chloride (Heinemann and Köchlin, *loc. cit.*), anhydrous stannic chloride (14 g.) was therefore used. Substitution took place almost entirely in the ring. The reacting products developed a faint pink tint.

No. 6. *Catalyst Phosphorus Pentachloride.*—In order to avoid complication arising from the possible formation of sulphur chloride *

* Sulphuryl chloride converts phosphorus into the trichloride (Köchlin and Heinemann, *Ber.*, 1881, **15**, 1736) and less readily into the pentachloride (North and Thompson, *J. Amer. Chem. Soc.*, 1918, **40**, 774), whilst the latter

the pentachloride (0·7 g.) was used. Chlorination proceeded even more slowly than without the catalyst, and the action was restricted entirely to side-chain substitution.

No. 7. *Catalyst Arsenic.*—Arsenic is rapidly converted into the trichloride by sulphuryl chloride (Köchlin and Heinemann, also Ruff, *loc. cit.*), The finely-ground element (0·7 g.) was therefore used. The reaction proceeded slowly, substitution occurring chiefly in the side chain.

No. 8. *Catalyst Antimony.*—Antimony reacts with sulphuryl chloride, forming the trichloride (Köchlin and Heinemann, *loc. cit.*). The element (0·7 g.) was therefore used. A steady and vigorous evolution of gas took place during the whole of the experiment, and the reaction was practically completed in 3 hours. The acceleration caused by this catalyst therefore amounted to 1300% approximately. The product, initially purple, gradually turned deep vandyke-brown. Substitution took place entirely in the ring.

No. 9. *Catalyst Bismuth.*—The action of sulphuryl chloride on this metal does not appear to have been previously examined. It dissolves readily, however, and was therefore introduced in the metallic form (0·7 g.). A vigorous action set in and a steady evolution of gas continued during the whole of the experiment. As a catalyst, bismuth behaves very similarly to antimony; the reaction mixture also passes through a precisely similar series of colour changes and substitution occurs wholly in the ring.

No. 10. *Catalyst Sulphur Chloride.*—According to Heinemann and Köchlin (*loc. cit.*) sulphuryl chloride does not act on sulphur at all; Ruff (*loc. cit.*), however, observed the formation of sulphur monochloride at 200°, and North and Thompson (*J. Amer. Chem. Soc.*, 1918, **40**, 774) observed it at 95—98°. Preliminary experiments with toluene showed that the hydrocarbon was very little attacked during the first 5 or 6 hours when elementary sulphur was used, but that after that the reaction proceeded just as rapidly as when sulphur chloride was added, thus proving beyond a doubt that sulphur is slowly converted into sulphur monochloride even at 70°. In order to avoid complication, therefore, the catalyst was intro-

---

substance reacts with a further quantity of sulphuryl chloride with formation of thionyl chloride, phosphorus oxychloride, and chlorine (Michaelis, *Jenaische Z. Med. Naturwiss.*, 1871, **6**, 79; *Z. Chemie Pharm.*, von Beilstein Fittig u. Hubner, 1871, **6**, 460). The thionyl chloride reacts with a further quantity of phosphorus trichloride, producing phosphorus sulphur chloride (Michaelis, *Z. Chem. Pharm.*, von Beilstein Fittig u. Hubner, 1871, **6**, 151), which in its turn is reconverted into phosphorus pentachloride and sulphur chloride by a further quantity of sulphuryl chloride (Michaelis, *loc. cit.*; compare also North and Thompson, *loc. cit.*); hence the risk of complications through the formation of sulphur chloride.

luced in the form of sulphur chloride (0·7 g.). A steady and fairly trong reaction took place during the whole experiment, the amount f side-chain substitution being doubled and that in the ring quad-upled by this catalyst. The reacting liquid assumed a pale amber tint.

No. 11. *Catalyst Selenium.*—Selenium is rapidly attacked by ulphuryl chloride with formation of the tetrachloride (Lehner and North, *J. Amer. Chem. Soc.*, 1907, **29**, 33). The element (0·7 g.) was therefore used. A vigorous reaction proceeded throughout the experiment and the product assumed a dark amber colour.

No. 12. *Catalyst Tellurium.*—Tellurium is converted first into he di-, then into the tetra-chloride on heating with sulphuryl chloride Lenher, *J. Amer. Chem. Soc.*, 1898, **30**, 737). The element (0·7 g.) was therefore used. The reaction was perceptibly more vigorous han with selenium, chlorination being complete in 5 hours and substitution taking place almost entirely in the nucleus. The nixture, too, assumed a much darker tint, changing from a dull purple-brown in the early stages to a very dark amber-brown at he end.

No. 13. *Catalyst Manganese Chloride.*—The manganese was intro-luced as anhydrous iron-free manganous chloride, in the presence f which chlorination appeared to proceed even more slowly than without any addition.

No. 14. *Catalyst Bromine* (added to the hydrocarbon).—Sulph-ıryl chloride decomposes hydrogen bromide with liberation of romine, but then the reaction appears to stop (Besson, *Compt. end.*, 1896, **122**, 467). In conformity with this observation it was ound that bromine added to the hydrocarbon exercised little or io influence on the rate of chlorination.

No. 15. *Catalyst Bromine* (added to the sulphuryl chloride).—Having regard to the possibility of the intermediate formation of ulphuryl bromide, Experiment No. 14 was repeated, bromine being dded to the sulphuryl chloride instead of the hydrocarbon. The eaction was much more vigorous, approximately double the amount f substitution occurring in 8 hours.

No. 16. *Catalyst Iodine* (added to the hydrocarbon).—According o Ruff (*Ber.*, 1901, **34**, 1749) sulphuryl chloride alone is without ction on iodine. On prolonged boiling, however, a dilute solution f iodine in sulphuryl chloride became colourless, presumably due o the formation of iodine chloride. Added to the hydrocarbon, odine (0·7 g.) accelerated ring substitution to a small extent at the xpense of the benzyl chloride formed.

No. 17. *Catalyst Iodine* (added to sulphuryl chloride).—Unlike romine, iodine (0·7 g.) added to the sulphuryl chloride produced a

similar result to that obtained when the halogen was added to the hydrocarbon.

No. 18. *Catalyst Iron.*—According to North (*Bull. Soc. chim.*, 1911, **9**, 646), who obtained ferric chloride by heating iron with sulphuryl chloride to 160°, this metal is attacked by sulphuryl chloride with some difficulty. Heated in the presence of the hydrocarbon, however, it (0·7 g.) rapidly passed into solution and induced vigorous substitution in the nucleus. The reacting mixture assumed a dark olive-green colour.

No. 19. *Catalyst Platinum.*—According to North (*loc. cit.*) platinum behaves like iron when heated with sulphuryl chloride. The finely divided metal (0·7 g. of 20% platinum asbestos) was therefore used. The bulk of the platinum gradually passed into solution and exercised a slight accelerating influence.

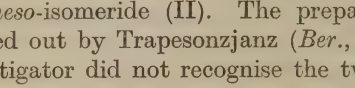
CCXXX.—*Stereoisomeric Azo-dyes.*

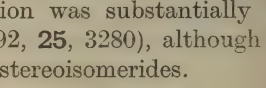
By GILBERT T. MORGAN and DONAL GEORGE SKINNER.

A STUDY of the absorption of asymmetric substances by animal fibres was made by Willstätter (*Ber.*, 1904, **37**, 2758), who employed racemoid alkaloids but without finding any preferential absorption of one optical component by wool or silk.

Porter and Hirst (*J. Amer. Chem. Soc.*, 1919, **41**, 1264) prepared a varied series of asymmetric azo-dyes with the object of establishing a definite relationship between the chemical structures of dyes and their function as vital stains. They report, but without giving practical details, one case of a racemoid dye on which wool acted selectively, absorbing more of the lævo- than of the dextrosomeride. Their azo-dyes, which contained an asymmetric carbon atom derived from *p*-aminobenzhydrol and the *p*-aminodiphenylalkylcarbinols, $NH_2 \cdot C_6H_4 \cdot CAlk(OH) \cdot C_6H_5$, were prepared by successively diazotising these amines and coupling the diazonium salt with β-naphthol, dimethylaniline, naphtholsulphonic acids, or naphthylaminesulphonic acids.



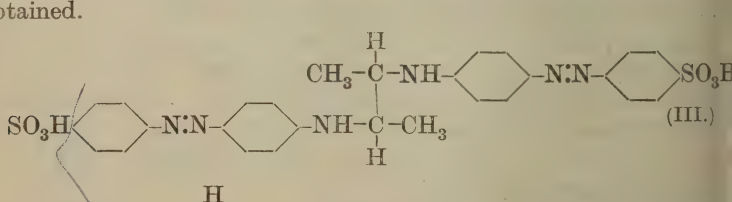
Ingersoll and Adams (*J. Amer. Chem. Soc.*, 1922, **44**, 2930) obtained *d*- and *l*-forms of *p*-aminobenzoyl-α-aminophenylacetic acid and converted these into two pairs of optically active dyes by diazotising and coupling with β-naphthol and dimethylaniline. The β-naphthol dyes were absorbed by wool in equal amounts, whereas the two dimethylaniline dyes were absorbed at unequal rates.



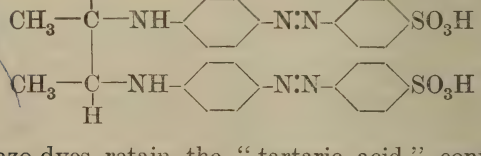
Racemoid aminomandelic acid was resolved by Porter and Ihrig through its cinchonine salt and its optically active components were diazotised and coupled with β-naphthol. When wool was dyed with a racemoid mixture of these azo-colouring matters, the dye-bath became lævorotatory owing to the higher rate of absorption of the dextro-form (*J. Amer. Chem. Soc.*, 1923, **45**, 1090).

In the experiments described below, two sets of stereoisomeric dyes were prepared and their enantiomorphous components were isolated.

n-Butyl alcohol, kindly supplied by Captain Desborough of the



Royal Naval Cordite Factory, was converted successively into β-butylene and βγ-dibromo-*n*-butane. The last product was then condensed with aniline, whereby two stereoisomeric bases were obtained, but the *dl*-diamine (I) was in much larger yield than its *meso*-isomeride (II). The preparation was substantially that carried out by Trapesonzjanz (*Ber.*, 1892, **25**, 3280), although this investigator did not recognise the two stereoisomerides.



(I.) 

(II.)

Both stereoisomeric bases were oily, but of their solid derivatives it was found that those of the *meso*-diamine were less fusible and less soluble than those of the *dl*-isomeride.

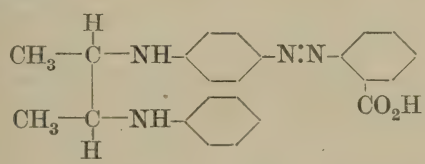
The two diamines were separated by means of their crystallisable salts (nitrate, sulphate, picrate) and were coupled separately with diazotised sulphanilic acid, when two stereoisomeric azo-dyes were obtained.

(III.)

(IV.)

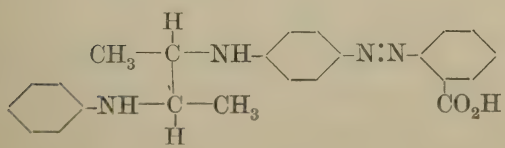
These disazo-dyes retain the "tartaric acid" configuration of the original bases. The compound IV from the *meso*-diamine was non-resolvable, whereas its isomeride III was resolved into optically active forms by means of the strychnine and cinchonidine salts.

The conditions under which solutions of the racemoid dye were kept in contact with wool for a prolonged interval at 20° were varied as to solvent, time of contact, and strength of solution, but only in one case was a slight optical activity observed in the dye-bath. The rates of absorption by wool of the four stereoisomeric dyes—the *dl*-, *d*-, *l*-, and *meso*-forms—were then investigated, and in all four cases the solutions of the dyes were of the same strength, the volume of the solution being proportional to



the weight of wool employed. At fixed intervals of time the amount of colouring matter remaining in solution was titrated by standard titanous chloride, this estimation giving a measure of the dye absorbed. The dextrorotatory dye was absorbed by the fibre at a slightly faster rate than the racemoid compound, whereas the lævorotatory isomeride was absorbed more slowly than either.

Although the differences in the measured rates of absorption of these three stereoisomeric forms were small, they were consistent for all the readings taken. The faster absorption of the *d*-compound was in agreement with the qualitative observation that a solution of the racemoid dye on prolonged contact with wool tended to become lævorotatory. The smallness of this optical activity had indicated that the differences in the rates of dyeing of the two enantiomorphs would also be small; the qualitative experiments confirm this anticipation and the greater rate of absorption of the *dextro*-form is also in agreement with the results of Porter and Ihrig (*loc. cit.*).



The *meso*-isomeride was found to dye wool at a much slower rate than any of its three stereoisomerides, this being the first case in which internally and externally compensated disazo-dyes have been contrasted.

Attempts were next made to demonstrate selective absorption by wool of less acidic colouring matters containing carboxyl groups and accordingly *dl*- and *meso*-diphenyl-βγ-diamino-*n*-butanes were coupled with diazotised anthranilic acid, when it was found that these diamines coupled with only one molecular proportion of the diazo-compound so that the resulting monoazo-dyes no longer retained any analogy with tartaric acid.

The *cis*- and *trans*-carboxyazo-dyes from the *meso*- and *dl*-diamines are represented respectively by formulæ V and VI, both being resolvable.

(V.)

(VI.)

Attempts were made with several alkaloids to resolve the latter more plentiful dye, dl-trans-2-*carboxybenzene*-4-*azodiphenyl*-βγ-*di*-

amino-n-*butane*, into its enantiomorphs, but only the lævorotatory isomeride was obtained and that through the agency of the strychnine salt.

The rates of absorption by wool of the three stereoisomerides when ascertained by the titanous chloride titration, showed that as in the case of the sulphonated disazo-dyes, the *lævo-trans*-compound was absorbed less readily than the *dl-trans*-isomeride, the differences being greater than those observed with the sulphonated dyes. The rates of absorption for the two racemoid, *cis*- and *trans*-carboxylated azo-dyes were practically identical.

Experimental.

Stereoisomeric Diphenyl-βγ-diamino-n-*butanes.*

The vapour of *n*-butyl alcohol was passed through a mixture of sand and phosphoric acid at 300—350° contained in a cylindrical copper vessel, and to the distillate of crude β-butylene, condensed and cooled with ice and salt, was added bromine drop by drop so that only a slight excess of halogen was present. The dibromide, washed with aqueous alkali and dried, was distilled fractionally until βγ-dibromo-*n*-butane was isolated, b. p. 157—158° (J., 1923, **123**, 97).

Aniline (600 g.) and 60 g. of βγ-dibromide were heated together at 160° for 4 hours, when the mixture became pasty owing to the separation of hydrobromides. After neutralisation with saturated aqueous sodium carbonate the mixture was distilled in steam to remove excess of aniline, and the residue extracted with benzene or ether. The crude diamines left on evaporating the solvent weighed 50 g. (yield 74%, calculated on βγ-dibromide).

dl-*Diphenyl-βγ-diamino*-n-*butane* (I).—The crude bases, consisting mainly of *dl*-diamine and a small proportion of *meso*-diamine, were dissolved in 50 c.c. of alcohol, 50 c.c. of nitric acid (*d* 1·42), and 100 c.c. of water, the solution being stirred and cooled in ice and salt. The crystalline *dl*-diamine nitrate which separated was recrystallised from alcohol until it melted with decomposition at 170—175° (weight 37 g.). The purified nitrate was decomposed with ammonia, the liberated base extracted with benzene and precipitated as picrate by adding picric acid (1 mol.) dissolved in the same solvent. The product was crystallised repeatedly from benzene until the purified *dl*-picrate melted at 136—137° (weight 36 g.). This method of purification depends on the fact that the small proportion of *meso*-diamine does not form a crystallisable picrate. Alternatively the *dl*-base may be purified by repeated crystallisation of its sulphate. This diamine, liberated by ammonia from its nitrate, was extracted with benzene, dissolved in alcohol,

and treated with the calculated amount of 30% sulphuric acid. The sulphate which separated was crystallised repeatedly from alcohol until a constant melting point—182°—was attained (Found: S, 9·4. $C_{16}H_{20}N_2,H_2SO_4$ requires S, 9·5%).

meso-*Diphenyl*-βγ-*diamino*-n-*butane* (II).—The *meso*-diamine, formed only in small amount by the condensation of βγ-dibromo-*n*-butane and aniline, is present together with *dl*-isomeride in the mother-liquors from the nitrate and picrate of the latter base. It was set free in the solutions by ammonia and extracted with benzene. The crude diamines obtained after concentrating the benzene extract weighed 21 g. and were converted into sulphate with 30% sulphuric acid, when the crystalline product obtained was *dl*-diamine sulphate. The filtrate was cooled and treated with dilute aqueous sodium nitrite; the viscid, brownish-yellow nitrosoamine was removed with ether and crystallised from petroleum (b. p. 80—100°) until it separated in pale yellow, arborescent growths of the purified *meso*-butylene-βγ-diphenyldinitrosoamine, m. p. 125°. A small amount of uncrystallisable oily residue was left consisting of the mixed *dl*- and *meso*-dinitrosoamines.

The dinitrosoamine was reduced with tin and hydrochloric acid in hot alcoholic solution, and the solution containing the stannichloride of the diamine was rendered alkaline with sodium hydroxide until the tin hydroxides redissolved. The oily diamine was extracted with benzene (yield 37%) and converted into its sulphate, which crystallised from alcohol and melted at 206°. This sulphate was not only less fusible but also less soluble in alcohol than the sulphate of the *dl*-diamine. The latter property was utilised in an alternative separation. Sulphate mother-liquors rich in *meso*-diamine were rendered alkaline with ammonia, extracted with benzene, the base converted into sulphate, and this salt crystallised repeatedly from alcohol until it melted at 206° (Found: S, 9·5. $C_{16}H_{20}N_2,H_2SO_4$ requires S, 9·5%).

Azo-dyes from Diphenyl-βγ-*diamino*-n-*butane*.

dl-*Di*-4′-*sulphobenzenedis*-4-*azodiphenyl*-βγ-*diamino*-n-*butane* (III).—*dl*-Diphenyl-βγ-diamino-*n*-butane (3·5 g.; 1 mol.), dissolved in 3·5 c.c. of concentrated hydrochloric acid and 10 c.c. of water, was added gradually to a solution of benzene-*p*-diazoniumsulphonate prepared from 5 g. of sulphanilic acid (2 mols.); a dark red disazo-dye separated (8 g. or 91%). This product dissolved readily in alcohol or glacial acetic acid, but was less soluble in acetone and insoluble in other organic solvents or water; it was dissolved in the minimum amount of dilute ammonia and reprecipitated by acid as a dark red, amorphous powder with bronzy reflex. The

dye developed intensely red colorations with concentrated mineral acids, had no definite melting point, but decomposed at 194°.

The *potassium* salt, obtained as a viscid solid by concentrating the solution of the dye in aqueous potassium carbonate, crystallised in an anhydrous form from dilute alcohol in small, orange needles (Found: K, 11·5; S, 9·3; azo-N_2 by titanous chloride, 8·1. $C_{28}H_{26}O_6N_6S_2K_2$ requires K, 11·4; S, 9·35; azo-N_2, 8·2%).

Dyeing Properties of the Racemoid Colouring Matter.—In the presence of sodium sulphate and sulphuric acid the dye liberated from its potassium salt in dilute solution dyed wool in deep orange shades, the colour being stripped by ammonia or strong soap solution.

Silk was dyed in boiled-off liquor and developed in a 1% sulphuric acid bath, giving golden-yellow shades. The partially exhausted solutions were examined in the polarimeter, a 12-volt, 24-watt Siemens lamp being used as a source of light (the wave-length being 6708 Å.). No activity was developed in the dye-bath whether the solvent employed was water, dilute alcohol, or 30% acetic acid, the strength of the dye-bath being approximately 0·75%.

In their successful attempt to show selective action of wool on a racemoid dye Porter and Ihrig (*loc. cit.*) used glacial acetic acid as solvent. The dye was employed in 1% solution, the quantity was 40% of the weight of wool, and the dyeing was carried out at 20° for 48 hours. A similar experiment was made taking 1 g. of dye in 75 c.c. of 30% acetic acid; 2·5 g. of wool were dyed at 20° for 24 hours. No activity was noticed at first, but after 72 hours a slight lævorotation was observed. Experiments with wool and silk using alcohol and dilute sulphuric acid as solvent for the dye showed no activity. These experiments on the racemoid dye did not furnish decisive evidence of preferential dyeing with either enantiomorph.

Resolution of dl-4′-*Sulphobenzenedis*-4-*azodiphenyl*-βγ-*diamino*-n-*butane.—Brucine salt.* Brucine acetate (2·65 g. or 2 mols.) in 20 c.c. of water was added to 2 g. of the potassium salt of the dye in 50 c.c. of water. The dibrucine salt of the dye separated as a brownish-yellow precipitate (decomposition point 189°); it was moderately soluble in chloroform, but insoluble in other organic media or water. From chloroform alone and from this solvent mixed with light petroleum the brucine salt separated in shellac-like or viscid forms, but not in a crystalline condition (Found: azo-N_2 by titanous chloride, 4·0. $C_{28}H_{28}O_6N_6S_2,2C_{23}H_{26}O_4N_2$ requires azo-N_2, 4·0%). The analysis showed that the substance was a dibrucine salt (2 mols. B + 1 mol. azo-compound).

The *strychnine* salt was prepared from strychnine hydrochloride and the potassium azo-dye salt as in the preceding preparation.

The bright yellow precipitate was readily soluble in chloroform, less soluble in alcohol or acetone, and insoluble in other organic media or water. When a dilute solution in absolute alcohol was allowed to evaporate very slowly, the strychnine salt separated in small needles, decomp. 179° (Found : azo-N_2, 4·4; total N, 11·1, 11·2. $C_{28}H_{28}O_6N_6S_2,2C_{21}H_{22}O_2N_2$ requires azo-N_2, 4·4; total N, 11·0%).

The strychnine salt was crystallised repeatedly from alcohol, the least soluble portions were examined polarimetrically, and crystallisation was continued until the rotation was constant: $[\alpha]^{17°}_{5563} = -308·3°$ for a 0·96% alcoholic solution ($l = 0·5$).

The salt having this specific rotation was warmed gently with aqueous potassium carbonate. The filtrate from strychnine was extracted repeatedly with chloroform to remove any of this base remaining in solution. The aqueous solution was allowed to evaporate, when the active potassium salt of the resolved dye separated slowly. A 0·99% solution gave $\alpha^{17°}_{6563} - 1·02°$ ($l = 0·5$) or $[\alpha]^{17°} = -206°$, $[M]^{17°} = -1409°$. The *l*-potassium salt, like its *dl*-isomeride, was anhydrous (Found : total N, 12·5; azo-N_2, 8·15, 8·2; K, 11·5. $C_{28}H_{26}O_6N_6S_2K_2$ requires total N, 12·3; azo-N_2, 8·1; K, 11·4%).

The mother-liquors from the lævorotatory strychnine salt were examined for the *d*-salt, but the more soluble fractions were viscid and on decomposition with potassium carbonate did not yield any dextrorotatory potassium salt.

Cinchonidine salts. The two stereoisomeric potassium salts were ultimately obtained through the cinchonidine salts. A solution of 2 g. (2 mols.) of cinchonidine hydrochloride in 20 c.c. of water was added to 2 g. of *dl*-potassium salt in 50 c.c. of water, when a yellow precipitate of the cinchonidine salt was obtained almost quantitatively (Found : total N, 11·9, 11·8; azo-N_2, 4·6, 4·7. $C_{28}H_{28}O_6N_6S_2,2C_{19}H_{22}ON_2$ requires total N, 11·7; azo-N_2, 4·7%).

The cinchonidine salt decomposing at 176° was moderately soluble in chloroform or alcohol, slightly soluble in benzene, but insoluble in other organic solvents and in water. By slow evaporation of a dilute alcoholic solution the cinchonidine salt was obtained in small needles and this crystallisation was repeated until the rotation was constant. A 0·97% solution gave $\alpha^{18°}_{6563} - 1·32°$ ($l = 0·5$) or $[\alpha]^{18°}_{5563} = -272°$.

This less soluble salt was decomposed by warming with aqueous potassium carbonate. The filtrate from cinchonidine was extracted repeatedly with chloroform to remove any traces of the alkaloid remaining in solution. The lævorotatory *potassium* salt (0·99% solution) gave $\alpha - 0·87°$, $[\alpha]^{16·3°} = -176·1°$, $[M]^{16·3°} = -1204°$

(Found: total N, 12·4; azo-N_2, 8·1, 8·15. $C_{28}H_{26}O_6N_6S_2K_2$ requires total N, 12·3; azo-N_2, 8·2%).

The dextrorotatory potassium salt. The cinchonidine salt of the dextrorotatory acid was isolated by concentrating the mother-liquor from the foregoing less soluble cinchonidine salt. The more soluble portions were crystallised repeatedly from alcohol until the rotation was constant; a 0·99% solution gave $\alpha - 0·29°$; $[\alpha]^{17°} = - 58·4°$.

The cinchonidine was then set free by aqueous potassium carbonate and the last traces were removed by chloroform. The aqueous solution slowly deposited the dextrorotatory potassium salt; a 0·977% solution gave $\alpha + 0·82°$; $[\alpha]^{18°} = + 167·8°$, $[M]^{18°} = + 1147·8°$ (Found: K, 11·5; azo-N_2, 8·1. $C_{28}H_{26}O_6N_6S_2K_2$ requires K, 11·4; azo-N_2, 8·2%).

The lævo- and dextro-rotatory potassium salts as obtained by the resolution with cinchonidine are in agreement with regard to optical activity, whereas the lævo-salt obtained through the strychnine resolution is more active. These differences, although not entirely explained, are not due to contamination with alkaloids, for these were recovered quantitatively. The resolution was probably more complete in one case than the other.

In the course of the attempts to isolate the dextro-form of the dye the following alkaloidal salts were prepared: *Morphine* salt, brownish-yellow precipitate insoluble in water or organic media, charring at 184°; *codeine* salt, a viscid, brownish-yellow mass more soluble in water than the other alkaloidal salts; *cinchonine* salt, brownish-yellow, amorphous powder fairly soluble in alcohol or chloroform, less so in acetone, but practically insoluble in other media or water; decomposed at 192°.

meso-*Di*-4′-*sulphobenzene*-4-*disazodiphenyl*-βγ-*diamino*-n-*butane*.—This substance was prepared in order to complete the series *dl*, *d*, *l*, and *meso* of the stereoisomeric azo-acids by adding 0·9 g. (1 mol.) of *meso*-diphenyl-βγ-diamino-*n*-butane dissolved in 1 c.c. of concentrated hydrochloric acid and 5 c.c. of water to a solution of benzene-*p*-diazoniumsulphonate from 1·3 g. (2 mols.) of sulphanilic acid. The dark red *meso*-azo-dye was precipitated (yield 87%). It was slightly soluble in alcohol or glacial acetic acid and almost insoluble in other organic media or water. It was purified through the potassium salt (Found: K, 11·5; S, 9·3. $C_{28}H_{26}O_6N_6S_2K_2$ requires K, 11·4; S, 9·35%).

This *meso*-azo-acid and its salts are more stable and less soluble than the corresponding externally compensated compounds. The *codeine* salt of the *meso*-acid is very insoluble, thus differing from the codeine salt of the *dl*-acid.

Rates of Absorption by Wool of the Stereoisomeric Azo-dyes (*dl*-, *l*-, and *meso*-forms).—The experiments with the four stereoisomerides were arranged to run concurrently, the dyeings being carried out in a thermostat at 20°. At intervals of 3, 24, 48, 72, and 96 hours, 5 c.c. of solution were removed and the amount of azo-dye was estimated by titration with dilute titanous chloride. The solutions of the dyes were made in 50% acetic acid.

I. Racemoid form : 2·4642 g. of wool in 100 c.c. of solution with 0·4576 g. of dye.
II. *Dextro*-form : 2·4886 g. of wool in 101 c.c. of solution with 0·4621 g. of dye.
III. *Lævo*-form : 2·4691 g. of wool in 100·2 c.c. of solution with 0·4555 g. of dye.
IV. *Meso*-form : 2·5007 g. of wool in 101·5 c.c. of solution with 0·4644 g. of dye.

Time (hours).	Amount (g.) in 5 c.c. of solution. I.	II.	III.	IV.
0	0·02288	0·02288	0·02288	0·02288
3	0·02276	0·02265	0·02278	0·02277
24	0·02153	0·02144	0·02164	0·02205
48	0·02024	0·02016	0·02033	0·02138
72	0·01923	0·01909	0·01933	0·02081
96	0·01887	0·01866	0·01896	0·02047

These tabulated data show that the dextrorotatory isomeride is absorbed by wool at a consistently though only slightly faster rate than the racemoid form and that the lævorotatory form is absorbed less rapidly than either the *dl*- or *d*-form, which result is in agreement with the polarimetric indications obtained (p. 1736) in the experiments on the selective action of wool on the racemoid azo-dye. A slight development of lævorotatory activity was detected in the dye-bath.

The *meso*-form is absorbed less readily than any of its three isomerides.

The differences in the rates of absorption of the *d*- and *l*-forms show that selective absorption from a racemoid mixture is quite feasible, but in the case of the sulphonated dyes examined in the preceding experiments the differences were not sufficiently large to admit of direct measurements of optical activity. Hence further experiments were made with less acidic carboxylated azo-dyes.

dl-trans-2′-*Carboxybenzene*-4-*azodiphenyl*-βγ-*diamino*-n-*butane* (VI).—An ice-cold solution of benzene-1-diazonium-2-carboxylate, prepared from 5 g. of anthranilic acid (1 mol.), 3·5 c.c. of concentrated hydrochloric acid and 2·5 g. of sodium nitrite in 60 c.c. of water, was added to 4·25 g. (1 mol.) of *dl*-diphenyl-βγ-diamino-*n*-butane dissolved in 15 c.c. of water containing 2 c.c. of glacial acetic acid and 2·5 g. of sodium acetate, when a dark red dye was precipitated.

After 3 hours the coupling was completed by warming on the water-bath. The dye was then collected and washed with ether to remove salicylic acid formed by hydrolysis of the diazonium salt (yield 78%).

Crystallised from 50% acetic acid, the red azo-dye separated in small, dark red needles, decomp. 113°. It was readily soluble in glacial acetic acid, less soluble in methyl and ethyl alcohols, and sparingly soluble in water. It exhibited amphoteric properties, being soluble either in mineral acids or in aqueous ammonia. The atter solution was used in purifying the dye, for on concentration the ammonium salt crystallised. The free acid was subsequently crystallised from glacial acetic acid (Found: total N, 14·6; azo-N_2, 7·1, 7·15. $C_{23}H_{24}O_2N_4$ requires total N, 14·4; azo-N_2, 7·2%). These analyses show that the compound is a monoazo-dye, only one diazo-group being coupled with the diamine.

The monoazo-colouring matter dyed wool in brownish-red shades and silk in dark salmon shades. Experiments were made with this racemoid monoazo-dye with varying conditions as to solvent, time of contact, and concentration of solution as with the racemoid sulphonated disazo-dye, but in no case was there any indication of optical activity.

Resolution of the Racemoid Carboxylated Dye.—The *strychnine* salt was obtained as a red precipitate on adding 1·8 g. of strychnine hydrochloride (1 mol.) in 25 c.c. of water to 2 g. (1 mol.) of the ammonium salt of *dl-trans*-2′-carboxybenzene-4-azodiphenyl-βγ-diamino-*n*-butane dissolved in 50 c.c. of water. This salt dissolved readily in alcohol or chloroform, more sparingly in acetone, but was practically insoluble in other organic solvents and in water. From its alcoholic solution the salt separated on slow evaporation in small needles, decomp. 121° (Found: total N, 11·8; azo-N_2, 3·8. $C_{23}H_{24}O_2N_4$,$C_{21}H_{22}O_2N_2$ requires total N, 11·6; azo-N_2, 3·9%).

Resolution was effected by repeated crystallisation in absolute alcohol until a constant value was obtained for the optical activity; 1% alcoholic solutions were employed with light of wave-length 6708 Å. A 1·02% solution gave α — 0·41° (l = 0·5); $[\alpha]^{19°}$ = — 80·5°. This strychnine salt was decomposed by warming gently with the calculated amount of ammonium carbonate in aqueous solution. The strychnine was precipitated, and the solution extracted repeatedly with chloroform to remove traces of the alkaloid. The filtrate was concentrated in a vacuum at the ordinary temperature until the ammonium salt crystallised. Approximately 1% aqueous solutions of this ammonium salt were examined polarimetrically. A 1·10% solution gave α — 0·24°; $[\alpha]^{16°}$ = — 43·7°,

hence $[M]^{16°} = -169{\cdot}6°$ (Found: azo-N_2, 6·8. $C_{23}H_{27}O_2N_5$ equires azo-N_2, 6·9%).

Attempts were now made to isolate the *dextro*-form of the azo-ompound from the more soluble mother-liquors from the *l*-strych-ine salt, but it was found impossible to obtain an even slightly extrorotatory ammonium salt. Other alkaloids such as brucine, iorphine, codeine, cinchonine and cinchonidine did not assist in ringing about this resolution.

dl-cis-2′-*Carboxybenzene*-4-*azodiphenyl*-βγ-*diamino*-n-*butane* (V).—nthranilic acid was diazotised and coupled with *meso*-diphenyl-γ-diamino-*n*-butane, when, owing to the circumstance that the iazonium carboxylate coupled with the diamine in molecular roportions, the resulting monoazo-derivative was no longer a *neso*-compound having internal compensation, but was capable f resolution.

The red dye crystallised from 50% acetic acid in small, red eedles, decomp. 116°; its solubility and dyeing properties are imilar to those of the corresponding *dl-trans*-compound (Found: zo-N_2, 7·15. $C_{23}H_{24}O_2N_4$ requires azo-N_2, 7·2%).

Rates of Absorption by Wool of the Stereoisomeric Carboxylated lzo-dyes.—The experiments were carried out precisely as de-cribed on pp. 1732, 1739, excepting that the solutions were made p with 30% acetic acid.

I. *dl-trans*-Form: 5·0116 g. of wool in 200 c.c. of solution with 1·2768 g. of dye.
II. *l-trans*-Form: 5·1334 g. of wool in 205 c.c. of solution with 1·3074 g. of dye.
III. *dl-cis*-Form: 5·0521 g. of wool in 201·6 c.c. of solution with 1·2870 g. of dye.

Time (hours).	Amount (g.) in 5 c.c. of solution. I.	II.	III.
0	0·03192	0·03192	0·03192
3	0·03148	0·03151	0·03150
24	0·02802	0·02929	0·02849
46	0·02503	0·02685	0·02546
72	0·02359	0·02454	0·02377
98	0·02282	0·02337	0·02298
120	0·02253	0·02283	0·02263

The foregoing data showed that the *cis*- and *trans-dl*-forms were bsorbed at practically the same rate and that the active lævo-rm was absorbed less rapidly than the corresponding racemoid rm, the difference in these rates of absorption being rather greater an in the case of the sulphonated azo-dyes.

Note on the Sulphonation of dl-*Diphenyl*-βγ-*diamino*-n-*butane.*

Treatment of this diamine with oleum (up to 20% SO_3) led to ydrolytic decomposition, so that the sulphonated product was

sulphanilic acid. Chlorosulphonic acid also gave rise to com plicated reactions and the formation of complex sulphonate sulphones. By neither treatment was a simple sulphonated pr duct of the base obtained, so that the attempt to resolve th *dl*-diamine through its sulphonic acid was abandoned.

The authors desire to express their thanks to the Researc Committee of the University of Birmingham and to the Advisor Council of the Department of Scientific and Industrial Researc for grants which have helped to defray the expense of th investigation.

CCXXXI.—*Theories of Polar and Non-polar Fre Affinities. A Practical and Theoretical Reply t some Recent Criticisms and Comparisons.*

By GEORGE NORMAN BURKHARDT and ARTHUR LAPWORTH.

IN a paper by C. K. Ingold (J., 1924, **125**, 93) the following sentence occur :

" The establishment of this formula provides an interesting tes of the hypothesis by means of which so many obscure points i chemistry are nowadays ' explained.' In nitrosobenzene oxygen i the ' key-atom '(Lapworth, T., 1922, **121**, 416), and the compoun may be represented as $C_6H_5—\overset{+}{N}=\overset{-}{O}$."

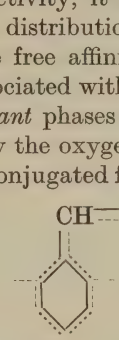
The sentences are misleading in several ways. As only on reference to the literature is given, it is necessary to point out (1 that Lapworth had never discussed the case of nitrosobenzene an (2) that the phrasing of the second sentence shows that Lapworth' conception of key-atoms is misunderstood. Ingold here, as else where (this vol., p. 514), confuses the conception with the earlie one of Flürscheim. Both theories attribute to bivalent oxyge for example, a special capacity to affect the properties of the rest o the molecule; Flürscheim's theory, however, postulates a fixe configuration for each compound, and Lapworth's (like that o Kermack and Robinson) does not.

The assumption that all " polarity theories " conform to the sam regulations as Flürscheim's is the origin of a number of misdirecte criticisms. When the inaptness of this line of attack is realised the critics substitute the objection that those theories are so flexibl as to have no prophetic power in potential test cases (compare C. K

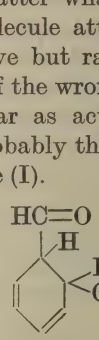
nd E. H. Ingold, this vol., p. 871). This peculiarity merely shows, owever, that the cases thought of are not test cases at all. Some eal test cases are mentioned later in the present paper.

The doctrine that theories such as those of Thiele and Flürscheim re not so flexible in their application as polarity theories is widely reached, and in view of its reappearance in the paper last mentioned it becomes necessary to prove that it is a fallacious one, in airness to the theories disparaged.

The theories of fixed non-polar free affinities * certainly give nequivocal and correct correspondence with fact, but only within ertain limited ranges. Outside those ranges they show on the same asis an unequivocal disagreement with fact. Thiele's form explains " the ordinary additive reactions of carbonyl correctly, ut on the same principle foretells *o*-*p*-substitution in benzaldehyde. 'lürscheim's form explains *m*-substitution in benzaldehyde, but ignally fails to explain the additive properties of carbonyl compounds. Flürscheim explains meta-substitution in benzaldeyde by assuming that the agent first attacks the meta-carbon tom; but he explains cyanohydrin formation by assuming that he agent first attacks the oxygen atom (*Chem. and Ind.*, 1925, **44**, 72).



Another excellent example of this is found in the explanation ffered for the addition of potassium carbazole to nitrobenzene, here the potassium attaches itself to an oxygen atom and the arbazole residue to the para-carbon atom (*ibid.*, 173): or, looking t it in a slightly different way, Flürscheim here throws over his own ormula and adopts Thiele's, its exact opposite. In these systems, herefore, there are nearly always two such possibilities and to uote Flürscheim's words in a similar connexion, " whichever way he experiment goes, one of these alternatives is bound to fit and hichever fits is adopted from case to case " (*ibid.*, 1925, **44**, 84). uch a process of reasoning is, of course, appropriate for the theory hich deduces configuration from observed facts, but is not dmissible for one which claims to predict facts from *a priori* onsiderations.

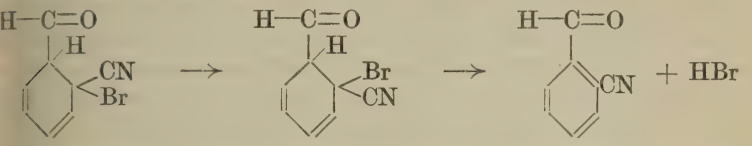


The claim that no arbitrary factor enters into the so-called

* The description of an hypothesis or a theory such as that of Flürscheim s one of " alternating affinity demand " cannot be used to distinguish it om theories of Kermack and Robinson or Lapworth which also postulate ternating affinity demands. It is necessary, therefore, to protest ematically against the terminology adopted in the above paper of Ingold nd Ingold (*loc. cit.*, p. 870) as likely to spread the perplexity to which one these authors has frankly confessed (this vol., p. 514, footnote). No uestion of priority can be admitted as sufficient reason for an implied istinction which does not exist.

predictions of the non-polar theories is therefore one which cann be taken seriously. No similar claim has ever been made by a responsible exponent of the polarity theories which Ingold discuss Polarity theories are acknowledged to be in a state of evolution a at present function properly as aids to interpretation, not substitutes for intellectual effort.

Polarity considerations solve some of the difficulties inseparab from the theories of Thiele and Flürscheim and in a very simp and logical way, because, with a polar agent which has consiste polar selectivity, it is evident that no matter what may be t dominant distribution of affinity in a molecule attacked by th agent, the free affinity will not be effective but rather inhibiti if it is associated with an electrical charge of the wrong sign. Thu the *dominant* phases of benzaldehyde, so far as activation of t nucleus by the oxygen is concerned, are probably those correspon ing with conjugated forms of the Thiele type (I).

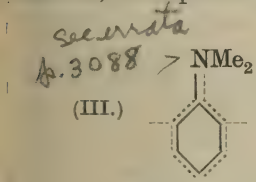


(I.) 

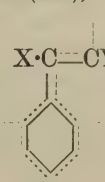
 (II.)

This corresponds with Robinson's "crotonoid" forms (*Che and Ind.*, 1925, **44**, 456) and the polarities of the excess free affiniti in the *o*- and *p*-carbon atoms are mainly positive, as the relati of these positions to the predominating key-atom in the conjugat system shows. The ordinary types of substitution in benzene, su as nitration, sulphonation, bromination, and diazonium couplin require a negative free affinity at the carbon atom at which subst tution of hydrogen takes place. Consequently with benzaldehyd phases of the above type are almost or quite inert towards su agents, substitution is very slow and perhaps takes place on in other phases of rare occurrence in the reacting system.

The circumstance that benzaldehyde is not known to pick u negative ions like cyanidion at the *o*- and *p*-positions in the nucleu although it does so readily at the carbonyl carbon atom, is not the least incompatible with the above view. The addition reactio of αβ-unsaturated carbonyl compounds with electrolytes a reversible, and in view of this, as well as the known tendency dihydro-derivatives to revert to benzenoid types, it is practical certain that the expected addition product (II) is a compound whi would not exist in any considerable proportion in equilibrium wi benzaldehyde and hydrogen cyanide. By introducing any oth conditions which would permit the initial addition compound wi



hydrogen cyanide to revert to an aromatic type in a different way, vidence might be obtained of the formation of that compound; such a condition would possibly be provided in *o*-bromobenzaldehyde, as the addition product here could react as follows if *cis-trans* change occurs before reversion :



This case would be exactly comparable with the ready replacement of halogen by hydroxyl in the *o*- and *p*-chloronitrobenzenes, which is claimed, not as a prediction from polar theories, but only as part of the evidence in favour of them.

Not less important and obviously very intimately connected with the known reversibility of the negative ion additions to αβ-unsaturated compounds, is the circumstance that tervalent carbon appears to tolerate a positive charge much more readily than it does a negative charge, and $\overset{\oplus}{C}H_3$ has frequently been detected by Sir J. J. Thomson in vacuum-tubes but $\overset{\ominus}{C}H_3$ never. Other things being equal, therefore, positive free valencies on aromatic carbon and on ethylenic carbon appear inert in comparison with negative free valencies.

In the case of phenol ethers, dialkylanilines and many others, the dominant conjugated forms or phases also have their excess free affinities in the *o*- and *p*-positions. Their structures, apart from polarities, correspond with Flürscheim's idea (III),

(III.)

(IV.)

but here the excess free affinities on the carbon atoms in the nucleus are negative; hence ordinary substitution compared with substitution in benzene is very rapid, and certain active positive ions (*e.g.*, diazonium ions) can attach themselves to the active *o*- and *p*-carbon atoms, but never negative ions. Form (III) also corresponds with Robinson's "crotenoid" forms (*loc. cit.*). If the two exterior atoms in (I) are singly bound to each other, conjugation can take place only to that very limited extent which corresponds with the

relatively feeble transmission of alternate polarities through tw single bonds.

The third type of conjugation, present in styrene, leads, in th ring, to excess valencies in the *o*-*p*-positions (IV); this obvious facilitates substitution in the nucleus when the excess free affiniti in the nucleus are the *negative* ends of the conjugated systems an *o*-*p*-substitution therefore results. In phases where these affiniti represent the *positive* ends, substitution takes place at the carbo atom once removed from the nucleus, where the negative free affinit is now found, so that, in competition with a group like carbon (and *a fortiori* with a group of the type $-\dot{\underset{\cdot\cdot}{C}}-\dot{O}R$), which, by conju gation, normally produces only phases with inhibited reactivit towards ordinary substituting agents, the group CX=CYH wi normally appear by far the more effective. α-Methoxystyren provides an instance of such competition within the same side-group

The present position is therefore this. Supporters of pola theories accept the general ideas of conjugation and of alternat affinity demand, but do not admit that there is any real distinctio between these two conceptions. They hold, however, that thes ideas have often been wrongly applied, and have little real predi ative power until polar considerations are introduced. It is equall true that the principle of induced alternate polarities is likely to b barren until considered simultaneously with conjugation and othe factors; *but this was pointed out in Lapworth's original paper* (*Mem Manchester Phil. Soc.*, 1920, **64**, ii, 10, last par.) which, it woul seem, is rarely consulted.

In the original paper (*loc. cit.*, p. 6), where the general idea " key-atoms " was broadly indicated, the molecule of formic aci was selected to illustrate that idea. It was explained that i considering different properties of formic acid sometimes oxygen an sometimes hydrogen was considered to be the " key-atom." Th " key-atom " in fact, as imagined by Lapworth, is not always th same in the same compound, but is any atom to the alternat inductive effect of which certain properties of the molecule are du On this conception, the effects of two " key-atoms " may be super imposed—perhaps are always so to some extent—or may so operat that each in turn may determine the properties in different phase of the same molecule (*loc. cit.*). The expression " the key-atom should be applied only to the atom which is considered respon sible for a certain effect and not merely to the one which produce the most striking effects or even to one which has an effect on ever property. A suggestion often heard that the introduction of th term " key-atom " merely corresponds with a christening

Flürscheim's fixed and also non-polarising atom is therefore but a uarter-truth.

It is possible now to return with advantage to Ingold's statement, iven at the beginning of the present paper.

As Ingold, with Weaver, has already pointed out (J., 1924, **125**, 458), there are many close analogies between the addition reactions f the nitroso-group and those of carbonyl. In fact, it may be said hat in such cases no evidence has ever been obtained that requires he introduction of the scheme $C_6H_5-\overset{-}{N}=\overset{+}{O}$. In reactions where the xygen is not directly involved, Ingold's remarks could not in any ase apply.

Ingold, however, in the paper first quoted, claimed to have roved that when nitrosobenzene combines with (*a*) methylene-nilines, compounds with four-membered rings are formed, the irection of addition being exactly the opposite of what the usual olarity ideas demand. In the later paper with Weaver (*loc. cit.*) e made similar claims for the reactions of nitrosobenzene with) hydrocarbons like styrene and diphenylethylene, (*c*) with ıethylenemalonic ester respectively.

Whilst his later experiments on nuclear substitution in nitroso-enzene and α-methoxystyrene (this vol., pp. 513, 870) introduce o new theoretical difficulties (having given exactly those results hich were to be expected), his interpretations of those three types f reaction mentioned in the preceding paragraph are difficult to :oncile with the usual polar additive properties of the compounds. s these interpretations were apparently based on very slender xperimental evidence, it was decided to re-examine these three ghly interesting cases. The fallacy in case (*c*) has already en detected and may now be dealt with.

Ingold and Weaver (J., 1924, **125**, 1459) found that nitrosobenzene id ethyl methylenemalonate combined to give a crystalline com-ound. They describe some of the properties of the compound in ie following terms: "it gives no colour with ferric chloride, no pper salt, and is oxidised by alkaline permanganate only with fficulty." The constitution ascribed to it was (V) and the forma-on of this compound was included among the cases in which "the rection of the addition is contrary to the indications of the polar eory." It was maintained that the polarity theory requires the rmation of (VI).

(V.) $\begin{matrix} CH_2—C(CO_2Et)_2 \\ | \quad\quad | \\ C_6H_5\cdot N——O \end{matrix}$ $\qquad$ $\begin{matrix} CH_2—C(CO_2Et)_2 \\ | \quad\quad | \\ O——N\cdot C_6H_5 \end{matrix}$ (VI.)

he present authors first prepared the product by the same method, ut observed that, although no crystalline copper derivatives could

be isolated, with their specimens a strong maroon coloration wa always produced when copper acetate was added to an alcohol solution of the compound.

The compound was a very sensitive one and was rapidly oxidise even in the cold by alcoholic ferric chloride, the odour of nitroso benzene becoming very perceptible in a minute or two; nitroso benzene was easily isolated by diluting the resulting solution wit water and extracting with ether. Although apparently stable t aqueous permanganate, doubtless owing to its sparing solubility i water, the compound was rapidly oxidised by permanganate in col acetone. It was evident that the properties of the compound wer not consistent with the ring formula previously ascribed to it. A Ingold and Weaver had furnished no direct evidence that th oxygen atom of the nitrosobenzene had taken any part in the act union, the following experiment was tried :

Ethyl hydroxymethylenemalonate (3 g.) is dissolved in 60% col methyl alcohol (10 c.c.), β-phenylhydroxylamine (2 g.) is adde when the solid dissolves at once. After 1 or 2 minutes, water added in sufficient quantity to cause a turbidity. (In the firs experiment no crystals were deposited until a trace of the solid prepared by Ingold and Weaver's method, was introduced, when th whole at once set to a sludge of needles which increased in quantit on further addition of water.) The product (3—3·5 g.) is filtere off, dried, and crystallised from dilute methyl alcohol. The com pound so made forms slender needles, m. p. 98—99°, and is identic in all respects (including the intensity and duration of the coloratio given in alcoholic solution with copper acetate) with the compoun previously described as " ethyl 2-phenyldimethylene-1 : 2-oxaimin 4 : 4-dicarboxylate " (Found : C, 60·0; H, 6·4. Calc., C, 60· H, 6·1%).

The compound, then, is one of the possible dynamic isomerid of the *N*-phenyloxime of the ester-aldehyde $O{:}CH{\cdot}CH(CO_2Et)$ of which ethyl hydroxymethylenemalonate, $HO{\cdot}CH{:}C(CO_2Et)$ is the enolic form. The *N*-phenyloxime of this aldehyde-est would be $O{:}N(C_6H_5){:}CH{\cdot}CH(CO_2Et)_2$ or, in modernised form $\overset{\ominus}{O}{\cdot}\overset{\oplus}{N}(C_6H_5){:}CH{\cdot}CH(CO_2Et)_2$. The dynamic isomeride of this corr sponding with ethyl hydroxymethylenemalonate is of cours $HO{\cdot}N(C_6H_5){\cdot}CH{:}C(CO_2Et)_2$ and it is scarcely possible to state wit certainty to which of these formulæ the solid itself correspond The behaviour of the compound in alcoholic solution with copp acetate, however, recalls that of the monoalkylated acetoacetic ester which also give evidence of the formation of dissociable copp derivatives in similar circumstances. It is as likely as not, therefor

non-hydroxylic form, or *dicarbethoxymethyl*-N-*phenylnitrone*, esponds with the solid and with the one which preponderates olution. Reference may be made to the work of Alessandri zzetta, 1924, **54**, 426) and others on the formation of *N*-phenyl-ones from nitrosobenzene and ethylenic compounds.

n the polarity theory, the first step in the process of union of ethylenic portion of ethyl methylenemalonate with nitroso-zene must be the union of the tervalent nitrogen of the nitroso-up with the β-carbon atom of the ester. This carbon atom has ery marked and quite consistent latent or real positive polar racter and the first addition process corresponds with ammonium formation :

$$\begin{matrix} CH_2{=}C(CO_2Et)_2 \\ O{=}N{\cdot}C_6H_5 \end{matrix} \longrightarrow \begin{matrix} CH_2{-}[C(CO_2\overset{\ominus}{E}t)_2] \\ O{=}\underset{\oplus}{N}{\cdot}C_6H_5 \end{matrix} \quad \text{(VII.)}$$

his initial product (VII) is a bipolar ion (to adopt Lowry's venient nomenclature), or internal ammonium salt; the signs wn in circles are electrical charges, the positive charge being ciated with the ammonium residue; the negative charge is e associated with a residue comparable in every way with the atively charged organic residue of ethyl *sodio*malonate.

tabilisation and internal neutralisation of this initial product sequently occur by " migration " of proton, or exchange of ton with the surrounding molecules in one or more of several sible ways.

he above conclusions are wholly consistent with our knowledge nitrones, with Lapworth's explanation of the polar additive tions of αβ-unsaturated carbonyl compounds (J., 1904, **85**, 1212), with Robinson's interpretation of the polar reactions of nitroso-zene (*Chem. and Ind.*, 1925, **44**, 456). The formation of addition ducts of ammonia, and primary and secondary amines, with nsaturated carbonyl compounds, nitriles, etc., can evidently explained on very similar lines, stabilisation and internal tralisation of the bipolar ions in such cases also taking place by roton migration or interchange, but in a slightly different mode.

will be instructive for those who have not previously followed various non-polar theories to their logical conclusions to observe the β-carbon atom of ethyl methylenemalonate is the one which s part in the actual union of the molecule of this compound with osobenzene. Now Flürscheim's theory of " orientation " in aromatic series postulates that the meta-orienting effect of group of compounds which includes carbethoxyl depends on the mption that these groups make a smaller affinity demand than

hydrogen, and this results in the development of an excess of f affinity at the meta-carbon atom in the ring, so that the ag attacks the meta-carbon atom preferentially. Applying t argument to ethyl methylenemalonate, it is obvious that repla ment of two hydrogens unsymmetrically in the symmetri ethylene (VIII) by carbethoxyl must lead to the affinity dist bution represented by (IX): or, expressed in words, the α-carb

(VIII.) $CH_2=CH_2$ $\qquad$ $CH_2=C<^{CO_2Et}_{CO_2Et}$ (IX.)

atom must have now a greater amount of unbound affinity than t β-carbon atom and therefore the α-carbon atom should be the c at which union with nitrosobenzene takes place: a predicti which fails.

It is not a little remarkable, therefore, that a reaction origina considered to be evidence against the polarity theory provides, wh more closely examined, the most elegant known demonstrati of the incorrectness of the Werner-Flürscheim theory. Hithe the most complete disproof would have involved a lengthy mat matical demonstration that it is impossible to construct mass-l equations which shall be capable of explaining the kinetics of t addition of the elements of hydrogen cyanide to cyanoacrylic aci where the nitrile group corresponds with the carbethoxyl grou (which correspond closely with ethyl methylenemalonate in stru ture), on any other hypothesis than that the first step in the additi process involves the union of the β-carbon atom with cyanidi (W. J. Jones, J., 1914, **105**, 1547, 1560. Compare also Lapwor J., 1903, **83**, 995; 1904, **85**, 1208).

All these facts, together with what is known of the conditions formation and decomposition of the cyanohydrins of simple al hydes and ketones, show that the revival of the Werner-Flürsche hypothesis can only have the effect of diverting attention fr important issues which have not yet been decided.

Lapworth stated in 1920 that bivalent oxygen is usually m effective than tervalent nitrogen, but the statement had refere to statistical aspects only. Enough is known to show that t dominance of either atom depends on many varying circumstan and the question whether these more frequently favour biva oxygen than tervalent nitrogen is not worth debating.

Note added July 12th, 1925.—Compare, on this point, *Chem. & Ind.*, 1925, **44**, 713.

THE UNIVERSITY, MANCHESTER. [*Received, May 16th*, 1925.]

CCXXXII.—*The Estimation of Arsenic in Organic Compounds.*

By George Newbery.

The most accurate and trustworthy method for the estimation of arsenic in organic arsenical compounds is undoubtedly that in which the arsenic is oxidised by the Carius method to arsenic acid and subsequently weighed as magnesium pyroarsenate. The methods in general use which have been devised in the endeavour to combine the accuracy of this procedure with greater simplicity and rapidity are those of Lehmann (*Apoth. Ztg.*, 1912, **27**, 545) and the modifications suggested by Fargher (J., 1919, **115**, 992) and Myers and Dumez (*U.S. Public Health Rep.*, 1918, **33**, 1003), that of Ewins (J., 1916, **109**, 1355) and of Robertson (*J. Amer. Chem. Soc.*, 1921, **43**, 182). The first of these involves a volumetric determination of doubtful accuracy (compare criticism by Gooch and Morris, *Amer. J. Sci.*, 1900, **10**, 151 and many others); the other two are somewhat tedious in the procedure proposed for the decomposition of the arsenical, and the high temperatures involved render possible some slight loss of arsenic by volatilisation (Myers and Dumez, *loc. cit.*).

The use of ammonium persulphate (in conjunction with nitric acid) for this decomposition has been suggested by Rogers (*Can. Chem. J.*, 1920, **3**, 398) and that of persulphate alone has long been employed in these laboratories. The following process involves this method of oxidation. With the majority of substances to which the method has been applied a determination in duplicate can be completed in the course of an hour: with a few, the boiling down with persulphate has to be prolonged and even repeated with a larger quantity, in order that a colourless solution may be obtained. The decomposition in the case of insoluble substances of acid character is facilitated by solution in caustic alkali before the addition of persulphate, the acid being thus thrown out in a finely divided condition. The details are as follows:—

A mixture of the substance (0·2 g.), 20 c.c. of water, and 4—5 g. of ammonium persulphate is heated to brisk ebullition in a 300 c.c. Erlenmeyer flask, provided with a device to prevent loss by spraying. When the mixture is quite colourless (usually less than 10 minutes is required), 40 c.c. of *N*-oxalic acid are added and the mixture is further heated for 2 minutes after the noticeable evolution of carbon dioxide has ceased. 2*N*-Sulphuric acid (20 c.c.) and 10% potassium iodide solution (10 c.c.) are then added, together with a fragment of porous pot. The mixture is once more vigorously boiled until the

liberated iodine has been almost completely expelled and th solution is of a pale straw colour (about 15 minutes). This colou is discharged by the cautious addition of $N/20$-sodium thiosulphat the mixture immediately diluted to about 100 c.c., 30 c.c. of 2N sodium carbonate are added, and the still acid solution is treate with a quantity of solid sodium bicarbonate about 1 g. in excess that required to render it neutral to litmus. The mixture is warme to 35—40° and titrated with $N/10$-iodine in presence of starc solution until the blue colour is permanent.

Appended is a list of some of the results obtained with arsenic products of various types. The figures themselves have not bee specially selected and are in all cases duplicate determinations mad on the same sample in the ordinary course of work.

NOTES.

Lithium Arc Spectrum for Polarimetric Use. By PERCY CORLET AUSTIN.

BY introducing lithium carbonate into the arc produced betwee carbon, copper, or silver electrodes and using a direct-vision spectr scopic eyepiece of high dispersive power it is possible to read extin tions quite easily, not only for the red line at $\lambda = 6708$ Å. togeth

ith the sodium line at $\lambda = 5893$ Å (Hunter, J., 1924, **125**, 1401), ut also for the orange line at $\lambda = 6104$ Å, the blue line at $\lambda = 602$ Å., and sometimes even the green line at $\lambda = 4972$ Å; but his is much weaker than the others and of comparatively small nportance. The red line is very strong and persistent, whilst the lue line is a valuable addition to the list of lines in common use in neasurements of optical rotatory dispersion, since it lies in the rather ide gap between the dark blue cadmium line at $\lambda = 4678$ Å. and the ercury line at $\lambda = 4359$ Å. Moreover, it is brighter and more asily read than the dark blue cadmium line, when this is produced n an open arc between electrodes of a cadmium–silver alloy.

The red and blue lines of lithium are widely separated from each ther and can be read with sufficient accuracy to enable them to erve as standards, which are independent of the usual mercury nes, in calculating the constants of Drude's equation. The most atisfactory results were obtained with copper electrodes at right ngles to each other. The top of the vertical (positive) pole is bound ith thin copper wire to retain a small quantity of a paste of lithium arbonate and water, and a current of 4·5 amperes is used. The lue copper lines are too weak to interfere with the readings of the lue lithium line.—Westminster Training College, 130 Horse-erry Road, S.W. 1. [*Received, June 16th*, 1925.]

---

otassium Antimonoxalate. By Leslie Henry Alfred Holmes and Eustace Ebenezer Turner.

RELIMINARY investigation of the antimonoxalates, which it was oped to resolve into optically active forms, has shown that ney are too unstable for the work in view. The potassium salt, or example, is described by different authors as having x, 2, 3, $3\frac{1}{2}$, $4\frac{1}{2}$, or 6 mols. of water of crystallisation (Hofmann, "Lexikon er anorganischen Verbindungen," Vol. I, 2nd half, 1237; Beilstein, Handbuch," 4th ed., Vol. II, 521).

The potassium salt has been prepared by slowly adding freshly-ecipitated antimonious oxide to a boiling saturated solution of otassium hydrogen oxalate, filtering, and allowing to cool: it parated as star-shaped clusters of needles, which were once crystallised from water below 50° (at or above this temperature was hydrolysed by water), and air-dried. The water of crystal-ation was not completely removed even in a vacuum at 140°, nd the determination of water was effected by ignition in a tube, c. (Found: K, 21·6; Sb, 22·5; C_2O_4, 49·2; H_2O, 6·8. $_3Sb(C_2O_4)_3,2H_2O$ requires K, 21·8; Sb, 22·35; C_2O_4, 49·15; $_2O$, 6·7%).

It is probable that previous workers overlooked the extreme unstable nature of the salt, and were dealing with impure specimen since it is unlikely that they would have obtained higher hydrat than that now described, which separated at low temperatures.

The expense of this work was met by a grant for which the autho are indebted to the Research Fund Committee of the Society.-

East London College, University of London. [*Received, Jun 4th*, 1925.]

A Simplified Method of Micro-combustion: the Micro-Dennste Method. By Casimir Funk and Stanislas Kon.

Some of the disadvantages of Pregl's method of microanalysis ha been overcome by Dubsky (see Houben-Weyl, "Methoden d Organischen Chemie," II. ed.), but the apparatus required is som what complicated. We have devised a simple and accurate proce by an adaptation of Dennstedt's method. The combustions a carried out in a pyrex tube, 43 cm. long, of the usual Pregl patter but fitted with an inner tube 22·5 cm. in length, of which 13·5 cr are inserted into the tube, and a diffusion stopper providing double supply of oxygen. The filling consists of a platinum conta "star," 6 cm. long, and three boats, 7·5 cm. long, one containi molecular silver and the others lead peroxide and red lead. T tube is heated in a Dubsky furnace terminated by a "regenerati block" kept at 150—170°; the burners are arranged as in t Dennstedt process, so that the contact star can be heated to redne while the portion of the tube containing the absorbents is kept about 320° with the aid of the tubular burner. Three Blum absorption tubes, each weighing 14—17 g. when full, are use filled as recommended by Dubsky; these tubes must always used in the same direction. A bubble-counter is attached to t third tube. The capillary rubber tubing used for all connexions specially treated, and the absorption tubes are cleaned and weighe according to Pregl's directions. It is advisable not to wipe t stoppers after a combustion to avoid the risk of removing sm traces of vaselin. The absorption tubes are weighed filled wi oxygen and should be refilled with dry oxygen if not used for day or more.

A newly-fitted combustion tube is burned out in a stream oxygen for 1½ hours. A small platinum boat containing t substance to be analysed (5—9 mg.) is placed in the inner tube the combustion tube, the double oxygen supply carefully adjuste and the combustion carried out as described by Dennstedt. It particularly important to maintain a sufficiently rapid outer strea of oxygen to prevent backward diffusion of the combustion produc

especially when dealing with volatile substances. The combustion takes 40—50 minutes, including the time (20 minutes) required to drive off the water formed; the absorption tubes are then detached, and weighed after 20 minutes.

The following precautions are essential: (1) a sufficient supply of oxygen must be maintained, the outer stream at the rate of two bubbles a second with a bubble-counter 1 mm. in diameter; (2) a good analysis can be obtained only after a satisfactory blank or a successful combustion. Otherwise the process requires no special care. The progress of the combustion can be watched so that any irregularity is noticed at once, the filling of the tube is simple, and the large absorption tubes do not require refilling for a considerable time.

We obtained consistently high results in the estimation of nitrogen by Pregl's method until we placed the layer of reduced copper at the end of the tube as in Dubsky's process; this arrangement obviated the dissociation of the carbon dioxide into carbon monoxide and oxygen. A very slow stream of carbon dioxide generated in a Kipp apparatus was maintained throughout the combustion; and no difficulty was experienced in getting air-free carbon dioxide when Pregl's directions for the filling of the Kipp apparatus were carefully followed.—STATE SCHOOL OF HYGIENE, WARSAW, POLAND. [*Received, April 15th*, 1925.]

CCXXXIII.—*Arylselenoglycollic Acids.*

By GILBERT T. MORGAN and WILLIAM HENRY PORRITT.

ARYLSELENOGLYCOLLIC acids are obtainable by the following process, which avoids the use of hydrogen selenide and is of general application. The first step, due to Taboury (*Bull. Soc. chim.*, 1903, **29**, 761), depends on the interaction of elemental selenium and a magnesium aryl bromide.

The additive product of the Grignard reagent and selenium is decomposed with ice and hydrochloric acid, and the arylselenomercaptan, extracted as alkali salt from its ethereal solution, is condensed with sodium chloroacetate in aqueous alcoholic solution. The process is summarised in the following scheme:

$$\text{Aryl·MgBr} \longrightarrow \text{Aryl·Se·MgBr} \longrightarrow \text{Aryl·SeH}.$$
$$\text{Aryl·SeNa} + \text{CH}_2\text{Cl·CO}_2\text{Na} = \text{Aryl·Se·CH}_2\text{·CO}_2\text{Na} + \text{NaCl}.$$

During its extraction with aqueous alkali 15—20% of the selenomercaptan undergoes aerial oxidation to the corresponding diaryl diselenide, Aryl·Se·Se·Aryl.

The arylselenoglycollic acids (yields 20—25%), when liberated

by mineral acids from their alkali salts, are well-defined, colourless solids, easily soluble in organic media, crystallising from hot water on account of their more sparing solubility in the cold solvent.

In general stability, the arylselenoglycollic acids resemble their sulphur analogues; they melt without decomposition and are not attacked by boiling mineral acids. Unlike the acids of the sulphur series, however, these selenium derivatives do not exhibit any marked tendency towards ring formation under the influence of chlorosulphonic acid at temperatures ranging from −5° to 40°. No seleno-indoxylic substances are produced and the products isolated resemble the decomposition products of the dichlorides of the arylselenoglycollic acids. This observation indicates that the chlorosulphonic acid contributes chlorine to the side chain, which radical subsequently undergoes complex condensation. That the valency of the selenium tends to increase is shown by the formation of crystalline chloro- and bromo-additive products on introducing these halogens into chloroform solutions of the arylselenoglycollic acids. The additive products of bromine are of two types, respectively yellow and red in colour, corresponding to the di- and tetra-bromides. They are easily hydrolysed with the formation of brownish-red oils, a complex change also occurring with the dihalogenides of the arylthioglycollic acids (Pummerer, *Ber.*, 1909, **42**, 2275).

Acidified permanganate solutions are decolorised by the arylselenoglycollic acids, probably with the formation of selenones. With 25% hydrogen peroxide in glacial acetic acid solution, the acids undergo direct oxidation with considerable evolution of heat to furnish well-defined, crystallisable arylselenoxyglycollic acids, Aryl·Se·O·CH_2·CO_2H (yields 95%).

Excess of hydrogen peroxide produces no further oxidation, although potassium permanganate is discoloured. This behaviour towards oxidising agents is similar to that of the aryl disulphides and thiodiglycollic acid (Gazdar and Smiles, J., 1908, **93**, 1833; Hinsberg, *Ber.*, 1908, **41**, 2836).

The arylselenoglycollic acids are very resistant to nitric acid and in Carius determinations the temperature must be maintained at 250° for several hours; they develop characteristic colours with concentrated sulphuric acid, the tint varying with the nature of the aryl radical present.

Both the arylseleno- and arylselenoxy-acids form soluble alkali and ammonium salts, the latter being readily dissociated. The alkali salts of the seleno-acids are stable towards alkali fusion at 250°. The silver salts of both series are only very slowly affected by light.

Experimental.

I. *Arylselenoglycollic Acids.*

1. *Phenylselenoglycollic Acid*, $C_6H_5{\cdot}Se{\cdot}CH_2{\cdot}CO_2H$.—Twenty g. of finely powdered selenium were added slowly to magnesium phenyl bromide, from 39 g. of bromobenzene and 6 g. of magnesium in dry ether; brisk effervescence occurred and the mixture was cooled in ice, the reaction being afterwards completed by warming on a water-bath. The cooled mixture was poured on to ice and hydrochloric acid, when a small quantity of hydrogen selenide was evolved and red selenium separated. The ethereal layer was extracted rapidly with 7 g. of caustic potash (100%) in 60 c.c. of water, and to the aqueous solution were added 100 c.c. of alcohol and a solution of sodium chloroacetate (from 6·7 g. of sodium carbonate and 11·8 g. of monochloroacetic acid). Heat was generated and the sodium salt of the glycollic acid was precipitated as a white powder. The reaction was completed on a water-bath, and on concentrating the solution to half its bulk, sodium phenylselenoglycollate crystallised in pinkish-white plates. *Phenylselenoglycollic acid* separated as a pale yellow oil on adding hydrochloric acid to an aqueous solution of its colourless, recrystallised sodium salt. This acid dissolved in a large quantity of boiling water, separating therefrom as a colourless oil, b. p. 160°/750 mm., which became crystalline on standing for several days; m. p. 40°. The potassium salt crystallised in colourless plates with a silvery lustre (Found: C, 44·6; H, 3·7; Se, 36·7. $C_8H_8O_2Se$ requires C, 44·65; H, 3·7; Se, 36·7%).

Phenylselenoglycollic acid, which dissolved in the majority of organic solvents, was only sparingly soluble in cold water; its aqueous solution was acid to litmus. With concentrated sulphuric acid, it developed a deep purple coloration; its bright green copper salt was insoluble in water.

2. p-*Bromophenylselenoglycollic Acid*, $C_6H_4Br{\cdot}Se{\cdot}CH_2{\cdot}CO_2H$.—The condensation of 13·3 g. of selenium and the Grignard reagent from 40 g. of *p*-dibromobenzene and 4 g. of magnesium powder in dry ether was completed on a water-bath and the cooled product subsequently decomposed with ice and hydrochloric acid. The resulting *p*-bromophenylselenomercaptan was extracted with 5 g. of caustic potash and 50 c.c. of water, and to the alkaline solution 50 c.c. of alcohol and an aqueous solution of sodium chloroacetate from 8 g. of monochloroacetic acid were added. After warming on the water-bath for 30 minutes, the solution, on cooling, deposited sodium *p*-bromophenylselenoglycollate slightly pink in colour. The free *acid* crystallised from hot water in colourless, lustrous needles, m. p. 127° (Found: C, 32·7; H, 2·4; Se, 26·9; Br, 27·2.

$C_8H_7O_2BrSe$ requires C, 32·2; H, 2·3; Se, 26·9; Br, 27·2%). *p*-Bromophenylselenoglycollic acid dissolved readily in most organic solvents, but was only sparingly soluble in cold water to a solution having an acid reaction to litmus. The silver salt was only slowly decomposed by light; the green copper salt was insoluble. A deep brown colour was developed in concentrated sulphuric acid.

3. p-*Tolylselenoglycollic acid*, $CH_3{\cdot}C_6H_4{\cdot}Se{\cdot}CH_2{\cdot}CO_2H$, prepared by the general method from magnesium *p*-tolyl bromide, separated from acidified solutions of its recrystallised sodium salt. When crystallised from hot water, this acid was obtained in well-defined lustrous, acicular prisms melting at 98° and giving a carmine-red coloration with concentrated sulphuric acid (Found: C, 47·1; H, 4·4; Se, 34·4. $C_9H_{10}O_2Se$ requires C, 47·2; H, 4·4; Se, 34·5%).

The alkali and ammonium salts were colourless, crystalline substances soluble in water; the green copper salt was insoluble.

4. *α-Naphthylselenoglycollic acid*, $C_{10}H_7{\cdot}Se{\cdot}CH_2{\cdot}CO_2H$, prepared by the general method from magnesium α-naphthyl bromide, separated from acidified solutions of its sodium salt, and as an oil from hot water. On remaining in a vacuum desiccator for 3 weeks the oil crystallised to a product, m. p. 54°, which gave a green coloration in concentrated sulphuric acid (Found: C, 54·3; H, 3·7; Se, 29·7. $C_{12}H_{10}O_2Se$ requires C, 54·3; H, 3·8; Se, 29·8%).

II. *Arylselenoxyglycollic Acids.*

1. p-*Bromophenylselenoxyglycollic acid*, $C_6H_4Br{\cdot}SeO{\cdot}CH_2{\cdot}CO_2H$, separated in well-defined, colourless needles, m. p. 187°, when 6 c.c. of hydrogen peroxide (25%) were added to 2·9 g. of *p*-bromophenylselenoglycollic acid dissolved in glacial acetic acid, the solution being cooled to moderate the reaction (Found: C, 40·0; H, 2·2; Se, 25·5. $C_8H_7O_3BrSe$ requires C, 40·0; H, 2·25; Se, 25·5%).

p-Bromophenylselenoxyglycollic acid, which dissolved in chloroform or alcohol, was less soluble in ether than the selenoglycollic acid. It dissolved only very slightly in cold, but more so in hot water. The alkali and ammonium salts were colourless and soluble. The pale blue copper salt was insoluble.

2. p-*Tolylselenoxyglycollic acid*, $C_6H_4Me{\cdot}SeO{\cdot}CH_2{\cdot}CO_2H$, produced as in the preceding preparation, separated from glacial acetic acid in colourless crystals, m. p. 165° (Found: C, 44·0; H, 4·0; Se, 32·5. $C_9H_{10}O_3Se$ requires C, 44·1; H, 4·1; Se, 32·2%).

Aqueous or acetic acid solutions of the foregoing arylselenoxy acids liberated iodine from aqueous potassium iodide.

III. *Halogenides of Arylselenoglycollic Acids.*

1. p-*Tolylselenoglycollic Acid Dibromide*, $C_6H_4Me{\cdot}SeBr_2{\cdot}CH_2{\cdot}CO_2H$.—A solution of 2·29 g. of *p*-tolylselenoglycollic acid (m. p. 98°) in 25 c.c. of dry chloroform was treated with 1·6 g. (1 mol.) of bromine and left in a vacuum desiccator. The dibromide separated in clusters of golden-yellow needles, which decomposed between 90° and 100° with evolution of bromine (Found: Br, 40·9; Se, 20·3. $C_9H_{10}O_2Br_2Se$ requires Br, 41·1; Se, 20·3%).

An aqueous solution of potassium iodide reacted with the dibromide, liberating iodine and regenerating a quantity of the original acid together with a proportion of the corresponding selenoxy-acid. The dibromide was unstable in moist air and was easily hydrolysed, giving brownish-red oils of complex constitution.

2. p-*Tolylselenoglycollic acid tetrabromide*,

$$C_6H_4Me{\cdot}SeBr_4{\cdot}CH_2{\cdot}CO_2H,$$

prepared in a similar manner to that described above by the addition of 3·8 g. of bromine (20% in excess of 2 mols.) to 2·29 g. of *p*-tolylselenoglycollic acid dissolved in dry chloroform, separated in small, scarlet needles which readily decomposed on warming (Found: Br, 58·3; Se, 14·4. $C_9H_{10}O_2Br_4Se$ requires Br, 58·3; Se, 14·4%). The tetrabromide was readily hydrolysed and liberated iodine from an aqueous solution of the acid.

3. p-*Bromophenylselenoglycollic acid dibromide*,

$$C_6H_4Br{\cdot}SeBr_2{\cdot}CH_2{\cdot}CO_2H,$$

prepared as above from 2·94 g. of *p*-bromophenylselenoglycollic acid and 1·6 g. of bromine, formed golden-yellow crystals decomposing at 120—130° with evolution of bromine (Found: Br, 52·8; Se, 17·4. $C_8H_7O_2Br_3Se$ requires Br, 52·9; Se, 17·4%).

4. p-*Bromophenylselenoglycollic acid tetrabromide*,

$$C_6H_4Br{\cdot}SeBr_4{\cdot}CH_2{\cdot}CO_2H,$$

prepared from 2·94 g. of *p*-bromophenylselenoglycollic acid and 3·8 g. of bromine in dry chloroform, formed scarlet needles which decomposed on warming with evolution of bromine (Found: Br, 65·0; Se, 12·8. $C_8H_7O_2Br_5Se$ requires Br, 65·15; Se, 12·9%).

The authors desire to express their thanks to the Government Grant Committee of the Royal Society and to the University of Birmingham Research Committee for grants which have helped to defray the expense of this investigation.

UNIVERSITY OF BIRMINGHAM,
EDGBASTON.

CCXXXIV.—*Aromatic Derivatives of Germanium.*

By Gilbert T. Morgan and Harry Dugald Keith Drew.

When germanium tetrabromide is treated with a large excess of magnesium phenyl bromide (36 mols.) it yields *germanium tetraphenyl* or *tetraphenylgermane*, $Ge(C_6H_5)_4$, *triphenylgermanium bromide* $Ge(C_6H_5)_3Br$, and the less phenylated germanium bromides $Ge(C_6H_5)_2Br_2$ and $Ge(C_6H_5)Br_3$. The first two products are readily separated, but the latter pair, which do not solidify when mixed, have been identified by the isolation of their hydrolytic products.

Hexaphenyldigermane, $(C_6H_5)_3Ge{\cdot}Ge(C_6H_5)_3$, has not been detected among the products of the Grignard reaction, so that under these experimental conditions there is little or no tendency for junction of two atoms of the metal (compare with tin and lead), but the compound is readily prepared by the action of sodium on triphenylgermanium bromide.

$$2GePh_3Br + 2Na = Ph_3Ge{\cdot}GePh_3 + 2NaBr.$$

The production of tetraphenylgermane and hexaphenyldigermane completes the following series :—

	CPh_4.	$SiPh_4$.	$GePh_4$.	$SnPh_4$.	$PbPh_4$.
M. p.	272°	233°	230—231°	225—226°	224—225°
	C_2Ph_6.	Si_2Ph_6.	Ge_2Ph_6.	Sn_2Ph_6.	Pb_2Ph_6.
M. p.	145—147°*	354°	340°	237°	155°*

* These abnormally low melting points are due to dissociation.

Hexaphenyldigermane when examined in dilute benzene solution shows no recognisable tendency to dissociation.

On hydrolysis the solid triphenylgermanium bromide yields *triphenylgermanium oxide*, $(C_6H_5)_3Ge{\cdot}O{\cdot}Ge(C_6H_5)_3$, corresponding with the silicon compound, $Ph_3Si{\cdot}O{\cdot}SiPh_3$. The analogue, $Ph_3Ge{\cdot}OH$, of triphenylsilicon hydroxide was not isolated.

Hydrolytic Products from Diphenylgermanium Dibromide and Phenylgermanium Tribromide.—When only 5 molecular proportions of magnesium phenyl bromide are employed to one of germanium tetrabromide, there is no formation of tetraphenylgermane but the product contains a mixture of mono-, di-, and tri-phenylgermanium bromides.

Diphenylgermanium dibromide yielded on hydrolysis two well-defined complex substances derived by dehydration from the hypothetical dihydroxide or diol, $(C_6H_5)_2Ge(OH)_2$. These products

which have considerable capacity for crystallisation, are *trianhydrotetrakisdiphenylgermanediol*,

$$HO{\cdot}GePh_2{\cdot}O{\cdot}GePh_2{\cdot}O{\cdot}GePh_2{\cdot}O{\cdot}GePh_2{\cdot}OH$$

(I), m. p. 149°, and *tetra-anhydrotetrakisdiphenylgermanediol*,

$$O<\begin{matrix}GePh_2{\cdot}O{\cdot}GePh_2\\GePh_2{\cdot}O{\cdot}GePh_2\end{matrix}>O$$

(II), m. p. 218°.

The formation of these complicated anhydro-compounds recalls the results obtained by Kipping and his collaborators (J., 1912, **101**, 2108, 2125; 1914, **105**, 484) on hydrolysing diphenylsilicon dichloride, when the diol $Ph_2Si(OH)_2$ and four anhydrides were identified. The two silicon derivatives corresponding with formulæ I and II melt respectively at 128—129° and 200—201°. Diphenylgermanium dibromide also undergoes hydrolysis to an insoluble amorphous substance (p. 1765), from which it is regenerated by concentrated hydrobromic acid.

Owing to this tendency to form anhydrides it is obvious that hydrolysis of a mixture of diphenylgermanium dibromide and phenylgermanium tribromide might lead to an anhydro-diol derived from more than one of the reacting bromides. This anticipation was realised by the isolation of a substance (m. p. 275°) having a composition and molecular weight approximating to $Ge_5(C_6H_5)_8O_6$, which may be regarded as a combination of $3GePh_2O$ with $GePhO{\cdot}O{\cdot}GePhO$, these oxides being derived from the hydrolysis of diphenylgermanium dibromide and phenylgermanium tribromide, respectively. This product, which arises apparently from a chance condensation of the two different oxy-compounds, was only obtained in one experiment.

The hydrolysis of phenylgermanium tribromide leads to *phenylgermanonic* or *germanibenzoic acid*, a colourless uncrystallised product soluble in aqueous caustic alkalis. Its properties in regard to degree of hydration vary with the experimental conditions of its preparation and isolation. In all probability its composition varies within the limits $C_6H_5{\cdot}GeO{\cdot}OH$ and $C_6H_5{\cdot}GeO{\cdot}O{\cdot}OGe{\cdot}C_6H_5$ (III) and the analytical numbers approximate to an intermediate complex formula still containing hydroxyl groups. Phenylgermanonic acid or germanibenzoic acid therefore comes into line with silicobenzoic acid and its analogues, which have been shown conclusively by Kipping and his collaborators (J., 1914, **105**, 679; 1915, **107**, 459) to consist of mixtures of condensation products varying in composition with the conditions of hydrolysis of the halogenated silicanes.

The foregoing results obtained with oxygenated phenylgermanium compounds indicate that the reactions of these substances are similar

to those of the oxyarylsilicon derivatives but of a somewhat simpler type with less tendency to the formation of syrups, colloids and infusible mixtures. In this respect germanium forms a link between silicon and tin, and the germanium atom should exhibit a tetrahedral distribution of valencies.

Experimental.

I. *Interaction of Germanium Tetrabromide with a Large Excess of Magnesium Phenyl Bromide.*

1. The Grignard reagent from 5·7 g. of magnesium, 30·2 g. of bromobenzene, and 120 c.c. of ether (36 mols. PhMgBr) was added to 2·1 g. of germanium tetrabromide in 75 c.c. of ether, and the mixture heated for 2 hours. The dark orange-yellow liquid was poured on to ice and acidified with hydrobromic acid, when a creamy white powder remained consisting of *tetraphenylgermane* (0·8 g. or 40%). The ethereal filtrate and extracts, dried over sodium sulphate and concentrated, yielded 0·5 g. of *triphenyl germanium bromide;* the final mother-liquor containing the less phenylated products was worked up as described on p. 1765.

2. During the action of less Grignard reagent (8 mols. PhMgBr) on 4·4 g. of germanium tetrabromide in 25 c.c. of pure chloroform (Boots') heat was generated. The resulting liquid, after being warmed on the water-bath for 1½ hours, was treated as above and yielded 0·93 g. of tetraphenylgermane (22%) and 1·1 g. of triphenyl germanium bromide (26%), the separation of the latter being hastened by adding petroleum (b. p. 60—80°). The ether-petroleum mother-liquors, distilled in steam to remove diphenyl, left a semi-solid yellowish-brown mass which after trituration left 0·4 g. of colourless crystalline *triphenylgermanium oxide*. The oily bromide were worked up as on p. 1765, whereas the aqueous layer from the hydrolysis of the Grignard product by ice deposited gradually a small amount of *phenylgermanonic* or *germanibenzoic acid*.

Tetraphenylgermane (*Germanium tetraphenyl*), $GePh_4$, crystallised from petroleum (b. p. 60—80°) in lustrous, refractive, transparent, prismatic needles, colourless in small quantities, cream-white in bulk. Very stable on heating, it melted at 230—231° and could be volatilised without decomposition (Found: C, 75·4; H, 5·6; Ge, 18·5. $C_{24}H_{20}Ge$ requires C, 75·7; H, 5·3; Ge, 19·0%).

Tetraphenylgermane was insoluble in water, sparingly soluble in ether, light petroleum, or cold acetone, and dissolved more readily in benzene, separating therefrom in acicular prisms. Boiling aqueous caustic alkalis had no effect on this substance; it was insoluble in cold concentrated sulphuric acid, but on warming sulphonation occurred destructively with elimination of phenyl

groups. Fuming nitric acid or a mixture of nitric and sulphuric acids caused nitration and oxidation with evolution of nitrous fumes.

Triphenylgermanium bromide, $GePh_3Br$, formed large, colourless, transparent, six-sided, refractive, prismatic needles or small, compact prisms. Insoluble in water but somewhat readily soluble in ordinary organic media, it was best crystallised from petroleum (b. p. 40—80°); it melted at 138° to a colourless liquid (Found: C, 56·6; H, 4·1; Br, 20·7. $C_{18}H_{15}BrGe$ requires C, 56·3; H, 3·9; Br, 20·8%).

Triphenylgermanium bromide became hydrolysed superficially to its oxide by boiling water or by warm aqueous caustic alkalis. It arose as a by-product in the preceding preparations, but became the chief product when five molecular proportions of the Grignard reagent were employed to one of germanium tetrabromide. When 0·3 g. of the latter substance were used, the ethereal solution, after heating on the water-bath and subsequent treatment with ice and hydrobromic acid, yielded, on concentration of the ether layer, 2·5 g. (or 27%) of triphenylgermanium bromide. The residual oil was then treated with aquo-alcoholic silver nitrate, filtered from silver bromide, and the filtrate evaporated and distilled in steam, when diphenyl and *o*-nitrophenol were removed in the distillate. The non-volatile semisolid residue was fractionated from boiling petroleum (b. p. 60—80°) and from cold ether, when the following crystalline substances were separated: (i) a colourless compound (0·7 g.) melting at 275°, practically insoluble in cold ether or light petroleum and only sparingly soluble in the latter on warming (see pp. 1761, 1767); (ii) *tetra-anhydrotetrakisdiphenylgermanediol* (0·2 g.) melting at 218°, more soluble in ether or petroleum (see p. 1761, 1766); (iii) an orange-yellow substance (0·1 g.) melting from 106° to 112°, very soluble in organic solvents or in water. This product (C, 51·3; H, 4·5%) contained no germanium and did not depress the melting point of ordinary *p*-nitrophenol (C, 51·8; H, 3·6%), but unlike the latter it was intensely yellow and more soluble in cold water. Being formed from phenylated germanium derivatives and silver nitrate in the absence of mineral acids, it may consist in part of an *aci*-form of *p*-nitrophenol. In addition to these solid products there was a considerable proportion of uncrystallisable germaniferous material which was worked up subsequently as described on p. 1766.

Triphenylgermanium Oxide, $Ph_3Ge{\cdot}O{\cdot}GePh_3$.—An alcoholic solution of triphenylgermanium bromide was boiled with silver nitrate, filtered from silver bromide, and diluted with water, when the oxide was obtained in quantitative yield. This product crystallised from hot petroleum (b. p. 60—80°) in transparent, colourless

prisms melting to a colourless liquid at 182—183°; it separated from ethyl acetate in thin, six-sided plates (Found: C, 69·2; H, 4·9; Ge, 23·2. $C_{36}H_{30}OGe_2$ requires C, 69·35; H, 4·85; Ge, 23·2%).

In organic media triphenylgermanium oxide was more soluble than tetraphenylgermane but less so than triphenylgermanium bromide; it was unattacked by 50% aqueous caustic potash, but was reconverted quantitatively into triphenylgermanium bromide by hydrobromic acid (*d* 1·45).

Hexaphenyldigermane, $Ph_3Ge{\cdot}GePh_3$. — Triphenylgermanium bromide (3 g.) dissolved in 37 c.c. of dry xylene was heated for 3 hours with excess of " molecular " sodium. The filtered solution deposited on cooling 2·2 g. of hexaphenyldigermane, and a further amount was obtained on concentration. The final filtrate contained a small quantity of the more soluble triphenylgermanium oxide arising as a by-product.

Hexaphenyldigermane separated from hot benzene in large, colourless, transparent cubes crumbling into powder on exposure to air: loss of benzene at 100° = 24·3%, corresponding with 3 mols. of C_6H_6. It was sparingly soluble in cold but more soluble in hot chloroform, separating therefrom in colourless micro-crystals, m. p. 340° [Found: C, 70·8, 70·7; H, 5·1, 5·3; Ge, 23·5; *M*, ebullioscopic in benzene, 566 ($c = 0·595$), 560 ($c = 1·328$). $C_{36}H_{30}Ge_2$ requires C, 71·2; H, 5·0; Ge, 23·85%; *M*, 606·8].

Hexaphenyldigermane was insoluble in boiling aqueous caustic soda, but on boiling with alcoholic silver nitrate a slight blackening occurred owing to liberation of silver.

Phenylgermanonic Acid (*Germanibenzoic Acid*, p. 1761).—The aqueous mother-liquors from the hydrolysis of the Grignard mixture slowly deposited a white, colloidal precipitate, which was purified for analysis by redissolving in aqueous caustic soda, the filtered solution being then acidified, when the white, amorphous powder separated and was dried at 100° (Found: C, 39·9; H, 3·2. The simplest formula, $C_6H_6O_2Ge$, requires C, 39·5; H, 3·3%).

From concentrated solutions of its sodium salt, phenylgermanonic acid separated at once (hydrogel form), but in dilute solutions it remained dissolved (hydrosol condition) and separated only after several weeks.

II. *Interaction of Germanium Tetrabromide and Magnesium Phenyl Bromide* (5 *mols.*).

A Grignard solution, prepared from 48·4 g. of bromobenzene (5 mols.), 9·1 g. of magnesium, and 200 c.c. of ether, was added slowly to an ice-cold solution of 24·5 g. (1 mol.) of germanium tetrabromide in 100 c.c. of ether, moisture and carbon dioxide being

excluded. The heavy colourless oil which separated persisted after heating on the water-bath. The cooled mixture was decomposed by ice and 50 c.c. of hydrobromic acid (*d* 1·45), when the crackling sound produced by the hydrolysis of germanium tetrabromide showed that this substance was not completely attacked even by excess of Grignard reagent. The solution was extracted with ether and the mixed ethereal extracts were dried over sodium sulphate. The aqueous layer, which gave no precipitate of phenylgermanonic acid (germanibenzoic acid) either when left or when partially neutralised, contained no other organic derivatives of germanium.

The ethereal extract, concentrated to a small bulk, gave 9 g. (37·5%) of *triphenylgermanium bromide.*

The residual oil, which contained a complex mixture of triphenylgermanium bromide, the less phenylated germanium bromides, and chiefly diphenylgermanium dibromide together with diphenyl and traces of bromobenzene, was dissolved in 150 c.c. of alcohol and added to 20 g. of silver nitrate in 100 c.c. of alcohol and 40 c.c. of water, when a dark brown precipitate separated. The mixture was heated under reflux for an hour and the alcoholic filtrates (A) separated from a black precipitate (B). This precipitate B, which consisted mainly of silver bromide but contained some organic germanium compound, was boiled with ammonia (*d* 0·88),* when a black residue remained which was extracted successively with aqueous sodium thiosulphate and dilute nitric acid, leaving 1·5 g. of a white, amorphous organic germanium compound. This substance melted partly at 260° and was insoluble in organic solvents, aqueous alkalis or ammonia; it was converted by hydrobromic acid into an oily bromide, from which the original amorphous substance was recovered by the action of water. This uncrystallisable product was also obtained by the hydrolysis of the oily bromide from tetra-anhydro-tetrakisdiphenylgermanediol, m. p. 218°.

The alcoholic filtrate A was evaporated and the oily residue distilled in steam, when diphenyl and *o*-nitrophenol passed over. The residue, a solid of pitchy consistence, was dissolved in ether and the yellow solution filtered and concentrated until an orange-yellow, semi-crystalline mass separated. This product, after extraction with cold petroleum (b. p. 80—100°) to remove diphenyl and other more soluble impurities, furnished 5 g. of an almost

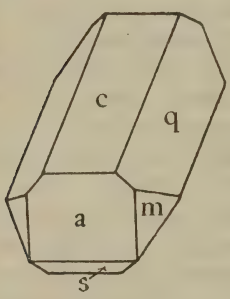
* The ammoniacal filtrate deposited on cooling lustrous spangles of silver bromide having a highly refractive reflex. This product was an insensitive form of the bromide, for it retained its bright metallic lustre after months of exposure to light. The ammoniacal liquor, which contained traces of organic derivatives of germanium, had the property of converting more yellow silver bromide to this insensitive form, the spangles separating at the surface of the solution.

colourless mixture of organic germanium derivatives now free from bromine. Repeated solution of this mixture in ethyl acetate followed by fractional crystallisation and hand-picking of the resulting crystals led to a separation of the following substances :—

1. *Triphenylgermanium oxide*, m. p. 182—183° (see p. 1763), separating from ethyl acetate in thin, rhomboidal or pentagonal plates.

2. *Tetra-anhydrotetrakisdiphenylgermanediol* (Formula II), crystallising in colourless, cubical and prismatic forms, the latter with bevelled and facetted faces. This complex diol was purified by crystallisation from petroleum or ethyl acetate, in which it was readily soluble, and then melted indefinitely at 218° [Found : C, 59·4, 59·1 ; H, 4·25, 4·4. $(C_{12}H_{10}OGe)_x$ requires C, 59·4 ; H, 4·2%.

Fig. 1.



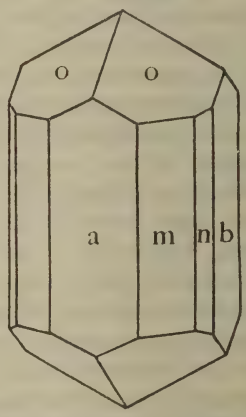


Fig. 2.

Found : by the ebullioscopic method in benzene ($c = 1·48$), M, 905. $(C_{12}H_{10}OGe)_4$ requires M, 970].

3. *Trianhydrotetrakisdiphenylgermanediol* (Formula I), m. p. 149°, obtained in colourless, hexagonal prisms or flattened, rhomboidal crystals with bevelled edges (Found : C, 58·8 ; H, 4·6. $C_{48}H_{42}O_5Ge_4$ requires C, 58·3 ; H, 4·25%).

Crystallographic Examination.

Two of the foregoing substances (Nos. 2 and 3) were kindly examined by Dr. T. V. Barker, who reports as follows :—

Tetra-anhydrotetrakisdiphenylgermanediol (Fig. 1).—The crystals of this substance are monoclinic with the forms $m(110)$, $a(100)$, $q(011)$, $c(001)$ and $s(201)$ developed in the proportions given in Fig. 1. The axial ratios, $a : b : c = 1·491 : 1 : 1·018$, $\beta = 111° 42'$, were computed from the following results given by four crystals.

	m.	*a*.	*q*.	*c*.	*s*.
ϕ.....	0° 0′	0° 0′	68° 21′	*68° 18′	*137° 0′
ρ.....	35 45	90 0	*46 35	90 0	90 0

Optically, the crystals are positive; the axial plane is $b(010)$, and one optic axis is nearly normal to $a(100)$.

Trianhydrotetrakisdiphenylgermanediol (Fig. 2).—The crystals are orthorhombic with the forms $a(100)$, $m(110)$, $n(120)$, $b(010)$, and $o(111)$ developed in the proportions given in Fig. 2. The axial ratios, $a : b : c = 0{\cdot}9539 : 1 : 0{\cdot}5399$, were computed from the following measurements derived from four crystals.

	b.	*n*.	*m*.	*a*.	*o*.
ϕ	0° 0′	27° 50′	*46° 21′	90° 0′	46° 21′
ρ	90 0	90 0	90 0	90 0	*38 2

Optically, the positive acute bisectrix is parallel to the *c*-axis, and the axial plane is *a*.

The Complex Diol melting at 275°.—When recrystallised from ethyl acetate, it separated in large, transparent, colourless prisms melting at 231° and containing solvent of crystallisation. At 140° the loss of weight was 4·45%, corresponding approximately with 2 mols. of diol combined with one of ethyl acetate (theory 3·9%). Crystallised from carbon tetrachloride, the compound melted to a transparent, colourless liquid at 277—278° but rather indefinitely [Found : C, 53·8; H, 3·9; Ge, 33·6; *M*, ebullioscopic in benzene ($c = 1{\cdot}000$), 1003. $C_{48}H_{40}O_6Ge_5$ requires C, 53·6; H, 3·7; Ge, 33·7%; *M*, 1074].

This complex diol was insoluble in water, dilute alcohol, ether, or petroleum and only sparingly soluble in other organic media.

Note on the Analysis of Aromatic Germanium Compounds.

In estimating carbon and hydrogen the combustion was effected entirely with oxygen in a tube containing copper oxide and lead chromate. The oxygenated germanium compounds required very prolonged heating at high temperatures in order to oxidise the last traces of carbon, which otherwise remained in the boat or on the side of the tube as a refractory black material.

For the estimation of germanium the weighed substance was digested during 8 or 10 hours with 18 c.c. of concentrated sulphuric acid (A.R. quality) in a flask with a ground-in air-condenser. The cooled liquid and undissolved germania were washed into a conical flask with 150 c.c. of water, any adherent germania being removed by boiling aqueous sodium carbonate (A.R.). The clear solution was thoroughly saturated with washed hydrogen sulphide and left in the closed flask for a day. The pinkish-white sulphide containing free sulphur and some organic matter was collected on a Gooch crucible with ashless paper filter, and washed successively with 4*N*-sulphuric acid saturated with hydrogen sulphide and aqueous hydrogen sulphide. After drying at 100° the precipitate and the portion

remaining on the filter-paper were converted into germania in separate porcelain crucibles by treatment with dilute and then with concentrated nitric acid. On igniting the crucibles strongly, germania was obtained in a perfectly white condition.

The authors desire to express their thanks to Messrs. Brunner Mond and Company, Limited, for a grant which has partly defrayed the expense of this investigation.

CCXXXV.—*The Stability of Additive Compounds between Esters and Acids.*

By JAMES KENDALL and JAMES ELIOT BOOGE.

THE parallelism between the electrical conductivity of an acid solution and its catalytic activity in ester hydrolysis formed one of the strongest supports of the Arrhenius ionisation theory in its early stages. More accurate measurements made it evident, however, that direct proportionality between hydrogen-ion concentration and reaction velocity could not be claimed. Other divergences were soon noted; not only did the rate of hydrolysis increase more rapidly than hydrogen-ion concentration, it also increased with the ester concentration. Many investigations have been performed upon ester–acid–water systems to explain these divergences, and several interesting theories—for example, the theory of the catalytic activity of the undissociated molecule and the theory of the anticatalytic effect of water—have been developed. The radiation hypothesis also has been applied to the problem by Lewis and his co-workers, but the mechanism of acid catalysis of ester hydrolysis is still unsolved.

Some advance has been made, nevertheless, in the general recognition of the fact that the concentrations of the reacting molecular species in a solution of this complicated character cannot be directly calculated from its composition. Formation of additive compounds certainly disturbs the stoicheiometric ratios very materially, and inasmuch as it appears most probable that the hydrolysis is effected in steps, with these compounds as intermediate products, it is clearly important to examine their character and stability as thoroughly as possible.

The first direct evidence of the existence of additive compounds between esters and acids was furnished by the present authors in an earlier article (*J. Amer. Chem. Soc.*, 1916, **38**, 1712), in which

xtensive references to previous work will also be found. Thirteen lefinite compounds of the general type R·CO·OR′,HX were isolated, nd it was shown qualitatively that the stability of such compounds n the liquid state increased as the radicals R and R′ were made more lectropositive, or as the radical X was made more electronegative. The most stable compounds were consequently obtained when an *ster of a weak acid* (*e.g.*, ethyl acetate) was paired with a *strong acid* *e.g.*, trichloroacetic acid), but some compound formation was still ndicated even in such an unfavourable system as methyl oxalate–cetic acid.

From the results of this investigation, the general conclusion was drawn that the formation of an ester–acid additive compound onstitutes the first step in ester hydrolysis. The following articles liscuss the stability of these complexes quantitatively, and also xamine the evidence with regard to their dissociation and the ormation of additive compounds of other types in the presence of he third component—water.

The progressive dissociation of ester–acid compounds on addition f water may be postulated as due to three distinct causes. In the irst place, the effect may be purely *diluent*, the equilibrium point n the reaction $R{\cdot}CO{\cdot}OR',HX \rightleftharpoons R{\cdot}CO{\cdot}OR' + HX$ being shifted n the forward direction merely by the diminution in the concen-rations of ester and acid as we proceed from the anhydrous system o a dilute aqueous solution. Secondly, the water may disturb the quilibrium still further by combining with the free acid or ester to orm binary complexes of the type HX,H_2O or $R{\cdot}CO{\cdot}OR',H_2O$. Thirdly, the water may combine with the ester–acid compound to ive a ternary complex of the type $R{\cdot}CO{\cdot}OR',HX,H_2O$.

In order to separate these three factors, as far as is feasible, the roblem has been taken up in stages. First, the extent of the lissociation of certain typical ester–acid compounds into their omponents on fusion has been examined by comparing the freezing-oint depressions induced by addition of free ester, an inert solute benzene), and the active solute water. Next, the extent to which ster–acid compounds are still existent in a dilute solution, when the olvent is inert, has been investigated by determining the freezing-oint depression curves of benzene on addition of ester and of acid, eparately and in company. Binary systems of the types acid–vater and ester–water are then discussed, and the final and most ntricate case of all (the ternary system: ester–acid–water) is thus pproached only after the results of the preceding work have fur-ished useful information as to the most promising methods of ttack.

The Stability of Ester–Acid Compounds on Fusion.

Three compounds are examined in this section, the complexes chosen being those formed by trichloroacetic acid with ethyl acetate benzyl benzoate and methyl succinate respectively. The extent of dissociation in each case is calculated from the form of the freezing-point depression curves of the compound, as indicated in Fig. 1.

This method was first suggested by Bancroft (*J. Physical Chem.* 1899, **3**, 72) and developed in detail by Kremann (*Monatsh.*, 1904 **25**, 1215). Unfortunately, the equations arrived at by Kremann are not free from error (Roozeboom and Aten, *Z. physikal. Chem.* 1905, **53**, 449) and it is important to note that the method is *strictly* applicable only when the heat of dissociation of the complex is zero. Nevertheless, since in mixtures of organic substances heats of dissociation are in general but small, and the stability of a given compound may be regarded as constant over a restricted temperature range, the method may be utilised to give approximately accurate values, the procedure being briefly as follows:

If an additive compound is perfectly stable on fusion, its freezing-point curve on addition of y moles of either component to 100 moles of compound will be given by the equation:

$$-\log_e\left(\frac{100}{100+y}\right)=\frac{Q}{R}\left(\frac{1}{T}-\frac{1}{T_0}\right) \quad . \quad . \quad . \quad \text{(I)}$$

where Q is the molar heat of fusion of the compound in calories, T_0 its absolute temperature of fusion in the pure state, T its absolute temperature of fusion in the solution, and R the gas constant 1·988. If, on the other hand, the percentage dissociation of the pure compound on fusion is x, then addition of y moles of either component to 100 moles of the compound will repress this dissociation to a smaller value x', and we obtain the equation:

$$-\log_e\left(\frac{100-x'}{100+x'+y}\right)=\frac{Q}{R}\left(\frac{1}{T}-\frac{1}{T_0}\right) \quad . \quad . \quad \text{(II)}$$

the graph for which will vary more and more from that given by equation (I), according as x increases. Various trial values may be assumed for x, and the resultant curves compared with that obtained experimentally until accordance is reached.

It remains to show how the "unknowns" in equation (II) may be evaluated. If K is the dissociation constant of the reaction $R{\cdot}CO_2R'$, $HX \rightleftharpoons R{\cdot}CO_2R' + HX$, then we have the two equations

$$\left(\frac{x}{100+x}\right)^2=K\left(\frac{100-x}{100+x}\right) \quad . \quad . \quad . \quad \text{(III)}$$

and

$$\frac{x'(x'+y)}{(100+x'+y)^2}=K\left(\frac{100-x'}{100+x'+y}\right) \quad . \quad . \quad \text{(IV)}$$

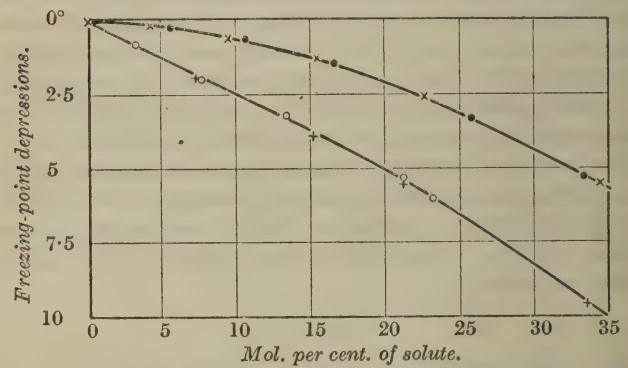
ience, as K is known for each assumed value of x, the variation of with y is derived. Q must be determined either calorimetrically, (by calculation) from the form of the freezing-point curve when an ert solute is added. R, of course, is known. The only remaining tor, T_0 (the hypothetical freezing point for the pure compound the absence of dissociation products), is obtained from equation I) by putting $y = 0$, when x' becomes x and T becomes the perimental freezing point.

1. *The Compound Ethyl Acetate–Trichloroacetic Acid.*—This mpound, as obtained by mixing equimolecular quantities of its refully purified components, melted sharply at $-26{\cdot}8°$. A nplified Beckmann type of apparatus was used to determine the ezing-point depression curves of this material on addition of hyl acetate, benzene and water, and in view of the approximate ture of the method and the difficulty of working at low temper- ures and maintaining anhydrous conditions, no attempt was made obtain readings for the freezing-point depression (ΔT) to a eater accuracy than 0·05° in the more dilute, or 0·1° in the more ncentrated solutions. Additions of solute were made by means of Grethan pipette. Compositions are expressed throughout in olecular percentages.

TABLE I.

Freezing-point Depression Curves of the Compound: Ethyl Acetate–Trichloroacetic Acid.

Solutes.						
hyl acetate	Mol. %	4·23	9·55	15·45	22·75	34·5
	$\Delta T°$	0·15	0·60	1·30	2·6	5·5
nzene	Mol. %	3·27	7·74	13·4	21·3	23·2
	$\Delta T°$	0·80	2·0	3·2	5·3	6·0
ater	Mol. %	7·47	15·24	21·3	33·7	
	$\Delta T°$	1·90	3·9	5·5	9·6	



These results are expressed graphically in Fig. 1. Partial dis- ciation of the compound on fusion is shown by the fact that hyl acetate does not give the same freezing-point depression rve as the other solutes. By application of equation (II) above, is found that the approximate degree of dissociation of the com- und in the liquid state is 12%. The assumption of this value x gives practically perfect agreement throughout the whole gth of the experimental and calculated curves.

The value for Q, obtained calorimetrically for use in these calcul- ons, was 5170 ± 50 calories. This was checked by a rather ricate calculation from the freezing-point depression curve tained with benzene as solute. The value so derived was 50 ± 100 calories.

A most unexpected result in the above table is the identity of th freezing-point depression curves obtained with benzene (an ine solute) and water (presumably reactive). In this connexion it ma be mentioned that the points on the water curve did not chang significantly with time during the course of the determination hydrolysis effects evidently being quite slow at the low temperature involved. Comment upon the abnormal position of the water curv will be made at the conclusion of this article.

FIG. 1.

Freezing-point depression curve of the compound: ethyl acetate–trichloroacetic acid.

○ = Benzene. + = Water. × = Ethyl acetate (experimental). ● = Eth acetate (calculated for 12% dissociation of pure compound on fusion).

2. *The Compound Benzyl Benzoate–Trichloroacetic Acid.*—Th pure compound in this case melted sharply at 13·6°. The freezing point depression results obtained with benzyl benzoate, benzene, an water as solutes are given below.

TABLE II.

Freezing-point Depression Curves of the Compound: Benzyl Benzoate–Trichloroacetic Acid.

Solutes.						
Benzyl benzoate	Mol. %	4·54	9·92	15·75	26·1	51·7
	$\Delta T°$	0·10	0·35	0·80	2·0	8·5
Benzene	Mol. %	5·37	13·6	27·6	42·6	
	$\Delta T°$	1·40	3·6	8·1	14·4	
Water	Mol. %	7·58	10·87	19·7	27·0	
	$\Delta T°$	1·80	2·9	5·8	8·6	

Again the benzene and water curves are very nearly identica Calculation of the degree of dissociation of the compound on fusio from the position of the benzyl benzoate curve, using a calorimetri ally determined value for Q of 5660 $\pm$ 40 calories, leads to a valu of (approximately) 35%.

3. *The Compound Methyl Succinate–Trichloroacetic Acid.*—A pure ample of this compound (which contains one molecule of ester to wo of acid) melted sharply at 8·3°.

TABLE III.

Freezing-point Depression Curves of the Compound: Methyl Succinate–Trichloroacetic Acid.

Solutes.						
Methyl succinate	Mol. %	4·52	9·27	18·55	29·3	44·8
	$\Delta T°$	0·30	0·50	1·70	3·8	9·6
Benzene	Mol. %	5·55	11·97	21·8	31·3	
	$\Delta T°$	0·85	1·90	4·0	6·3	

The calculation of the degree of dissociation of this 1 : 2 compound rom the position of the methyl succinate curve is more complicated han in the previous cases. It is also more uncertain, since a com- ound of the type AB_2 may give an intermediate dissociation pro- uct AB as well as its simple components A and B. Fortunately, his particular compound is exceptionally stable, so that it is still ossible to fix its degree of dissociation between the upper and lower mits of 6 and 4% respectively. In this calculation, the value used or Q (9600 calories) is derived from the benzene curve, assuming this or the sake of simplicity to be ideal.

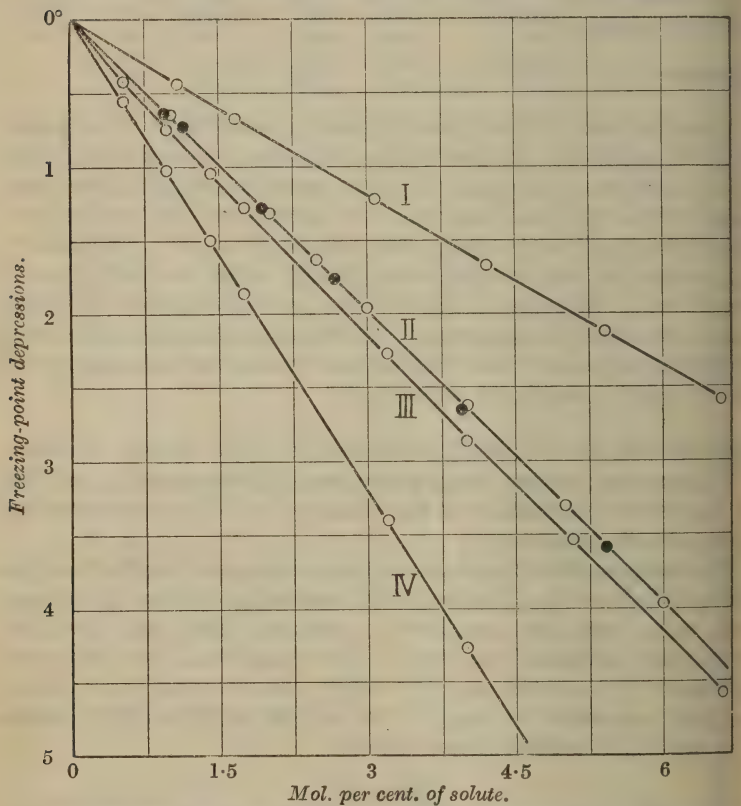
The Stability of Acid–Ester Compounds in Dilute Benzene Solution.

The next step in the investigation was to determine the stability f acid–ester compounds in the presence of a large excess of an nert solvent—benzene.

The compound ethyl acetate–trichloroacetic acid was first studied. able IV gives the freezing-point depression curves of benzene ith ester, acid and compound as solutes. The same data are epresented graphically in Fig. 2. For comparison, the ideal curve btained by substituting $Q = 2370$ calories and $T_0 = 278{\cdot}48$ n the equation $-\log_e(1-x) = Q/R \,.\, (1/T - 1/T_0)$, where = mol. % of solute] is also added.

TABLE IV.

Freezing-point Depression Curves of Benzene (System: Ethyl Acetate–Trichloroacetic Acid).



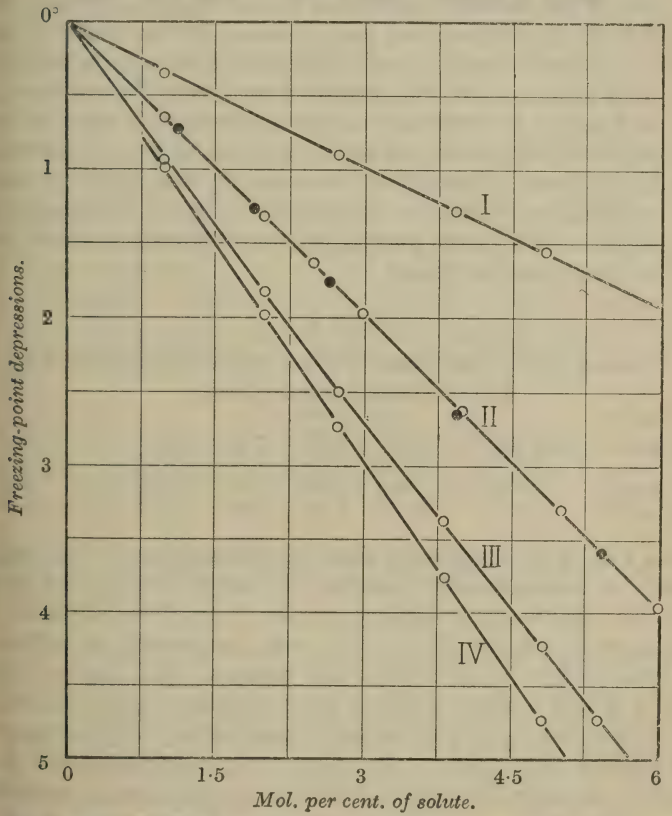
Solutes.								
Ideal	Mol. %	1·0	2·0	2·5	3·0	4·0	5·0	6·0
	$\Delta T°$	0·652	1·308	1·637	1·967	2·631	3·299	3·967
Ethyl acetate	Mol. %	0·965	1·138	1·934	2·670	3·966	5·425	
	$\Delta T°$	0·643	0·727	1·276	1·775	2·640	3·598	
Trichloro-	Mol. %	0·543	1·063	1·654	3·068	4·22	5·41	6·63
acetic acid	$\Delta T°$	0·213	0·432	0·672	1·222	1·674	2·120	2·582
Acid–ester	Mol. %	0·520	0·952	1·410	1·743	3·205	4·065	5·075	6·62
compound	$\Delta T°$	0·417	0·740	1·038	1·273	2·264	2·866	3·532	4·580

Specially purified benzene was employed in this work, and temperatures were read to 0·001° by the Beckmann method. The thermometer employed was calibrated by the Bureau of Standards and all precautions were taken to ensure accuracy.

The ethyl acetate curve, it will be seen from the diagram, follows

FIG. 2.

System: ethyl acetate–trichloroacetic acid. Benzene as solvent.



I *Trichloroacetic acid.* II *Ethyl acetate* (●); *ideal curve* (○). III *Additive compound.* IV *Sum of* I *and* II.

the ideal within error limits. The freezing-point depressions induced by trichloroacetic acid, however, are much less than normal. Examples of this type have been interpreted in the past as indicative of the fact that the solute is associated in the solution, but the conception of Hildebrand (*J. Amer. Chem. Soc.*, 1916, **38**, 1452) that a positive deviation from Raoult's law is consequent upon differences in the internal pressures of the two components of the solution

ffers an alternative explanation. This point will be discussed later. he curve given by the compound, if this were completely dissociated n the solution into ester and acid, would be the sum of the depressions iven by its components separately. This is shown as curve IV on ie diagram. (For strict purposes of comparison, it may be noted,

FIG. 3.

System: ethyl acetate–acetic acid. Benzene as solvent.

I *Acetic acid.* II *Ethyl acetate* (●); *ideal curve* (○). III *Ethyl acetate+ etic acid (experimental).* IV *Sum of* I *and* II.

ie deviation of the ideal freezing-point depression curve from nearity should be taken into account, and curve IV should fall ightly below the sum of curves I and II, but the error introduced y the simpler procedure here adopted is negligible throughout this ork.) The actual curve obtained, curve III, lies considerably ove curve IV, demonstrating that a large proportion of the mpound is still existent as such in the system in spite of its reduced

concentration. The exact degree of dissociation at any given dilution cannot, however, be determined, since we have no means of knowing whether the curve for the undissociated compound follows the ideal or not. Most probably it would lie intermediately between the curves given by its two components, and we may therefore infer that the bulk of the compound is still undissociated when its concentration is diminished to 1—6 mol. %.

In view of the indefinite character of the results obtainable, the work in benzene solution was not extended to the additive compounds of benzyl benzoate and methyl succinate with trichloroacetic acid discussed in the preceding sections. It did seem of sufficient interest, nevertheless, to determine whether the existence of an ester–acid compound, already so unstable in the liquid state as to inhibit its direct isolation from the binary system by the freezing-point method, could still be established in dilute solution in an inert solvent. The results for the system ethyl acetate–acetic acid are given below and in Fig. 3.

TABLE V.

Freezing-point Depression Curves of Benzene (System: Ethyl Acetate–Acetic Acid).

Solutes.							
Acetic acid	Mol. %	0·993	2·75	3·93	4·84		
	$\Delta T°$	0·343	0·905	1·284	1·559		
Acetic acid + ethyl acetate	Mol. %	1·000	2·016	2·751	3·834	4·82	5·38
	$\Delta T°$	0·938	1·827	2·503	3·372	4·215	4·835

From Fig. 3 it is apparent that the freezing-point depressions induced by equimolecular quantities of ethyl acetate and acetic acid taken together are slightly smaller than those obtained by summing up the effects of the two separate components, an indication that some additive compound is still present. The degree of dissociation of this compound at any given dilution is again uncertain, owing to the abnormality of the acetic acid curve, but it is evidently much greater than that of the ethyl acetate–trichloroacetic acid compound, as might be expected with a weak acid as one component.

The Internal Pressure Factor in Freezing-point Depression Curves.

It remains to discuss briefly the abnormalities noted in the various systems examined. These, it will be found, all occur in systems in which we have a polar solute and a non-polar solvent, and in all cases the observed freezing-point depression is less than anticipated. Now Hildebrand (*loc. cit.*) has shown that an abnormally small freezing-point depression is a general characteristic of such systems, in which the internal pressures of the two components

n the liquid state are markedly different. While, therefore, associ-tion of the solute may occur to a minor extent in the cases of richloroacetic acid and acetic acid in benzene, yet the abnormally mall freezing-point depressions obtained must be ascribed, in the nain, to the internal pressure factor.

The freezing-point depression curves of the ester–acid compounds vith water as solute may be explained in the same way. We should ertainly expect water to dissociate these compounds to a far greater legree than benzene, yet the two solutes give curves which are ractically coincident. The curves ought to be widely divergent, part from any question of instability of the solvent, since water nd benzene have internal pressures so very far apart from each ther that they cannot both be ideal solutes in the same liquid. Iost probably, therefore, very extensive dissociation of the ester–cid compound on addition of water does occur, but the negative eviation from Raoult's law consequent thereupon is obscured by a imultaneous positive deviation from Raoult's law due to the internal ressure factor. Confirmation for this view will be found in the esults of the succeeding article, in which the stability of ester–acid ompounds in dilute aqueous solution is examined in detail.

Summary.

The stability of three ester–acid additive compounds on fusion as been investigated. The approximate degrees of dissociation re :

(*a*) Ethyl acetate–trichloroacetic acid (m. p. −26·8°); 12%.
(*b*) Benzyl benzoate–trichloroacetic acid (m. p. 13·6°); 35%.
(*c*) Methyl succinate–trichloroacetic acid (m. p. 8·3°); 4—6%.

These values refer to different temperatures (an unavoidable efect of the freezing-point method employed), but the order of tability is in accordance with previous work. Changes in degree f dissociation with temperature are presumably small. The mole-ular heats of fusion of the three compounds are 5170, 5660, and 600 calories respectively.

In dilute benzene solution (at temperatures slightly above 0°) ie compound ethyl acetate–trichloroacetic acid is still markedly :able, and the decomposition of such a weak complex as ethyl cetate–acetic acid is not complete.

CCXXXVI.—*Additive Compounds in the Ternary System: Ester–Acid–Water.*

By James Kendall and Cecil Victor King.

Several distinct lines of attack have been followed in this investigation, in the hope that the results obtained by converging upon the problem from different angles, together with the various suggestions derived from the simpler binary systems, might furnish greater opportunity for an advance. The freezing-point depression data which form the main part of the work are consequently discussed and correlated with conductivity and reaction velocity determinations at 0°. It is unfortunate that the extensive experimental data of previous investigators on certain of the systems studied cannot be employed to any considerable degree in this comparison, but the majority of such measurements refer to higher temperatures and are not readily reducible to molecular concentration units.

In this paper the four systems ethyl acetate–hydrochloric acid, ethyl acetate–trichloroacetic acid, ethyl acetate–chloroacetic acid and ethyl acetate–acetic acid are examined in detail, with the idea of ascertaining how conditions vary when a representative ester is paired against a series of acids of widely divergent strengths.

Binary Systems Acid–Water and Ester–Water.

Systems of the type acid–water have already been critically investigated by Kendall, Booge, and Andrews (*J. Amer. Chem. Soc.*, 1917, **39**, 2303), and the general law has been deduced that compound formation increases with the strength of the acid. Little work has been done upon systems of the type ester–water. Griffith and Lewis (J., 1916, **109**, 80) have postulated an additive ester-water compound as an intermediate step in ester hydrolysis, but the freezing-point depression data of Rivett for ethyl acetate (*Z. physikal. Chem.*, 1912, **80**, 547), when recalculated on a molecular concentration basis, follow the ideal curve almost exactly. On account of this fact the opinion was expressed (*J. Amer. Chem. Soc.*, 1916, **38**, 1716) that ester–water compounds could not be formed in more than minute quantity. Our own freezing-point depression determinations for ethyl acetate, presented in Table I below (see also Fig. 1), are in complete accordance with those of Rivett, yet a more intensive study of the system leads us now to reverse our judgment.

Briefly, ethyl acetate is a "pseudo-ideal" solute in water, two opposing factors practically counterbalancing each other. The fact that ethyl acetate and water are only partly miscible (due to

ternal pressure differences) precludes all possibility of a normal eezing-point depression curve; the experimental depressions ould be considerably less than the ideal (see Hildebrand, "Solulity," A. C. S. Monograph Series, 1924; also p. 1777 of the preding article). The only factor that could depress the curve ack again to correspond with the ideal is extensive compound rmation between ester and water, and there are several points hich indicate that extensive compound formation actually does cur. Liquids which are partially miscible normally give absorpon of heat on admixture, but heat is evolved, not absorbed, when hyl acetate is dissolved in water. The rapid increase in the lubility of the ester as the temperature is lowered suggests that compound is formed, the stability of which increases with falling mperature (Hildebrand, *loc. cit.*, p. 144). The fact that the ensity of the saturated solution at 0° is greater than unity (Seidell, Solubilities of Inorganic and Organic Compounds," D. van ostrand Co., 1919, p. 285) demonstrates that remarkable conaction accompanies admixture, and this contraction is most mply explained on the assumption of compound formation.

Other systems of the type R·CO·OR′–H_2O are now being examined discover how these two opposing factors—internal pressure fference and compound formation—vary with the nature of the dicals R and R′. For the present, it suffices to know that all ree possible binary systems (ester–acid, acid–water, and ester–ater) give additive compounds, and it becomes necessary to termine to what extent these survive in the ternary system and hether any ternary compounds are formed.

Freezing-point Depression Determinations.

The freezing-point depression results obtained with water on ldition of ethyl acetate, the four acids, and equimolecular quantities ester and each acid taken together, are presented in Table I. ne data for the hydrochloric and acetic acid systems are also ven in Figs. 1 and 2, respectively.

At first the measurements for solutions containing both acid nd ester were made at known time intervals after mixing, with e intention of extrapolating to zero time to correct for the change freezing point due to hydrolysis. This procedure was, however, und to be unnecessary, as the freezing point in the most conntrated solution of the strongest acid did not vary more than a w thousandths of a degree in a whole hour. The experimental ocedure was the same as that employed with benzene as solvent the preceding article. The values given below are the results duplicate measurements, checking to $\pm 0{\cdot}002°$.

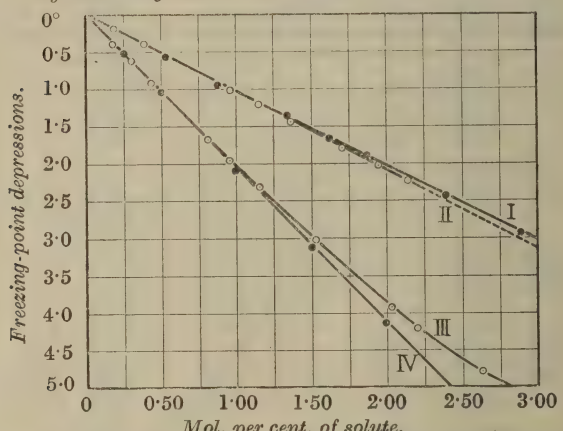
The significance of the data may be most readily appreciate by reference to the diagrams. In the hydrochloric acid syste (Fig. 1), the freezing-point depressions induced by acid and este taken together (curve III) are almost identical with the sum o the depressions induced by corresponding concentrations of th two separately (curve IV). Now if the ester–acid comple R·CO·OR′,HX were completely stable in solution, we shoul expect its curve to follow approximately the ethyl acetate (c ideal) curve (I) in the event of its being a non-electrolyte, or th hydrochloric acid curve (II) in the more probable event of it being a strong electrolyte giving the ions $[R·CO·OR',H]^+$ and X^-

n intermediate position between (I) and (II), or between (II) d (IV), would follow from partial dissociation. The actual sition of the curve indicates, however, complete dissociation the compound into its components, and also demonstrates that rnary complexes cannot exist in any significant quantity in the lution. (In point of fact, curve III lies very slightly below rve IV. This discrepancy may be explained, however, by king into account the slight deviation of the ideal curve from earity [compare p. 1775], accentuated in this case by hydration the solutes.) To explain the total instability of the ester–acid mpound in water solution we need only to consider that the

FIG. 1.

System : ethyl acetate–hydrochloric acid. Water as solvent.

I *Ethyl acetate* (*also ideal curve*). II *Hydrochloric acid.* III *Ethyl acetate* + *rochloric acid* (*experimental*, ○). IV *Sum of* I *and* II (●).



er and the water function as rival bases, competing for the session of the hydrochloric acid. Alone, each is able to furnish able additive compound (or oxonium salt); but in dilute aqueous ition the enormous excess of water and its more highly basic racter lead to essentially complete destruction of the ester–acid plex.

n the acetic acid system (Fig. 2), on the other hand, the freezing- nt depressions obtained with acid and ester together are, at higher concentrations examined, appreciably less than the n of those obtained with the two solutes separately. The same ults are given by the trichloroacetic and chloroacetic acid systems, difference at equivalent concentrations (*e.g.*, 1 mol. %) increasing h the strength of the acid. This might be argued to indicate

that a small fraction of the ester–acid complex does, after al escape decomposition, the fraction increasing with the strengt of the acid. On this basis, the results for the hydrochloric aci system alone would have to be regarded as abnormal. Alter atively, the three freezing-point depression curves in a syste containing an organic acid may be considered as not strictly con parable, owing to differences in internal pressure and associatio factors. It is significant, in this connexion, that chloroacetic an acetic acids already give small positive deviations from Raoult law in concentrated aqueous solution, before any addition of este

FIG. 2.

System : ethyl acetate–acetic acid. Water as solvent.

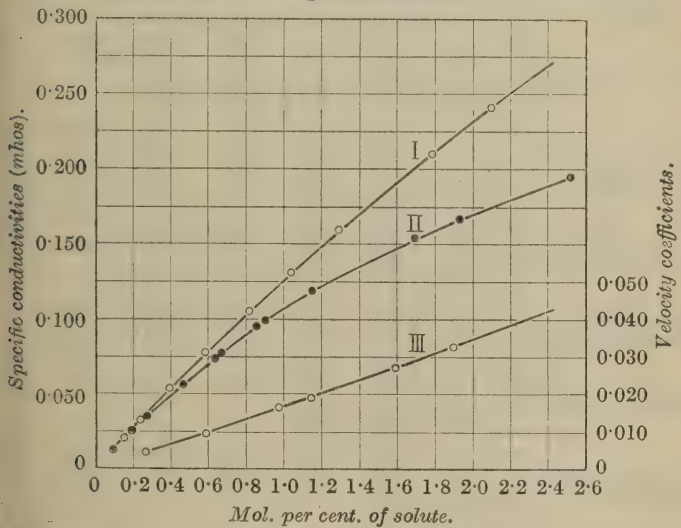
Before this question is discussed further, the conductivity a velocity of reaction results for equimolecular mixtures of eth acetate with the four acids will be presented. A final feature the freezing-point depression curves may be noted here: t maximum concentration that can be investigated varies ve remarkably in the four systems. It is not possible, of course, carry out exact solubility measurements under the conditions experiment, but the approximate molecular concentrations which two liquid layers first persist, when equivalent quantiti of ethyl acetate and acid are added to water at 0°, are as follow



Ester alone.	Ester + HCl.	Ester + $CCl_3 \cdot CO_2H$.	Ester + $CH_2Cl \cdot CO_2H$.	Ester + $CH_3 \cdot CO_2H$.
2·2	2·55	1·1	1·75	2·75

It would be hazardous to offer even a tentative explanation these solubility changes. If the second phase were fixed (as

he case of a solid solute), an increase in solubility could be interreted as indicative of compound formation. In the present nstance, however, the saturating phase is not pure ethyl acetate, ut a second liquid layer containing dissolved water and acid, so hat no general comparison can be made. The run of the figures certainly very curious, the strongest and weakest acids causing ncreased solubility and the intermediate acids decreased solubility. The 50% decrease of solubility in the presence of trichloroacetic cid, a substance perfectly miscible with both ester and water, is articularly mystifying.

Specific Conductivity Determinations.

A General Radio Co. audio-oscillator, giving a nearly pure sine-ave alternating current at a frequency of 1000 per second, was sed as the source of current. With solutions of high resistance a harper minimum was obtained by inserting a two-stage thermionic mplifier (compare Hall and Adams, *J. Amer. Chem. Soc.*, 1919, 4, 1515). The bridge was a Leeds and Northrup 4·7 metre circular side-wire instrument, with resistance coils from 0·1 to 10,000 ohms. Ildwin type G telephones were employed.

The conductivity cells were of the Washburn dumb-bell type, with unplatinised electrodes. Their constants, 128·66 and 0·3694

respectively, were determined according to the directions of Kra and Parker (*J. Amer. Chem. Soc.*, 1922, **44**, 2422). Small variab air condensers were used across the resistances to balance out th cell capacity. All measurements were made in a large bath cracked ice and water, the temperature of which was constan at $-0{\cdot}02 \pm 0{\cdot}005°$. Conductivities taken at known time interva after mixing the acid–ester solutions showed that in no case wa it necessary to extrapolate back to zero time, hydrolysis at being sufficiently slow to exercise no significant effect during th time of measurement.

The curves for the hydrochloric and acetic acid systems ar shown in Figs. 3 and 4. It will be seen that the addition of a equivalent quantity of ethyl acetate brings about a considerab diminution in the specific conductivity of the acid solutions, th effect being more pronounced the higher the concentration. I the acetic acid system, the reduction is actually sufficient to cau a decrease in the specific conductivity at concentrations abo

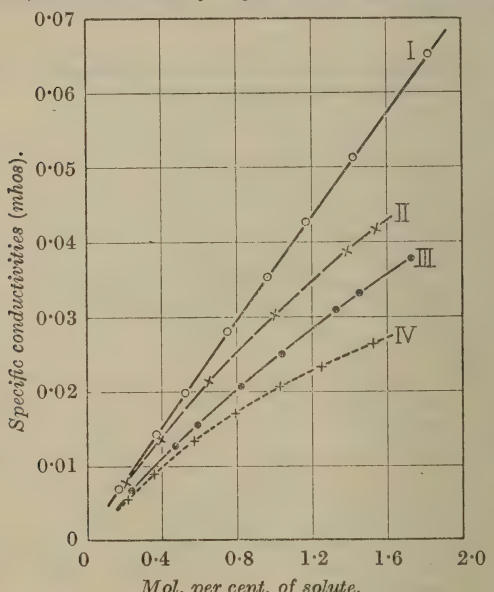
·6 mols. %. The percentage reduction increases as the acidic trength decreases, the lowering of specific conductivity for the our systems at 1·0 mol. % being : HCl, 16% ; $CCl_3{\cdot}CO_2H$, 18% ; $H_2Cl{\cdot}CO_2H$, 23% ; $CH_3{\cdot}CO_2H$, 24%. (The increase in the volume f the solution due to the addition of ester at this concentration, may be noted, is less than 5%. The reduction in specific con- uctivity, therefore, is not simply due to dilution.)

This phenomenon has been noted previously by Griffith and ewis (*loc. cit.*). The most obvious means of accounting for the bserved decrease is to assume compound formation of ester with cid in the solution. If the ester–acid complex R·CO·OR′,HX

FIG. 4.

System : ethyl acetate–acetic acid. Specific conductivities and reaction velocities in aqueous solution at 0°.

I *Acetic acid, alone.* II *Acetic acid + ethyl acetate.* III *Reaction velocities : uimolecular acid–ester solutions.*



mained non-ionised, then its formation would lower the con- ntrations of both H^+ and X^-, whilst if it were an electrolyte the ain factor would be the replacement of the rapidly-moving ion H^+ the less mobile complex $[R{\cdot}CO{\cdot}OR',H]^+$. Two alternative planations, however, must also be considered : (*a*) the addition ester may cause a decrease in the dielectric constant of the lution and so reduce the extent of ionisation of the acid, or (*b*) the ldition of ester may simply decrease the mobility of the ions thout changing their nature (compare alcohol–water mixtures, dlewski, *Z. physikal. Chem.*, 1905, **51**, 751).

None of these three explanations is in entire harmony with the ezing-point depression results already recorded for the same stems. The extent of compound formation demanded by the

first is much greater than that indicated by the freezing-poi curves for the three organic acids, while the hydrochloric acid da are in direct conflict with any assumption of ester–acid comple survival in the system. Under the second explanation, not onl are the observed freezing-point depression curves abnormal i the case of the two strong acids, but it is necessary to assume a enormous decrease in the dielectric constant for the addition of small amount of ester. The following experiments may be regarde

FIG. 5.

I *Potassium chloride, alone.* II *Potassium chloride + ethyl acetat* III *Potassium acetate, alone.* IV *Potassium acetate + ethyl acetate.*

as definitely eliminating these two hypotheses, and thereby increasi the likelihood that the third is, in general, valid.

The effect of addition of ester on the specific conductivities neutral salt solutions may first be considered. Potassium chlori and potassium acetate were selected as typical derivatives of strong and a weak acid respectively, and the determinations, carri out exactly as in the case of the acid solutions, are summarised Table III and Fig. 5.

It is evident from Fig. 5 that the addition of ester decreases t specific conductivity of a neutral salt solution just as effective as it does that of an acid solution. At a concentration of 1·0 mol.

ıe decrease for potassium chloride is 17%, and for potassium :etate 18%. Now there is certainly no compound formation :twee the ester and the neutral salts in the solution to the extent dicated by these figures. We must consequently conclude that .e decrease in specific conductivity induced by the presence of .e ester is due to some general effect, quite unconnected with the rmation of specific additive compounds.

A choice between the second and the third hypothesis is possible rough hydrogen-ion concentration measurements. If the decrease specific conductivity is due to a lowering of the dielectric con-ınt, the hydrogen-ion concentration of the solution should diminish ıen ester is added, whereas a mere diminution in ionic mobilities ould leave the hydrogen-ion concentration unchanged. Un-:tunately, attempts to obtain direct hydrogen-ion concentration terminations by the hydrogen electrode method gave inconclusive ;ults, since it was found that the potential of the hydrogen-ion :ctrode in a freshly prepared acid–ester solution at 0° was practic-y the same as in the same solution after hydrolysis had run to mpletion, or as in a solution containing equivalent quantities the hydrolysis products, acetic acid and ethyl alcohol. Appar-tly the hydrolysis is catalysed so rapidly by the platinum black ıt in the immediate vicinity of the electrode equilibrium con-ions are reached almost instantaneously. This point is being ıdied further, with modifications of method.

The matter may be decided indirectly, however, by determining) effect of the addition of ethyl acetate on the rate of sucrose ersion in an acid solution. Previous experiments by Coppadoro (*Gazzetta*, 1901, **31**, i, 425) with methyl acetate suggested that a ısiderable reduction does occur, but Henri and des Bancels

(*Compt. rend. Soc. Biol.*, 1901, **53**, 784) and Griffith and Lew (*loc. cit.*) agree that the same ester exercises practically no influenc With ethyl acetate the following results at 0° were obtained :

Mol. % of solutes.	Inversion constan
I. Sucrose 1·5; HCl 1·5	0·01045
II. Sucrose 1·5; HCl 1·5; ethyl acetate 1·5	0·01035

The inversion was followed in a Schmidt and Haensch polar meter, reading to 0·01°. The solutions were placed in a 220 mm tube, immersed in a bath kept at 0 ± 0·01° and fitted as describe by Nelson and Beegle (*J. Amer. Chem. Soc.*, 1919, **41**, 559). Th inversion constants given above have an accuracy of ± 1%, s it is clear that addition of ester induces practically no change i the rate of inversion and presumably, therefore, no significa change in the hydrogen-ion concentration of the solution. Dimi ution of ionic mobility is consequently to be regarded as the probab cause of the lowering in specific conductivity recorded in Tables I and III.

Determinations of Velocity of Hydrolysis.

The rates of hydrolysis of ethyl acetate at 0° in the presenc of equivalent quantities of the four acids up to the saturatio concentration are given in Table IV below. The curves for th hydrochloric and acetic acid systems are shown also in Figs. and 4. The course of the hydrolysis was followed by the usu method of withdrawing samples from the bath at intervals an titrating against potassium hydroxide, standardised against hydr chloric acid and free from carbonate. The time required fo solutions of the weaker acid to reach equilibrium varied fro 1 to 8 weeks. In a few instances, it was necessary to determin the end value by raising the temperature to 25° for a time an then returning to 0° for a week or so to obtain a final adjustmen In view of the very small change with temperature of the positio of the equilibrium point in ester hydrolysis, no significant erro could be introduced by this hastening of the reaction.

The variation in the rate of hydrolysis, k, for the three strong acids approximated 1% in a single run. Duplicate runs agree also within this limit. For the acetic acid solutions, where hydr lysis proceeded extremely slowly, the variation was as much a 2—3%.

For simplicity, the reaction is treated here as if it were of simple unimolecular type, and all the constants are calculate on that basis. Griffith and Lewis (J., 1908, **109**, 67) have show it is true, that the hydrolysis must finally be regarded as bimol cular and reversible, but space does not permit us to discuss i

tail here the complete analysis of our data according to their uations. This matter will be taken up in full in a later paper; will suffice to state at this stage that the general conclusions veloped below are substantially unchanged under the more rigid ethod of calculation.

TABLE IV.

	$k \times 10^4$	0·444	0·644	0·829	0·934	0·987	1·015

From the velocity coefficient curves for the hydrochloric acid stem in Fig. 3 it will be seen that the rate of hydrolysis increases uch more rapidly than the specific conductivity, and more rapidly deed than the molecular concentration of the acid. This may interpreted in two ways. First of all, it may be regarded as dicative of the fact, already noted in the freezing-point depression rve, that the "activity" of the hydrogen ion increases more pidly than the acid concentration, even when this is expressed molecular units. Alternatively, it may be construed, according the theory that the non-solvated hydrogen ion alone is catalytic- y active (recently revived by Rice, *J. Amer. Chem. Soc.*, 1923, , 2808), as signifying that the non-hydrated fraction of the drogen ion increases steadily as the concentration of the two utes is increased, owing to the diminishing concentration of e water present in the solution. The two statements are not ıtually exclusive, in all probability, but merely different methods expressing the same situation.

The curve for the acetic acid system (Fig. 4), on the contrary, ows a velocity coefficient increasing less rapidly than the specific nductivity of the acid in the absence of ester, although more pidly than the specific conductivity of the acid in the presence ester. A maximum reaction velocity is obtained at about · mols. %. Just as in the case of the freezing-point depression ta, the curves for the trichloroacetic acid and chloroacetic acid stems are similar in character to that for acetic acid, although ir rate of change of slope becomes less and less rapid as the ength of the acid is increased.

Further discussion of the rate of reaction curves would not be

profitable at this point, inasmuch as no quantitative comparison can be made between them and the specific conductivity curves until density and viscosity data for the solutions are available. These data will also render it possible to transpose the measurements here recorded to volume concentration units, and to utilise the results of previous workers. Whilst the conclusions drawn from this investigation are only preliminary and qualitative, yet the use of molecular concentration ratios has enabled several important deductions to be made. The main points of the work may be summarised briefly as follows:

Summary.

(1) Ethyl acetate gives a "pseudo-ideal" freezing-point depression curve in aqueous solution, and must consequently be extensively hydrated.

(2) The freezing-point depression caused by equivalent quantities of ethyl acetate and hydrochloric acid taken together is greater than the sum of the depressions due to the two separately. It follows that ternary complexes and ester–acid additive compounds are not existent in significant quantity in the aqueous solution. This conclusion is supported by specific conductivity data.

(3) Although the freezing-point depression curves obtained for trichloroacetic, chloroacetic, and acetic acids with ethyl acetate appear to indicate the survival of some ester–acid complex, yet the specific conductivity results in these systems also demonstrate decisively that no appreciable fraction actually persists. The freezing-point curves with these organic acids are presumably not strictly comparable, owing to internal pressure and association changes.

(4) The specific conductivity of a neutral salt, as well as of an acid, in aqueous solution is lowered by the addition of ethyl acetate. This lowering is due to diminished ionic mobilities.

(5) The rate of hydrolysis of ethyl acetate in the presence of hydrochloric acid in equivalent quantity increases more rapidly than the molecular concentration of the acid. With weaker acids the rate of hydrolysis increases less rapidly. In fact, the curve for acetic acid shows a maximum rate near the saturation point.

(6) The solubility of ethyl acetate in water at 0° varies very remarkably when electrolytes are also present in equivalent quantity.

(7) The rate of inversion of sucrose in hydrochloric acid solution at 0° is not affected by the addition of ethyl acetate. Inasmuch as the rate of ester hydrolysis is greatly increased by the addition of sucrose, it is clear that the mechanisms of the two reactions must be fundamentally different.

In conclusion it must be emphasised that, although it has been demonstrated that ester–acid additive compounds and ternary complexes of these with water do not exist in quantity in aqueous solution, yet this cannot be considered as proof that such compounds do not constitute intermediate steps in the reaction. An infinitesimal quantity of a compound at any one time would suffice for this purpose, its very instability serving, indeed, as a potent factor in the catalysis. The minimal extent to which these ester–acid compounds survive precludes further study of them by the freezing-point depression method, but valuable results are promised from a more intensive study of compounds of the type ester–water. The factors influencing the stability of compounds of this general type $R{\cdot}CO_2R',H_2O$ in the presence of an acid HX as R, R′, and X are varied, will be discussed in a forthcoming paper.

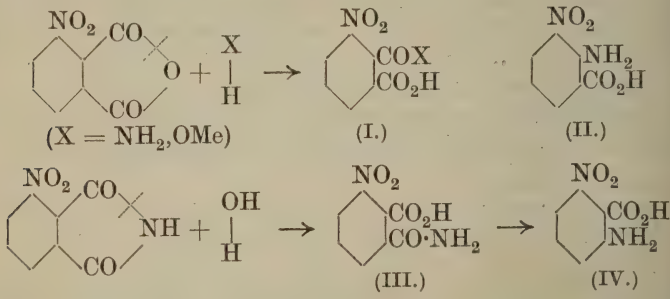
CCXXXVII.—*The Preparation of Phthalamic Acids and their Conversion into Anthranilic Acids.*

By ERNEST CHAPMAN and HENRY STEPHEN.

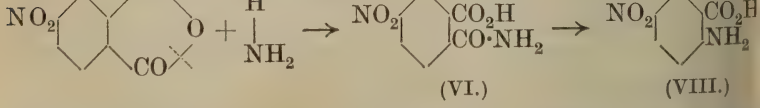
PHTHALAMIC acid results from two additive reactions: (*a*) from water and phthalimide (Aschan, *Ber.*, 1886, **19**, 1403), and (*b*) from ammonia and phthalic anhydride (Auger, *Bull. Soc. chim.*, 1888, **9**, 349).



The modification and extension of Auger's method now described show that reaction (*b*) affords phthalamic acids in excellent yield. Since these acids react smoothly with sodium hypochlorite, anthranilic acids become readily accessible. Anthranilic acid and 3 : 5-dibromoanthranilic acid are readily obtained from the corresponding anhydrides.*

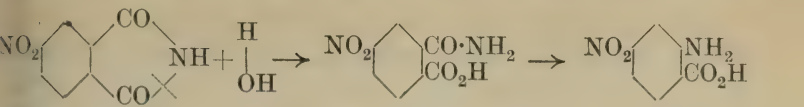
Unsymmetrical phthalic anhydrides, according to reaction (*b*), may give rise to one or both of two isomeric phthalamic acids, and it is of interest to discover (1) which amic acid is produced, alone or in the greater quantity, and (2) whether this amic acid is the same as that formed as chief product from the corresponding imide according to (*a*). The behaviour of 3- and 4-nitrophthalic anhydrides has been investigated from this point of view.

3-Nitrophthalic anhydride yielded exclusively 3-nitrophthalamic acid (I) (X = NH_2), which gave, in 90% yield, the 3-nitroanthranilic acid (II) obtained in small yield by Hübner by treatment of



* The carboxyl group of phthalamic and anthranilic acids is numbered 1 and the amide or amine group 2.

" β-nitrosalicylic ester " with ammonia (*Annalen*, 1879, **195**, 37). Since 3-nitrophthalimide is converted by Hofmann's method almost entirely into 6-nitroanthranilic acid (IV) (Seidel, *Ber.*, 1901, **34**, 4352; Seidel and Bittner, *Monatsh.*, 1902, **23**, 415; Kahn, *Ber.*, 1902, **35**, 472), its preliminary hydrolysis must yield 6-nitrophthalamic acid (III).* The addition of methyl alcohol to 3-nitrophthalic anhydride is similar to that of ammonia (compare Wegscheider and Lipschitz, *Monatsh.*, 1900, **21**, 796).



A comparison of these reactions shows that the negative component of the added molecule attaches itself to the carbonyl in the ortho-position to the nitro-group, and fission in all cases takes place at the same bond.

4-Nitrophthalic anhydride treated according to (*b*) gave an inseparable mixture of 4- and 5-nitrophthalamic acids (V and VI). The orientation and relative amounts of these acids were determined by conversion into the 4- and 5-nitroanthranilic acids (VII and VIII). These were obtained in the proportion of 2 to 3, whereas 4-nitrophthalimide gave the same mixture of acids but in the proportion of 4 to 1 (Seidel and Bittner, *loc. cit.*). This case is therefore parallel with that of the 3-nitro-compounds above, since the amic acid produced in greater yield by (*b*) is obtained in smaller yield by (*a*) and *vice versa*. The modes of addition which predominate in each reaction are as follows :

* Bogert and Boroschek (*J. Amer. Chem. Soc.*, 1901, **23**, 740) prepared this acid by the action of baryta on 3-nitrophthalimide, but wrongly described it as 3-nitrophthalamic acid. Kahn (*ibid.*, p. 3866) proved conclusively that it was 6-nitrophthalamic acid identical with the acid obtained by the action of ammonia on " 3-nitrophthal-β-methyl ester."

(V.) (VII.)

Here the negative components of the added molecules become ttached to the carbonyl in the *para*-position relatively to the nitro-roup.

In each of the cases considered, the course of the reactions cor-esponds with that observed with camphoric anhydride and camphor-mide, the former with ammonia (reaction *b*) giving α-camphoramic cid, whilst the latter on alkaline hydrolysis (reaction *a*) gives -camphoramic acid (see Lapworth, "On the Constitution of amphor," *Brit. Assoc. Reports*, Section B, 1900, p. 6).

Experimental.

Phthalamic Acid.—Phthalic anhydride (60 g.), added gradually ith stirring to warm aqueous ammonia (90 c.c.; d 0·88), dissolved eadily with considerable evolution of heat, and *ammonium phthal-mate* separated in fine, white crystals, the amount increasing on ooling (yield 70 g.; 94%) (Found: NH_3, 18·7. $C_8H_{10}O_3N_2$ requires NH_3, 18·4%). The salt was readily soluble in water, and was con-erted into phthalimide at about 200° without fusion. Phthalamic cid was obtained by treating the ammonium salt (30 g.) in cold ater (30 c.c.) with a slight excess of the equivalent quantity of oncentrated hydrochloric acid (20 c.c.) and washing the crystal-ne paste produced with cold water until it was free from hloride (yield 22 g.; 81%). The acid melted at 149° with loss of ater, solidified at 155°, and remelted at 231° (phthalimide). schan (*loc. cit.*) and Auger (*loc. cit.*) give m. p. 149° and 140° espectively. Aqueous solutions of the acid are more stable at the rdinary temperature than would be expected from Aschan's tatements.

Anthranilic Acid from Phthalamic Acid.—The "standard sodium ypochlorite solution" employed in this and all other cases to be escribed contained 47 g. of sodium hypochlorite and 50 g. of sodium ydroxide per litre.

Well-powdered phthalamic acid (20 g.) was gradually added to he stirred, cooled standard hypochlorite solution (200 c.c.), which ecame dark reddish-brown. Sodium hydroxide (10 g.) dissolved n water (50 c.c.) was now added, the mixture warmed at 80° for few minutes, cooled, and acidified with acetic acid. The anthr-nilic acid isolated by means of copper acetate and liberated from he copper salt with hydrogen sulphide melted at 145°.

4 : 5-*Dibromophthalamic Acid.*—4 : 5-Dibromophthalic anhydride prepared by boiling the corresponding acid with acetic anhydrid for several hours, separated from the filtered solution on cooli in fine, buff-coloured needles, m. p. 204—208°. Blümbein (*Be* 1884, **17**, 2490) gives m. p. 208°, Lesser and Weiss (*Ber.*, 191 **46**, 3937) give 214—215°. *Ammonium* 4 : 5-*dibromophthalama* was obtained in pale brown crystals (15·5 g.; 91%) by treating th anhydride (15 g.) with concentrated aqueous ammonia (22 c.c. On heating, it partly melted at 227° with loss of water and ammoni resolidified a few degrees higher, and remelted at 238—242° (th m. p. of 4 : 5-dibromophthalimide is given as 242—245° by Bruc *Ber.*, 1901, **34**, 2741, and as 245—246° by Lesser and Weiss, *loc. cit* see also below). 4 : 5-*Dibromophthalamic acid* was obtained fro the ammonium salt by addition of acid (yield 93%) (Found : B 49·6. $C_8H_5O_3NBr_2$ requires Br, 49·5%). It softened with loss water at 215—216°, being converted into the imide. Its aqueo solution reacted acid to litmus.

4 : 5-*Dibromophthalimide* was obtained in glistening yello needles, m. p. 242—243° (Found : Br, 52·85. Calc., Br, 52·4% by fusing the above amic acid and crystallising the product fro alcohol.

4 : 5-*Dibromoanthranilic Acid.*—Dibromophthalamic acid (10 g 1 mol.) was added as before to standard hypochlorite solutio (50 c.c.), and the yellow solution, after addition of sodium hydroxid (3 g.; 2 mols.) in water (20 c.c.), warmed to 80°, the colour becomin deep red. The 4 : 5-dibromoanthranilic acid precipitated from th solution, when cold, by a slight excess of hydrochloric acid crysta lised from dilute alcohol as a pale brown powder, m. p. 224° (decomp (8·5 g.; 94%) (Found : Br, 54·4. Calc., Br, 54·2%). Lesser an Weiss (*loc. cit.*) give m. p. 228—229°. The acid is almost insolubl in cold water, slightly soluble in hot water, and dissolves in th usual organic solvents except benzene, chloroform, and ligroin.

Treatment of the acid with acetic anhydride gave 4 : 5-*dibromo-2 acetylaminobenzoic acid*, fine, buff-coloured needles from dilut alcohol, m. p. 240° (Found : Br, 47·3. $C_9H_7O_3NBr_2$ require Br, 47·4%). Lesser and Weiss (*loc. cit.*, p. 3944) state that the obtained the acetyl derivative of the anhydride of the acid, m. p 184—185°.

* Anhydrides of dibasic acids are conveniently and rapidly prepared i almost quantitative yield as follows. The finely powdered, dry sodiu hydrogen salt (1 mol.) is warmed with thionyl chloride (3 mols.) for ½ hou and the excess of thionyl chloride removed by distillation. The residue anhydride and sodium chloride is boiled with benzene, and the solution filtered the pure anhydride crystallising from the filtrate.—H. S.

3- *and* 4-*Nitrophthalic Anhydrides*.—The corresponding acids re obtained by nitrating phthalic anhydride by Lawrence's thod (*J. Amer. Chem. Soc.*, 1920, **42**, 1872). An attempt to nvert the 4-nitro-acid into its anhydride by heating at 165—168° 3 hours as described by Lawrence (*loc. cit.*) proved unsatisfactory, product containing much unchanged acid. Both anhydrides re finally obtained by fusing the acids and then reducing the ssure to 22 mm. The temperature (thermometer in the liquid), 0—230° for the 3-nitro-acid and 170—180° for the 4-nitro-acid, s maintained for 1 hour. The brown melts crystallised on oling, and after recrystallisation from acetic anhydride or acetyl loride, 3-nitro- and 4-nitro-phthalic anhydrides were obtained ich melted at 163—164° and 115°, respectively, as stated by wrence.

3-*Nitrophthalamic Acid*.—The ammonium salt and the acid were tained from the anhydride (30 g.) and concentrated aqueous monia (45 c.c.) by the methods previously described (yield 87%). e *ammonium* salt consisted of fine, white needles, m. p. 172° comp.), giving 3-nitrophthalimide, m. p. 217—218° (Bogert and roschek, *loc. cit.*, m. p. 215—216°; Kahn, *Ber.*, 1902, **35**, 471, p. 216°). 3-*Nitrophthalamic acid* softens with loss of water at 3—174°, being converted into the imide. It is sparingly soluble cold and readily in hot water.

3-*Nitroanthranilic Acid*.—Finely powdered 3-nitrophthalamic d (10 g.; 1 mol.) was treated with 75 c.c. of standard hypochlorite ution (1 mol. NaOCl) in the usual way, and sodium hydroxide g.; 2 mols.), dissolved in water (10 c.c.), was added to the yellow ution. When the mixture was warmed at 80°, its colour gradually ame brick-red and a bright red precipitate of sodium 3-nitro- hranilate separated. Sufficient water was added to the cooled cture to dissolve the salt, and treatment with a slight excess of centrated hydrochloric acid precipitated 3-nitroanthranilic acid a bright yellow, crystalline powder (7·8 g.; 90%). The acid s obtained in fine, yellow needles, m. p. 208—209°, from hot er (Hübner, *loc. cit.*, gives m. p. 204°); in other respects the perties of the acid agree with those described by Hübner. duction of the acid with stannous chloride showed no indication he formation of a derivative of *m*-phenylenediamine, and hence absence of 6-nitroanthranilic acid.

-*Nitro*-2-*acetylaminobenzoic acid*, obtained by boiling the above el (2 g.) with acetic anhydride (4 c.c.) for 5 minutes, crystallised m hot water or acetic acid in bright yellow, silky needles, m. p. 8—181° (Found: N, 12·6. $C_9H_8O_5N_2$ requires N, 12·5%).

· *and* 5-*Nitrophthalamic Acids*.—A mixture of the ammonium

salts of these acids was obtained by dissolving 4-nitrophthal anhydride (60 g.) in warm aqueous ammonia (90 c.c.). The produ (50 g.), consisting of fine, white needles, melted at 190—192° wi decomposition, solidified, and remelted at 197—198°, having be converted into the imide (Bogert and Boroschek, *loc. cit.*, a Seidel and Bittner, *loc. cit.*, give m. p. of 4-nitrophthalimide 197° and 202°, respectively). The mixture of 4- and 5-nitr phthalamic acids was obtained in almost theoretical yield by ad tion of concentrated hydrochloric acid (40 c.c.) to the ammoniu salts (48 g.) in water (60 c.c.). Attempts to separate the acids we unsuccessful. The mixture melted at 150—155° with loss of wat resolidified and remelted at 198°, since both acids yield 4-nitr phthalimide.

4- *and* 5-*Nitroanthranilic Acids.*—A mixture of these acids w obtained by treating the above mixture of phthalamic acids (35 with standard hypochlorite solution (266 c.c.) as described in t previous case. Acidification of the resulting red solution gave mixture (22 g.; 73%) of yellow and orange particles, m. p. 250 260° (decomp.). A portion of the mixture (15 g.) was extract in a Soxhlet apparatus for 2 days with boiling xylene, which beca orange-red. The insoluble, pale yellow residue of 5-nitroanthrani acid, amounting to 60% of the original mixture, crystallised fr dilute alcohol in glistening, yellow needles, m. p. 280°, agreeing wi m. p. given by Seidel and Bittner (*loc. cit.*). The m. p. of 5-nitr anthranilic acid is also variously given as follows: 263° (Hübn *loc. cit.*); 270° (Rhalis, *Annalen*, 1879, **198**, 112); 261—263° (Kra *J. pr. Chem.*, 1896, **53**, 222); 263° (Rupe, *Ber.*, 1897, **30**, 109 269·5° (Ullmann and Uzbachian, *Ber.*, 1903, **36**, 1802). The a showed the characteristic reactions described in the literature 5-nitroanthranilic acid, and was converted into 5-nitro-2-acet aminobenzoic acid, melting at 216—217°, by boiling with ace anhydride. Seidel and Bittner (*loc. cit.*) and Ullmann and Uzbachi (*loc. cit.*) give, respectively, 214—215° and 221° as the melting po of the acetyl derivative.

The xylene solution obtained above left on evaporation a d orange, flaky mass (40% of the original mixture) of 4-nitroant anilic acid containing a little of its isomeride. Attempts to pur the acid by repeated crystallisation from alcohol as described Seidel and Bittner (*loc. cit.*) were unsuccessful, as the final prod melted indefinitely between 237—240°, and was evidently stil mixture. It was therefore converted into the acetyl derivative boiling with acetic anhydride for a few minutes. The crude prod melted at 190—195°, but after crystallising several times from dil alcohol, 4-nitro-2-acetylaminobenzoic acid was obtained in lo

lender needles, m. p. 217° (Seidel and Bittner, *loc. cit.*, give 188°; Wheeler and Barnes, *Amer. Chem. J.*, 1898, **20**, 229, give 215°). A solution of the acetyl compound in a small quantity of hot alcohol was boiled with a few c.c of concentrated hydrochloric acid; on cooling, pale yellow needles of the hydrochloride of 4-nitroanthranilic acid separated.

The hydrochloride was dissociated by water and the 4-nitroanthranilic acid produced crystallised from dilute alcohol in stout, deep orange prisms, m. p. 269° (Wheeler and Barnes, *loc. cit.*, Wheeler and Johns, *Amer. Chem. J.*, 1910, **44**, 443, and Seidel, *Ber.*, 1901, **4**, 4352, give the m.p. of 4-nitroanthranilic acid as 264°). 4-Nitroanthranilic acid was difficultly soluble in hot water, and on reduction with stannous chloride and hydrochloric acid gave an indication of the formation of a derivative of *m*-phenylenediamine.

It is desired to acknowledge a grant made to one of us (E. C.) by the Department of Scientific and Industrial Research, which enabled him to participate in this work.

THE UNIVERSITY, MANCHESTER. [*Received, May 19th*, 1925.]

CXXXVIII.—*Derivatives of δ-o-Aminobenzoylvaleric Acid.*

By MARGARET JOYCE PATERSON and SYDNEY GLENN PRESTON PLANT.

THE acid, m. p. 129°, obtained by Perkin and Plant (J., 1923, **123**, 778) and thought to be δ-*o*-aminobenzoylvaleric acid,

$$NH_2 \cdot C_6H_4 \cdot CO \cdot [CH_2]_4 \cdot CO_2H,$$

has been converted into δ-*o*-hydroxybenzoylvaleric acid, identical with the compound prepared by von Braun (*Ber.*, 1922, **55**, 3761) by the oxidation of hexahydrodiphenylene oxide, and its constitution thus proved.

δ-*o*-Aminobenzoylvaleric acid cannot be made to yield a phenylhydrazone, oxime, or semicarbazone under the usual conditions, but the corresponding derivatives of δ-*o*-hydroxybenzoylvaleric acid are readily obtained.

δ-*o*-Benzoylaminobenzoylvaleric acid is converted by alkalis into δ-*o*-aminobenzoylvaleric acid and a small quantity of γ-4-hydroxy-2-phenylquinoline-3-butyric acid (Perkin and Plant, *loc. cit.*). We now find that δ-o-*acetylaminobenzoylvaleric acid* gives better yields of the corresponding γ-4-*hydroxy*-2-*methylquinoline*-3-*butyric acid* as well as some δ-*o*-aminobenzoylvaleric acid. δ-o-*Formylaminobenzoylvaleric acid*, on hydrolysis under various

conditions, gave exclusively δ-*o*-aminobenzoylvaleric acid, no trace of a quinoline derivative being detected.

Experimental.

δ-o-*Hydroxybenzoylvaleric Acid.*—The diazo-solution prepared from δ-*o*-aminobenzoylvaleric acid (4 g.) in concentrated hydrochloric acid (20 c.c.) and water (40 c.c.) by means of sodium nitrite (1·3 g. in 15 c.c. of water) was heated on the steam-bath until nitrogen ceased to be evolved. The oil produced, which solidified on cooling, was boiled in dilute sodium hydroxide solution for 15 minutes with charcoal. δ-*o*-Hydroxybenzoylvaleric acid, obtained by acidifying the solution with hydrochloric acid, crystallised from petroleum in long, colourless needles, m. p. 94°; von Braun (*loc. cit.*) gives m. p. 94° (Found: C, 65·0; H, 6·3. Calc., C, 64·8; H, 6·3%).

The phenylhydrazone, prepared by warming the acid with an excess of phenylhydrazine for a few minutes and treating the mixture with dilute acetic acid, had, after recrystallisation from aqueous alcohol, the m. p. (173°) recorded by von Braun.

δ-o-*Acetylaminobenzoylvaleric Acid.*—A mixture of δ-*o*-aminobenzoylvaleric acid with twice its weight of acetic anhydride was heated on the steam-bath for an hour, the excess of acetic anhydride removed under reduced pressure, and the residue poured into water. The viscous product was boiled in alcohol with charcoal, and the δ-o-*acetylaminobenzoylvaleric acid* precipitated, after filtration, by the gradual addition of water was recrystallised from aqueous alcohol, separating in colourless plates, m. p. 153° (Found: C, 64·1; H, 6·7. $C_{14}H_{17}O_4N$ requires C, 63·9; H, 6·5%).

A solution of δ-*o*-acetylaminobenzoylvaleric acid (2 g.) and potassium hydroxide (5·5 g.) in water (35 c.c.) was heated for an hour on the steam-bath, cooled, acidified with hydrochloric acid and the small colourless precipitate removed. The filtrate yielded δ-*o*-aminobenzoylvaleric acid on successive treatment with potassium hydroxide and acetic acid. The small precipitate was recrystallised from alcohol, when γ-4-*hydroxy*-2-*methylquinoline*-3-*butyric acid* was obtained in colourless prisms, m. p. 241° (Found: N, 5·7. $C_{14}H_{15}O_3N$ requires N, 5·7%).

δ-o-*Formylaminobenzoylvaleric Acid.*—δ-*o*-Aminobenzoylvaleric acid (3 g.) was heated with formic acid (6 g.) on the steam-bath for 3 hours under reflux, the excess of formic acid was then allowed to escape, and the residue yielded a colourless solid on rubbing with alcohol. The product was recrystallised from alcohol and δ-*o*-*formylaminobenzoylvaleric acid* separated in colourless plates, m. p. 160° (Found: N, 5·5. $C_{13}H_{15}O_4N$ requires N, 5·6%).

One of us (S. G. P. P.) wishes gratefully to acknowledge the receipt f a grant from the Chemical Society Research Fund which has efrayed a part of the cost of this investigation.

CCXXXIX.—*Bismuth Dihydride.*

By Edward Joseph Weeks and John Gerald Frederick Druce.

Having prepared solid hydrides of arsenic (*Chem. News*, 1924, **129**, 1) and antimony (this vol., p. 1069), we turned our attention to he analogous solid bismuth dihydride. The method of preparation vas similar to one employed in the case of antimony dihydride. A olution of bismuth chloride in hydrochloric acid was added radually to a mixture of zinc (free from iron, carbon, and arsenic) nd fairly strong hydrochloric acid which was rapidly evolving ydrogen. At each addition of bismuth chloride the evolution of as slackened and could even be made to stop altogether until the ismuth chloride was converted into a flocculent, grey precipitate : $BiCl_3+8H=Bi_2H_2+6HCl$. When all the zinc (which was used in xcess) had dissolved, the liquid was rapidly filtered in an atmo- phere of hydrogen, and the precipitate washed many times, first with ot strong hydrochloric acid, then with hot dilute acid, and finally ith water until the wash water was neutral. The residue was rained and dried, first in hydrogen and finally in a vacuum esiccator over concentrated sulphuric acid.

On heating in a vacuum, bismuth dihydride gave off hydrogen nd left metallic bismuth—quite different from the amorphous ihydride. 0·9184 G. gave 44 c.c. H_2, measured at *N.T.P.*, and ·9144 g. Bi : H, 0·45; Bi, 99·57. 1·4606 G. lost 0·0088 g. H_2 : Bi, 99·39; H, 0·60. On combustion 0·4849 g. gave 0·0235 g. H_2O : I, 0·54 (Bi_2H_2 requires Bi, 99·52; H, 0·48%).

The volume of hydrogen produced was determined as follows : he apparatus, with a quicklime tower in series, was twice filled ith nitrogen (previously passed over red-hot copper) and exhausted s completely as possible. The pressure (p) was noted, and the ihydride heated until there was no further pressure change. The nal pressure (P) was noted, the apparatus re-exhausted until the ressure was p, and nitrogen, measured at atmospheric pressure, dded until the pressure P was restored.

Bismuth dihydride, heated in a tube in absence of air, gave a irror of bismuth just beyond the heated zone. It thus appeared hat the dihydride might decompose into bismuth and bismuthine :

$3Bi_2H_2=2BiH_3+4Bi$. (On heating, cuprous hydride decomposes into copper and cupric hydride [Barlett and Merrill, *Amer. Chem. J.*, 1896, **17**, 185], and arsenic dihydride into arsenic and arsine [Moser and Brukl, *Monatsh.*, 1924, **45**, 25]). To test this supposition, bismuth dihydride was heated in a stream of purified hydrogen. The issuing gas produced in silver nitrate solution a grey precipitate soluble in nitric acid. This was presumably silver bismuthide, as its nitric acid solution, after removal of silver as chloride, gave with hydrogen sulphide a dark brown precipitate, the solution of which in warm dilute nitric acid deposited bismuth hydroxide on addition of ammonia.

Bismuth dihydride prepared as described above was free from zinc, carbon, and iron, but contained a trace of chlorine (less than 0·02%, estimated by Volhard's method).

Fused potassium nitrate reacted very vigorously with the dihydride (as with antimony dihydride), but only slowly oxidised finely divided bismuth.

BATTERSEA GRAMMAR SCHOOL,

CCXL.—*The Nature of the Alternating Effect in Carbon Chains. Part III. A Comparative Study of the Directive Efficiencies of Oxygen and Nitrogen Atoms in Aromatic Substitution.*

By ERIC LEIGHTON HOLMES and CHRISTOPHER KELK INGOLD.

THAT directive action in aromatic substitution is the result of an alternating effect transmitted throughout the ring from a key-atom is generally agreed, and a convincing confirmation has recently been given by Pyman and Stanley (J., 1924, **125**, 2484; compare *Ann. Report*, 1924, pp. 110—111). It is the authors' hope to elucidate more precisely the nature of the alternation, and to discover, by the close study of different key-atoms, what property of them it is that is so effectively propagated.

In Part I (this vol., p. 513) it was stated (and this is the starting point of the present investigation) that whilst Kermack and Robinson's hypothesis of an induced electropolar effect requires that oxygen, owing to the greater pre-formation of its octet, should predominate over nitrogen as a negative key-atom,* the theory of alternating free and bound affinity demands that the more unsaturated element, tervalent nitrogen, should have greater influence.

* For references see Part I.

From this theoretical distinction there followed a difference in the predicted orienting effect of the nitroso-group, which was determined, and found to be in agreement with the affinity theory. It was then suggested, however (compare Part II, this vol., p. 870),

(1) that a group with two competing negative atoms constituted a case too complicated for prediction by the polarity principle * (Lapworth),

(2) that the observed facts could be accommodated by means of a different point of view when the atom united to the ring contained a " lone pair " of electrons (Robinson).

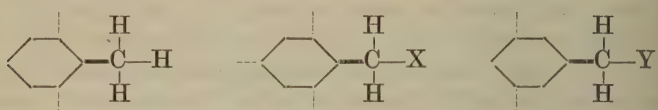
A group was therefore examined which (*a*) contained only one negative atom, oxygen, (*b*) was joined to the benzene ring through carbon; and again results were obtained indicating that directive action depends on the unsaturation rather than the polar character of the atom producing it. Since these results were communicated, however, a further suggestion has been made (Robinson, *Chem. and Ind.*, 1925, **44**, 260) which fundamentally affects much of the work in progress. It is

(3) that atoms, previously regarded as negative, such as the oxygen atoms of ethers, may, upon occasion, act as *positive* key-atoms by functioning as " onium " elements.†

Such an occurrence would obviously reverse all the effects to be expected on the basis of the polarity theory, which could thus, in a given case, be reconciled with results otherwise opposed to it.

A series of experiments has therefore been instituted which, while still adhering to conditions (*a*) and (*b*) imposed by the earlier arguments of Lapworth and Robinson (1) and (2), in addition exercises a definite control over the suggestion that " onium " action may account for the exceptions to the polar hypothesis.‡

In order to understand the method employed it is necessary to consider the position of toluene and its monosubstituted products with regard to the principles both of alternating affinity and of alternate polarities.



It is fundamental to the affinity theory (compare Flürscheim, *Z. pr. Chem.*, 1907, **76**, 197; *Chem. and Ind.*, 1925, **44**, 249) that carbon exerts valencies of more, or less, than the normal affinity content only when compelled to do so by the varying requirements of an unsaturated, or over-saturated, attached atom or group

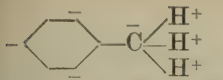
* That of 1920 was referred to.

† For example, by forming salts with the reagent employed.

‡ Yet another argument (4), recently advanced by Lapworth, is alluded to below (p. 1808).

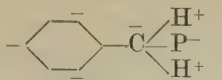
(mechanism of propagation). In toluene, the phenyl group is unsaturated (possesses residual affinity), and hence the methyl carbon atom is strongly bound, a condition leading to *op*-substitution (I). If, now, one of the methyl hydrogen atoms is replaced by a feebly unsaturated atom (X), the demand made by this atom on the affinity of the carbon atom may be insufficient to counterbalance the unsaturation of the phenyl group, and again *op*-substitution will be the rule (II). On the other hand, if, in place of X, a strongly unsaturated atom (Y) be introduced, then the unsaturation of the phenyl group may be overcome, when a condition will arise leading to *m*-substitution (III):

(I.) (II.) (III.)



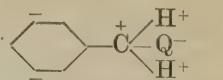
Now bivalent oxygen is a feebly unsaturated atom, whilst tervalent nitrogen is strongly unsaturated. Hence, if we consider comparatively benzyl alcohols (IV) and benzylamines (V) (using these terms in a general sense to include alkyl and acyl derivatives, etc.), the former should be more closely represented by condition (II), and the latter by condition (III):

(IV.) C_6H_5—CH_2—OA $\qquad$ C_6H_5—CH_2—NAA′ (V.)



That is to say, the benzylamines should show a greater tendency than the benzyl alcohols towards *m*-direction, as against *op*-direction. Of course, if oxonium or ammonium salt-formation were to take place *op*-direction might result, but, whilst benzyl alcohols should exhibit *op*-direction *in any event*, benzylamines should show *m*-direction if and when salt formation does not occur. *It is still true, therefore, that according to the affinity theory derivatives of benzylamine should show a greater tendency towards* m-*substitution, and a smaller tendency towards* op-*substitution, than the benzyl alcohols, and that* m-*directive action should never prevail amongst the latter.*

On the other hand, according to polarity principles, hydrogen is feebly key-positive (Lapworth, *Mem. Manchester Phil. Soc.*, 1920, **64**, No. 3, p. 5); thus, the *op*-substitution of toluene may be explained (VI). If, now, in place of one of the methyl hydrogen atoms a weakly negative atom (P) be introduced, this may conceivably be insufficient to counterbalance the effect of the two remaining hydrogen atoms, and, in this case, *op*-substitution will still prevail (VII). If, however, a strongly negative atom (Q) is



ntroduced, the influence of the hydrogen atoms should be over-come and *m*-direction should ensue (VIII).

(VI.)

(VII.)

(VIII.)

Now, if the oxygen atom in benzyl alcohols acts as a negative key-atom, it must be assumed to be like " P " rather than like " Q," for benzyl alcohol derivatives display *op*-substitution (see below). It follows, however, from the electronic principles alluded to at the commencement that if *oxygen* is not negative enough effectively to control substitution from the position it occupies in the benzyl alcohols, then, *a fortiori*, more feebly negative *nitrogen* in the same position will be unable to do so. Assuming, then, that we have to do with *negative* key-atoms in both cases, there should be a greater tendency to *op*-substitution, and a smaller tendency to *m*-substitution, amongst benzylamines than amongst benzyl alcohols.

Let it now be supposed that these elements act in their " onium " forms, that is, as *positive* key-atoms. This would supply a convenient explanation of *op*-substitution in benzyl alcohols, since the methyl carbon atom would now be attached to three positive atoms as in toluene. But the same principles which require that oxygen shall be more effective than nitrogen as a negative key-atom also demand that nitrogen shall be more powerful when both are positive (Robinson, *loc. cit.*). Hence, in this case also, benzylamines should show the greater tendency to *op*-substitution.

The only remaining case is that which would arise if, under the condition of substitution, oxonium salts could not be formed, whilst the more stable, analogous, ammonium salts could; oxygen would then be a negative key-atom, but nitrogen might be a positive one. Obviously, however, the expected differences would, in this case, *still* be in the sense previously stated, only greater. *Thus, in all three cases, polarity principles require that benzylamines shall show a greater tendency to* op-*substitution, and a smaller tendency to* m-*substitution, than benzyl alcohols.*

It follows, then, that in the comparison of benzyl alcohols with benzylamines we have a clear issue, from which the theory of " onium-action " provides no exit.

Before the commencement of this investigation several observations had already been made indicating the prevalence of *op*-substitution in benzyl alcohol derivatives of the type $C_6H_5 \cdot CH_2 \cdot O \cdot A$. Thus Beilstein and Kühlberg (*Annalen*, 1868, **147**, 341) obtained

p-nitrobenzyl acetate by direct nitration of benzyl acetate (A = ·CO·CH_3), whilst Staedel (*Annalen*, 1883, **217**, 177) prepared several *p*-nitrobenzyl derivatives by the nitration of benzyl phenyl ethers and benzyl tolyl ethers (A = Aryl).

These results have now been generalised by the study of a number of new cases, chosen in such a way as to give oxonium salt formation, if it occurs, the greatest possible opportunity to manifest its effects.

As is well known, the stability of ammonium salts (and, it may be assumed, of "onium" salts in general) is diminished by the introduction of an acyl group in the place of an alkyl group (compare the basicity of acetanilide with that of methylaniline); and the greater the strength of the acid from which the acyl group is derived, the more completely is the salt formation suppressed. It might therefore be supposed that even if oxonium salt formation, resulting in "positive" oxygen, is the cause of the *op*-substitution of benzyl ethers (A = Alkyl), the tendency to this type of substitution would become less marked in benzyl esters of weak acids (*e.g.*, benzyl acetate; A = ·CO·CH_3), and non-existent in benzyl esters of strong mineral acids (*e.g.*, benzyl nitrate; A = ·NO_2), since an anhydro-union with strong mineral acids, like nitric acid and sulphuric acid, is known to suppress the ammonium salt formation of even comparatively strong nitrogen bases.

Cases have therefore been selected in such a way as to furnish examples of all these three classes; and in every case it has been found that substitution occurs mainly or exclusively in the para-position; *m*-substitution has in no instance been observed, despite the variation in the character of "A."

The examples on which the above general statement is based are collected together in the following table. They afford, it is believed, strong grounds for the conclusions (a) *that* op-*substitution prevails amongst benzyl alcohol derivatives of the type* C_6H_5–CH_2–OA, *whether A = alkyl or acyl;* (b) *that oxonium salt formation with the reagent employed is not the cause of this phenomenon.*

	Nitric acid	*p*	,, ,,

* Staedel also nitrated the ethers in which A = phenyl, *o*-tolyl, and *p*-tolyl. In each of these cases nitro-groups entered both rings, but that which entered the benzyl group did so in the *p*-position.

In the case of the benzylamines the only compounds of the type $C_6H_5 \cdot CH_2 \cdot NAA'$ which have been examined (so far as we have ascertained) in regard to ring substitution prior to this investigation are (i) acetobenzylamide (A = H; A′ = $\cdot CO \cdot CH_3$) and (2) phenylethylbenzylamine (A = Et; A′ = Ph). Acetobenzylamide was found by Amsel and Hofmann to nitrate in the *p*-position (*Ber.*, 1886, **19**, 1286), a result which we have confirmed. Phenylethylbenzylamine was stated by Schultz and Bosch (*Ber.*, 1902, **35**, 1292) to nitrate in the *m*-position in the benzyl group; but doubt has been cast on this result (Flürscheim, *Chem. and Ind.*, 1925, **44**, 285), a doubt which is increased by the investigation recorded in this paper of the closely analogous case of methyldibenzylamine (A = Me; A′ = CH_2Ph).* It was apparent at the outset, therefore, that no general conclusion with regard to the substitution of benzylamine could be reached on the basis of previously recorded observations, and that before the comparison with benzyl alcohols could be made a series of experiments on representative benzylamines was necessary.

Such a series has now been carried out, and, in contrast to the results obtained with the benzyl alcohols $C_6H_5 \cdot CH_2 \cdot OA$, it has been found that predominant *m*-substitution is of common occurrence amongst derivatives of benzylamine, $C_6H_5 \cdot CH_2 \cdot NAA'$.

As in the previously described experiments, examples were selected in such a way as to obtain a maximum of control over effects due to ammonium salt formation.

The effects to be expected from this cause may be inferred from the case of aniline. As Bamberger has shown (*Ber.*, 1895, **28**, 399), aniline nitrate, $C_6H_5 \cdot NH_3 \cdot O \cdot NO_2$, which is *m*-orienting, readily loses water under ordinary nitration conditions, giving the nitroamine $C_6H_5 \cdot NH \cdot NO_2$, which, being insufficiently basic to form a stable salt, substitutes in the *op*-positions; hence arise the different results obtained with different concentrations of nitric acid. Now according to the theory of alternating free and bound affinity the nitrogen atom in benzylamine should direct oppositely to that in aniline when both are in analogous states of combination. Hence it might be expected that under ordinary conditions (concentrated nitric acid in the cold) the conversion of the nitrate $C_7H_7 \cdot NH_3 \cdot O \cdot NO_2$ into a non-basic nitroamine, $C_7H_7 \cdot NH \cdot NO_2$, would determine predominant substitution in the *m*-position. Actually this is what occurs, and, apart from analogy with aniline, there are four inde-

* We have not, however, repeated the experiments of Schultz and Bosch, since Prof. Robinson has recently announced his intention of doing so (*Chem. and Ind.*, 1925, **44**, 227).

pendent experimental reasons for concluding that it takes place in the manner suggested.

First, under the conditions stated, the *m*-nitro-derivative, although the main product (about 80%), is not the only one; a certain quantity of *p*-isomeride is also formed, and (possibly) a trace of ortho. If the explanation given is correct, this must mean that, at the temperature employed (0° to 20°), only a part of the benzylamine nitrate is dehydrated to benzylnitroamine. But an increase of temperature would easily complete this reaction and should thus suppress the by-products of the nitration. This was found to be the case: on nitration at temperatures approaching 100° the *m*-nitro-compound was obtained as sole product and in practically quantitative yield.*

Secondly, it follows from the explanation given that the phenomena observed with benzylamine should be reproduced in secondary benzylamines, $C_7H_7{\cdot}NHAlk$, but should disappear in tertiary derivatives, $C_7H_7{\cdot}N(Alk)_2$, since these lack the amino-hydrogen atom necessary for dehydration of the salt to the nitroamine. This was also observed, exactly as predicted: methylbenzylamine, $C_7H_7{\cdot}NH{\cdot}CH_3$, and dibenzylamine, $C_7H_7{\cdot}NH{\cdot}C_7H_7$, behave like benzylamine, directing mainly or exclusively towards the *m*-position, according to temperature; methyldibenzylamine, however, $(C_7H_7)_2NMe$, showed no tendency towards *m*-direction, but, on the contrary, gave *op*-products.

Thirdly, since the introduction of one acyl group into a primary amine greatly increases the difficulty of replacing the second amino-hydrogen atom by another acyl group, the prior mono-acylation of a benzylamine should prevent the formation under nitration conditions of a nitroamine, excepting, perhaps, at high temperatures. Now benzylamines are strong bases, and hence, if the acyl group introduced is derived from a weak acid, the substituted amide should be definitely basic, and it is true that acetobenzylamide, acetodibenzylamide, and acetomethylbenzylamide form moderately stable salts with mineral acids. Substitution in these compounds should therefore take place mainly, if not exclusively, through their salts, that is, in the *op*-positions. Further, since acetodibenzyl-

* This temperature effect may be contrasted with that observed in the sulphonation of aniline, which gives *m*-sulphanilic acid in the cold (substitution of sulphate) but *p*-sulphanilic acid at higher temperatures (the sulphate passing into the sulphamic acid under these conditions). Thus an increase of temperature causes a *p*-product to appear in the place of *m*-, in the case of aniline, but a *m*-product in the place of *p*-, when the directing nitrogen atom is one place further from the nucleus, as in benzylamine—a clear illustration, similar in some respects to that given by Pyman and Stanley (*loc. cit.*), of the essentially *alternating* character of the effect transmitted.

mide, $(C_7H_7)_2NAc$, is a definitely weaker base than methyldi-enzylamine, $(C_7H_7)_2NMe$, larger quantities of *m*-by-products ould be produced in the former case than in the latter. Again, nce acetobenzylamide and acetomethylbenzylamide are stronger ases than acetodibenzylamide, the last should yield the largest uantity of *m*-compound. Again, in the case of the very feebly asic acetodibenzylamide, the addition of different quantities of ater to the nitric acid used in the nitration should, by altering ie degree of hydrolysis of the salt, change the proportion of by-roducts: the more dilute the acid, the greater should be the roportion of *m*-product obtained. All these predictions have een verified in every detail.

Fourthly, diacetylbenzylamine, $C_7H_7{\cdot}N(CO{\cdot}CH_3)_2$, is non-basic, nd it obviously cannot form a nitroamine; it must therefore itrate as such. It follows that if *m*-substitution in benzylamine erivatives depends essentially on tervalent nitrogen, then this iacetyl compound, unlike the monoacetyl derivatives previously ientioned, should undergo substitution wholly or mainly in the -position. This was found to be the case.

These results, which are summarised in the following table, ive strong grounds * for the conclusion that *not only is* m-*substi-ution a frequent experience with benzylamine derivatives,*

$$C_6H_5{\cdot}CH_2{\cdot}NAA',$$

ut that it prevails in every case in which substitution through a salt precluded.

† Only perceptible at low temperatures.

Comparing now the benzyl alcohols and benzylamines, we see iat, as the affinity theory demands, compounds of the former ass belong exclusively to the *op*-directing series, whilst those of ie latter display a strong tendency to *m*-substitution. Polarity

* For the sake of maintaining the strict comparison with benzyl alcohol erivatives, no use is here made of the few known instances of ring-sub-itution in benzylamines already substituted in the benzyl group, although ie data are consistent with the results now described.

principles, as shown above, require a difference of precisely th opposite kind.

In Part II * (*loc. cit.*) a peculiarly substituted benzyl ether wa examined in which the two side-chain hydrogen atoms of th ordinary benzyl group were removed from possible competitio with the oxygen atom by replacing them by a doubly-bound methyl ene group, $:CH_2$. The compound was α-methoxystyrene,

$$C_6H_5\cdot C(OMe):CH_2,$$

and some importance was attached to the case because it indicate in a particularly clear manner that *unsaturation*, rather tha negative character, is the cause of directive action. Recently however, a new suggestion, additional to those mentioned abov (1, 2, and 3, p. 1801), has been advanced. It is

> (4) that the unsaturated group, C:C, *itself* might behave a a " negative " key-group in the sense of the polarity rule, an hence in methoxystyrene act as would an oxygen atom directl attached to the benzene nucleus (Lapworth, *Chem. and Ind.* 1925, **44**, 228, 398).

We express no opinion as to the *a priori* probability of thi suggestion, but wish to point out that it (like every argument which has been advanced in defence of the polarity theory sinc these investigations were commenced) has been taken into seriou account in devising the experiments now described. It is com pletely answered. For if the *op*-direction of methoxystyrene is du to the " negative " double bond, why does it persist, against th polar principles cited above, when that double bond is absent, as i the benzyl ethers, $C_6H_5\cdot CH_2\cdot OA$? The cause lies not in the tw hydrogen atoms (pp. 1802—1803, 1807, 1808), nor in a " positive " oxygen atom (pp. 1804—1805, 1807), nor in the group A (pp. 1804— 1805, 1805—1807); for if it did, the *m*-direction of analogou benzylamines could not be explained. The same difficulty confront any attempt to base an explanation, or argument,‡ on the " dampin

* On p. 871, lines 11–12, " two intrinsically negative atoms in competitio for the function of key-atom " should be read in place of " two competin negative key-atoms," since the ellipsis used has caused misunderstanding.

† General arguments, such as the imputation of " insisting that any aton you like to choose must be a key-atom " (Robinson, *Chem. and Ind.*, 1925 **44**, 227), we regard as not justified in view of the full reasons that hav invariably been given for each assumption made. Arguments of this kin are excepted from the statement to which this footnote refers.

‡ The relevance to the polarity theory of the cases under discussion wa admitted by Robinson when predicting, on the basis of his theory, th position of substitution of the benzylamine examined by Schultz and Bosc (p. 1805); which should obviously yield *op*-substitution derivatives accordin to *any* of the theories discussed in this paper.

tion " of the saturated carbon atom (Robinson, *Chem. and Ind.*, 25, **44**, 148; Lapworth, *ibid.*, p. 398), or on lack of " conjugation " the key-atom with the nucleus.

It seems to us that there is only one *consistent* explanation of ese facts, namely, that which has uniformly and correctly fore- ld events throughout this series of investigations. Proof has en given that the efficiencies of " negative " key-atoms stand, not the order of their electron affinities, but in the order of their saturation; and it seems fair, therefore, to conclude that un- turation is the property transmitted. This is the essence of ürscheim's form of the alternating theory. We are aware that identifying unsaturation with potentially mobile electrons, and alternating distribution with a similarly propagated electronic splacement, a nearly equivalent theory may be formulated * ompare Robinson, *Chem. and Ind.*, 1924, **43**, 1297; 1925, **44**, 8; this vol., p. 370). But this cannot add validity to the ndamental idea, nor can it inspire enhanced confidence whilst e interpretation of the chemical terms remains speculative. We ggest, therefore, without denying the possibility of polar altern- ion, that the facts thus far adduced constitute grounds for the nclusion that the propagation of alternating unsaturation is the ime directive process in ordinary aromatic substitution.

Experimental.

(*A*) *Nitration of Benzyl Ethers and Esters.*

(i) s-*Tribromophenyl Benzyl Ether*, $C_6H_2Br_3{\cdot}O{\cdot}CH_2Ph$.—Equi- olecular quantities of benzyl chloride and *s*-tribromophenol were ded to a suspension of sodium ethoxide in boiling toluene, the tered solution was evaporated, and the residue recrystallised om alcohol. The product, m. p. 86—87°, had the properties scribed by Auwers (*Annalen*, 1907, **357**, 92).

For the nitration, the ether was added in small quantities to ncentrated nitric acid at about — 5°, the solution kept for 1 hour, ured on to ice, and the solid obtained, after draining from a nall quantity of adhering oil, crystallised from alcohol, when it parated in small prisms, m. p. 145° (Found : N, 3·1. $C_{13}H_8O_3NBr_3$ quires N, 3·0%). An impure by-product was obtained of higher trogen content.

s-*Tribromophenyl* p-*nitrobenzyl ether*, $C_6H_2Br_3{\cdot}O{\cdot}CH_2{\cdot}C_6H_4{\cdot}NO_2$, th which the above substance was identified, was prepared for mparison by the interaction of *p*-nitrobenzyl chloride and sodium ribromophenoxide in benzene solution. It separated in a moder-

* It involves, however, a reversal of postulated key-atom efficiencies.

ately pure form when ligroin was added to the filtered and evaporate liquid.

(ii) op-*Dinitrophenyl Benzyl Ether*, $C_6H_3(NO_2)_2 \cdot O \cdot CH_2Ph$.—Thi compound, which was prepared by Kumpf's method (*Annalen* 1884, **224**, 131), was nitrated under the conditions used in th previous experiment; on addition of ice a precipitate was obtaine which, twice crystallised from benzene, gave well-defined, orange yellow needles, m. p. 198°, of *op*-dinitrophenyl *p*-nitrobenzyl ethe (Staedel, *loc. cit.*; Kumpf, *loc. cit.*). The latter method, using however, *p*-nitrobenzyl chloride in place of the iodide, and heatin in the absence of a solvent at 150°, was employed in order to obtai a specimen for comparison.

(iii) *Benzyl Nitrate*, $C_6H_5 \cdot CH_2 \cdot O \cdot NO_2$.—Prepared from benzy chloride and silver nitrate by Nef's method (*Annalen*, 1889, **309** 171), and isolated and purified by distillation in a vacuum, thi substance, which, after twice distilling, had b. p. 101—105°, wa analytically pure, and free from halogen, was run during abou 4 hours through a fine capillary tube into seven times its weigh of 95% nitric acid at about −10°, and the solution immediatel poured on to ice. The oil thus precipitated slowly solidified, an the solid, which was drained on porous porcelain and crystallise from warm aqueous alcohol, was identified as *p*-nitrobenzyl nitrat by its m. p. (71°) and by direct comparison with a specimen prepare by Nef's method from *p*-nitrobenzyl chloride and silver nitrate. O oxidation with 3% alkaline permanganate solution (equiv. to rathe more than 2O) at about 100°, *p*-nitrobenzoic acid was obtained.

A considerable amount of oxidation took place during attempt to nitrate benzyl ethyl ether, and even more in the case of benzy alcohol. The attempts were therefore abandoned.

(B) *Nitration of Primary, Secondary, and Tertiary Benzylamines and of certain Mono- and Di-acetyl Derivatives.*

(iv) *Benzylamine*.—This was prepared from potassium phthal imide and benzyl chloride by Gabriel's method (*Ber.*, 1887, 20 2227), but the tedious process of hydrolysing the phthalobenzyl imide with hydrochloric acid in sealed tubes was replaced by th following two-stage method, which is conveniently carried ou with larger quantities of material. The phthalobenzylimide i boiled for ½ hour with half its weight of potassium hydroxide ir 10% aqueous solution. The *phthalobenzylamic acid*,

$$CH_2Ph \cdot NH \cdot CO \cdot C_6H_4 \cdot CO_2H,$$

produced on acidification crystallises from alcohol in slender needles m. p. 155° (Found: C, 70·0; H, 5·1. $C_{15}H_{13}O_3N$ requires C, 70·3 N, 5·1%).

The crude amic acid was boiled for 18 hours with 20% hydrochloric acid (3 parts), the phthalic acid removed from the cooled solution, and the filtrate evaporated to dryness. The benzylamine isolated from the residue of hydrochloride by means of ether and sodium hydroxide was purified by distillation.

Another method, also a convenient one for the preparation of large quantities, consists in warming in chloroform solution a mixture of equal weights of hexamethylenetetramine and benzyl chloride, and hydrolysing the product with a mixture of concentrated hydrochloric acid and 95% alcohol (1 : 3 by volume).

Nitration of Benzylamine at Different Temperatures.—The general results of the experiments on the nitration of benzylamine at temperatures ranging from $-10°$ to 105° have already been described. The experiments were all carried out, so far as possible, under comparable conditions as to strength and amount of nitric acid. Details of two illustrative cases are given below.

(*a*) Benzylamine (2 g.) was run through a capillary tube during 3 hours into 10 c.c. of 95% nitric acid cooled to $-10°$. After remaining for 1 hour at this temperature, the product was mixed with ice. The crystals (1·4 g.) which separated during the next few hours consisted of almost pure *m*-nitrobenzylamine nitrate, m. p. 210° (the correct m. p. being 214°; see below). The filtrate was made alkaline with sodium hydroxide and extracted with ether, the extract shaken with a small excess of 2*N*-nitric acid, and the aqueous solution of nitrates evaporated. From the mixture thus obtained a further quantity of *m*-nitrobenzylamine nitrate was readily isolated by fractional crystallisation. The *p*-isomeride, which was also present, could not be fully purified, however, and the more soluble nitrates were therefore converted into the free bases, and these were acetylated with acetic anhydride in the usual manner. Crystallisation from water readily gave the pure acetyl derivative of *p*-nitrobenzylamine. The presence of an *ortho*-compound in the ultimate residues of this and similar experiments was suspected, but could not be definitely established owing to the smallness of the quantity.

(*b*) Benzylamine was added quickly to nitric acid at 100° and the product worked up in the manner just described. The yield of *m*-nitrobenzylamine nitrate was practically quantitative; no trace of the *p*- or *o*-compound could be detected.

o-, *m*-, and *p*-Nitrobenzylamines, which have not been previously described, were prepared by methods which determined their constitution.

o-*Nitrobenzylamine.*—A mixture of *o*-nitrobenzyl chloride (5 g.)

with 10% alcoholic ammonia (50 c.c.) was shaken for 2 hours and kept until the deposition of solid matter ceased (1—2 weeks). The solution was filtered and evaporated, and the residue, which was partly solid and partly liquid, lixiviated with water, in which the solid portion dissolved. On evaporation of this aqueous solution to dryness a well-crystallised hydrochloride was obtained, from which o-*nitrobenzylamine*, a colourous oil, was extracted with ether after the addition of sodium hydroxide. The base could not be induced to crystallise and was therefore characterised by means of its salts and acetyl derivative.

The *hydrochloride* separated from water in colourless needles, m. p. 248° (Found: Cl, 18·6. $C_7H_9O_2N_2Cl$ requires Cl, 18·8%), and the *nitrate* from the same solvent in small, white prisms, m. p. 173—174° (decomp.).

m-*Nitrobenzylamine*.—This was prepared from *m*-nitrobenzyl chloride by the same method and was obtained as a colourless oil which refused to crystallise.

The *hydrochloride* crystallised from water in large, colourless leaflets, m. p. 250°; and the *nitrate* in colourless, flattened needles, m. p. 214° (decomp.) (Found: C, 39·1; H, 4·2. $C_7H_9O_5N_3$ requires C, 39·1; H, 4·3%).

p-*Nitrobenzylamine*.—This was prepared in a like manner from *p*-nitrobenzyl chloride, but could not be induced to solidify. It was identified by means of its known acetyl derivative, a specimen of this being prepared for comparison by the method of Amsel and Hofmann (*loc. cit.*). The free base was further characterised by its *hydrochloride*, which separated from ethyl alcohol in colourless, flattened needles, m. p. 224° (Found: Cl, 18·9. $C_7H_9O_2N_2Cl$ requires Cl, 18·8%); and its *nitrate* crystallised from water in yellow plates, m. p. 180—181°.

(v) *Methylbenzylamine*, $C_6H_5{\cdot}CH_2{\cdot}NHMe$.—The preparation of this substance in quantity by methods given in the literature presented initial difficulties, but two satisfactory methods were ultimately obtained, one a modification of Hinsberg's process, and the other depending on the regulated interaction of benzyl chloride with methylamine.

(*a*) p-*Toluenesulphonbenzylamide*, $CH_3{\cdot}C_6H_4{\cdot}SO_2{\cdot}NH{\cdot}CH_2Ph$.—Benzylamine (20 g.) was dissolved in dry pyridine and 40 g. of *p*-toluenesulphonyl chloride were added cautiously and with shaking. The mixture, which became hot and of a deep red colour, was kept for 1 hour and then poured into water. The oily precipitate, which solidified on rubbing, was crystallised from alcohol, when long, stout, colourless prisms, m. p. 114°, were obtained (Found: N, 5·2. $C_{14}H_{15}O_2NS$ requires N, 5·37%).

p-Toluenesulphonbenzylmethylamide, $CH_3 \cdot C_6H_4 \cdot SO_2 \cdot NMe \cdot CH_2Ph$.—The above amide (40 g.), methyl iodide (80 g.), alcohol (20 c.c.), and aqueous sodium hydroxide were shaken together for about an hour, the sodium hydroxide being kept in sufficient excess to render the mixture strongly alkaline throughout the period. The mixture was heated on the steam-bath for 15 minutes and poured into water, and the oily precipitate, which solidified, was crystallised from alcohol, from which the pure benzylmethylamide separated in colourless plates, m. p. 95° (Found : N, 5·4. $C_{15}H_{17}O_2NS$ requires N, 5·1%).

Some difficulty was experienced in hydrolysing this substance, the convenient general process of warming with a mixture of acetic and sulphuric acids failing owing to the instability of the product under the conditions. Hydrolysis was, however, effected by heating the amide for 7 hours at 165—170° with 1·5 times its weight of concentrated hydrochloric acid. (Below 155°, the hydrolysis is extremely slow, whilst above 175° an extensive separation of carbon takes place.) The base was extracted with ether from the cooled, basified solution, and separated from neutral impurities by re-extraction with aqueous hydrochloric acid. It was finally recovered from the crystallised hydrochloride by extraction with ether in the presence of alkali, and purified by distillation.

(*b*) A mixture of benzyl chloride (20 g.), alcohol (200 c.c. of 95%), and aqueous methylamine (70 c.c. of 33% solution) was heated in a well-stoppered flask at 60° for an hour and allowed to cool. The alcohol was removed by distillation, the residue made alkaline and extracted with ether, and the extract dried with potassium carbonate and evaporated. The residue thus obtained, on distillation, yielded a large fraction, b. p. 180—200°, which on redistillation boiled almost completely at 184—186°, consisting of pure methylbenzylamine. The fraction boiling above 200° was heated with an excess of acetic anhydride for a few minutes, and then with water. The solution, after being made alkaline, was extracted with ether, and the extract washed with very dilute hydrochloric acid and then evaporated. The residue, on boiling for 12 hours with 20% hydrochloric acid, yielded a further quantity of methylbenzylamine hydrochloride, which was decomposed to give the free base.

The base prepared by any of these methods had b. p. 184—186°, and was characterised by means of its *hydrochloride*, which separated from ethyl alcohol in rosettes of needles, m. p. 195° (Found : Cl, 22·4. $C_8H_{12}NCl$ requires Cl, 22·5%).

Nitration of Methylbenzylamine at Different Temperatures.—Nitration at low temperature was conducted much as described for

the case of benzylamine, but no precipitation was obtained on the addition of ice. The product was therefore made strongly alkaline and extracted with ether, and the combined ethereal extracts were shaken several times with dilute hydrochloric acid. On evaporation of the acid solution crystals were not obtained until the whole of the solvent had been removed, when a solid remained which was recrystallised from ethyl alcohol. In this way a small quantity of a moderately soluble salt was easily separated from the large amount of a very soluble salt which accompanied it. The somewhat sparingly soluble salt, after twice crystallising, separated in colourless, flattened needles, m. p. 226°, which did not depress the m. p. of an authentic specimen (see below) of methyl-*p*-nitrobenzylamine hydrochloride. The readily soluble salt separated sometimes as laminæ and sometimes in rosettes of needles. After thrice crystallising, it melted at 181° and was identified as methyl-*m*-nitrobenzylamine hydrochloride by comparison and by the m. p. of a mixture with a genuine specimen (below). The yields of *p*- and *m*-isomerides were usually about 10% and 80% respectively, about 10% of the material being either lost during manipulation or not separated. Careful search was made for the *o*-compound, but this could not be isolated, and all the impure residues had their m. p.'s depressed by admixture with a specimen of pure methyl-*o*-nitrobenzylamine hydrochloride. When the nitration was conducted at temperatures approaching 100°, no *p*-isomeride was formed, the product consisting wholly of the *m*-nitro-compound.

Methyl-o-*nitrobenzylamine*, $NO_2 \cdot C_6H_4 \cdot CH_2 \cdot NHMe$.—After a mixture of *o*-nitrobenzyl chloride (5 g.), 95% ethyl alcohol (30 c.c.) and 33% aqueous methylamine (30 c.c.) had been kept for a week the solution was filtered and evaporated and the semi-solid residue mixed with dilute hydrochloric acid and evaporated to dryness. The oily base liberated from this hydrochloride refused to crystallise and was therefore identified through its hydrochloride, which when crystallised from water, formed small, pale yellow prisms having the m. p. (175°) and properties recorded by Gabriel and Jansen (*Ber.*, 1891, **24**, 3090).

Methyl-m-*nitrobenzylamine* was prepared from *m*-nitrobenzyl chloride and methylamine as described above, and as it was an oil which would not solidify, was characterised by means of its salts.

The *hydrochloride* separated from alcohol in small, colourless flattened needles, m. p. 182° (Found: Cl, 17·5. $C_8H_{11}O_2N_2Cl$ requires Cl, 17·4%), and the *nitrate* from dilute nitric acid in long flattened needles, m. p. 150°.

Methyl-p-*nitrobenzylamine* was also obtained as an oil and char

terised by its *hydrochloride*, flattened needles, m. p. 226° (Found : 17·5. $C_8H_{11}O_2N_2Cl$ requires Cl, 17·4%).

(vi) *Dibenzylamine*, $(C_6H_5{\cdot}CH_2)_2NH$: *Nitration at Different Temratures.*—As heretofore, a description is given of one experiment rried out at a low temperature and one at a high temperature.

(*a*) Kahlbaum's dibenzylamine (4 g.) was allowed to flow during iours through a capillary tube into 20 c.c. of nitric acid (*d* 1·5) aintained at — 5° to 0°. After keeping for a further hour at e same temperature, the product was poured on to ice and the rstalline precipitate collected and crystallised from 800 c.c. of iling water, when 5·0 g. of pure *mm'*-dinitrodibenzylamine rate separated in clusters of needles, m. p. 235° (decomp.). It s identified by analysis and by direct comparison with a genuine ecimen (below), and also by converting it into the free base, ich was crystallised and similarly identified. The crystals tained on evaporating the mother-liquors (2 g.) obviously conted of a mixture, and, by fractional crystallisation from water, d extraction with small amounts of boiling water, were divided o a less soluble salt, identical with that obtained above, and a re soluble salt, which, when pure, had m. p. 210° and was identid as *pp'*-dinitrodibenzylamine nitrate by analysis and by comrison with a specimen obtained as described below. The yields *pp'*- and *mm'*-dinitro-products isolated were 5% and 80% pectively. A third isomeride appeared to be present, but could be fully purified; it may have been the *mp'*-compound, as it pressed the m. p. of an authentic specimen of the *oo'*-isomeride admixture.

(*b*) On adding dibenzylamine rapidly to 10 parts by weight of ric acid (*d* 1·5) at 70—90°, and pouring the product into water, *a'*-dinitrodibenzylamine nitrate was obtained in almost theoretical ld. No isomeride could be isolated.

oo'-Dinitrodibenzylamine, $(NO_2{\cdot}C_6H_4{\cdot}CH_2)_2NH$.—This substance, pared by Gabriel and Jansen's method (*loc. cit.*), melted at °, and its hydrochloride at 238° (decomp.). Gabriel and Jansen ord the m. p. of the base as 99—100° and that of the hydroloride as "above 220°." Birk gives m. p. 236° for the hydroloride (*J. pr. Chem.*, 1897, **56**, 360).

The *nitrate* separated from water in pale yellow needles, m. p. 0)—203° (decomp.) (Found : C, 47·9; H, 3·9. $C_{14}H_{14}O_7N_4$ quires C, 48·0; H, 4·0%).

mm'-Dinitrodibenzylamine.—A solution of *m*-nitrobenzyl chloride 5 parts of 10% alcoholic ammonia was kept until crystals ceased form, when they were collected, lixiviated with water to remove monium chloride, and crystallised from alcohol or ether, from

which stout, lemon-yellow prisms separated, m. p. 83·5°. further quantity was obtained from the semi-solid mass remaini on evaporation of the ammoniacal alcoholic solution by alternate extracting with water and crystallising from alcohol (Found C, 58·6; H, 4·4. $C_{14}H_{13}O_4N_3$ requires C, 58·5; H, 4·5%).

The *hydrochloride*, formed by dissolving the base in hot dilu hydrochloric acid and cooling, crystallised in small, very pa yellow prisms, m. p. 253°; whilst the *nitrate*, prepared similarl or by nitration as described above, separated in bunches of ve pale yellow needles, m. p. 235° (decomp.) (Found: C, 48·2; H, 4· $C_{14}H_{14}O_7N_4$ requires C, 48·0; H, 4·0%).

pp′-*Dinitrodibenzylamine*.—This was prepared from *p*-nitr benzyl chloride and alcoholic ammonia as in the experime described above. The base separated from alcohol in pale bu needles, m. p. 93° (Found: C, 58·5; H, 4·6%). It is only sparing soluble in ether (distinction from the *mm′*-compound).

The *hydrochloride* crystallises from hot water in clusters of colou less needles, m. p. 217—218°, and the *nitrate*, prepared either nitration of dibenzylamine as described above, or by cooling solution of the dinitro-base in hot dilute nitric acid, forms ve pale yellow leaflets, m. p. 210—211° (decomp.) (Found: C, 48· H, 4·3. $C_{14}H_{14}O_7N_4$ requires C, 48·0; H, 4·0%).

(vii) *Methyldibenzylamine*, $(C_6H_5{\cdot}CH_2)_2NMe$.—Benzyl chlori (20 g.) was dissolved in 200 c.c. of ethyl alcohol and mixed wi 40 c.c. of 33% aqueous methylamine. The reaction was allow to proceed in the cold and finished by heating at 60° for a sho time. After evaporation of the alcohol the bases were extract with ether, after the addition of sodium hydroxide, and treat with *p*-toluenesulphonyl chloride as described on p. 1812. extracting an ethereal solution of the crude product thus obtain with dilute hydrochloric acid a solution of dibenzylamine hydr chloride was obtained; the free base, isolated from this by extra tion with ether after the addition of alkali, had b. p. 290° (uncor (Emde, *Arch. Pharm.*, 1909, **247**, 369, records b. p. 304—30 corr.). The *hydrochloride*, crystallised from a concentrated soluti in hydrochloric acid, has m. p. 200—201° (Found: Cl, 14 $C_{15}H_{18}NCl$ requires Cl, 14·0%).

The nitration of this substance was carried out both in carefu cooled, and in warm, nitric acid, but substantially the same resu were obtained in the two cases, and the following description w suffice as illustration. The base was allowed to flow through fine capillary tube into seven times its weight of 95% nitric a at 0°. The product was allowed to warm to the ordinary te perature during 2 hours and was then mixed with ice, when

ly precipitate was obtained which solidified. This was suspended aqueous sodium hydroxide and shaken with ether, and the hereal solution obtained was dried and evaporated, yielding a lid residue consisting mainly of *pp'*-dinitrodibenzylmethylamine. his substance was readily isolated by crystallisation from alcohol id was identified with an authentic specimen prepared as described elow. The ultimate residues from these crystallisations were oily, it responded to seeding with a crystal of the pure *oo'*-dinitro- mpound, a small amount of which was isolated by draining e adhering oil into porous porcelain and crystallised from her. It was identified by direct comparison and a mixed m. p. termination.

oo'-Dinitrodibenzylmethylamine, $(NO_2 \cdot C_6H_4 \cdot CH_2)_2N \cdot CH_3$.—A mixre of *o*-nitrobenzyl chloride (5 g.), absolute alcohol (30 c.c.), and % aqueous methylamine (15 c.c.) was kept at the ordinary mperature for a week. The crystals which had separated were crystallised from alcohol, when stout, yellow prisms were obtained greeing in their m. p. (63°) and properties with the description of '-dinitrodibenzylmethylamine given by Gabriel and Jansen (*loc.* .).

The *hydrochloride* crystallised from dilute hydrochloric acid in lourless needles, m. p. 216° (Found: Cl, 10·3. $C_{15}H_{16}O_4N_3Cl$ quires Cl, 10·5%), and the *nitrate* from dilute nitric acid in very le yellow prisms, m. p. 125° (decomp.).

mm'-Dinitrodibenzylmethylamine, prepared in like manner from -nitrobenzyl chloride and methylamine, separated from ethyl cohol in colourless needles, m. p. 83—84° (Found: C, 59·9; , 5·1. $C_{15}H_{15}O_4N_3$ requires C, 60·0; H, 5·0%).

The *hydrochloride*, prepared by evaporating a solution of the se in hydrochloric acid and crystallising the residue from alcohol, rmed pale buff prisms, m. p. 223—224° (Found: Cl, 10·2. $_5H_{16}O_4N_3Cl$ requires Cl, 10·5%), and the *nitrate*, crystallised m dilute nitric acid, was obtained as small, pale yellow prisms, p. 163° (decomp.).

pp'-Dinitrobenzylmethylamine.—This was obtained by the same thod and had the m. p. and properties recorded by Paal and renger (*Ber.*, 1897, **30**, 63).

The *hydrochloride*, prepared as in the previous case, crystallised m ethyl alcohol in stout, pale yellow prisms, m. p. 204—205° ound: Cl, 10·4%), whilst the *nitrate*, after twice crystallising m water, formed pale yellow prisms, m. p. 146° (Found: C, 49·3; 4·7. $C_{15}H_{16}O_7N_4$ requires C, 49·4; H, 4·4%).

(viii) *Acetobenzylamide*, $C_6H_5 \cdot CH_2 \cdot NH \cdot CO \cdot CH_3$.—The nitration this substance has been described by Amsel and Hofmann (*loc.*

cit.), who obtained aceto-*p*-nitrobenzylamide; but they do not mention any by-products. Having repeated the experiment, utilising our experience in the separation of the acetyl derivatives of *o*-, *p*-, and *m*-nitrobenzylamines, we have come to the conclusion that, although aceto-*o*- or -*m*-nitrobenzylamide (or both) is probably formed along with the *p*-compound, the quantity must be very small, for it could not be identified with certainty. This is in agreement with the rather strongly basic character of acetobenzylamide.

(ix) *Acetomethylbenzylamide*, $C_6H_5 \cdot CH_2 \cdot NMe \cdot CO \cdot CH_3$.—This substance was prepared by boiling methylbenzylamine with 2·5 parts of acetic anhydride for 15 minutes, and then boiling the product for a few minutes with excess of water. The oil, extracted with ether after the addition of excess of sodium hydroxide, gradually solidified on keeping in an evacuated desiccator and could then be crystallised from ether–ligroin (b. p. 40—60°), from which it separated in large, colourless cubes, m. p. 41—43°, b. p. 155°/16 mm. (Found: C, 73·3; H, 7·9. $C_{10}H_{13}ON$ requires C, 73·6; H, 8·0%). The same substance was obtained as a by-product in the preparation of dibenzylmethylamine described above. It is completely soluble in cold 3% hydrochloric acid.

The nitration was carried out by adding the substance in small portions to 10 parts of nitric acid (*d* 1·5) at $-10°$. The liquid was allowed to warm during 1 hour to the ordinary temperature, and was then mixed with ice. No precipitation took place under this treatment, and the solution was therefore rendered alkaline and extracted with ether, when, on evaporation of the solvent, a solid residue was obtained which crystallised from ligroin in clusters of colourless needles, m. p. 80—81°. The substance also separated from alcohol–ligroin in stout prisms of the same m. p. It was identified as aceto-*p*-nitrobenzylmethylamide by analysis and by comparison with a synthetic specimen (below). The mother-liquors were carefully searched for an isomeride, but although a further quantity of the *p*-nitro-compound was obtained (total yield 90%), the *o*- and *m*-nitro-isomerides could not be identified with certainty, although traces of a more fusible compound were present.

Aceto-o-*nitrobenzylmethylamide*, $NO_2 \cdot C_6H_4 \cdot CH_2 \cdot NMe \cdot CO \cdot CH_3$, was prepared by Gabriel and Jansen's method.

Aceto-m-*nitrobenzylmethylamide* was prepared from the hydrochloride of *m*-nitrobenzylamine by boiling it (1 g.) for 15 minutes with acetic anhydride (4 c.c.) and anhydrous sodium acetate (1 g.). The product was warmed with water to decompose the excess of acetic anhydride, and the solution made alkaline and extracted with ether, from which, on evaporation, an oily residue was obtained

which quickly solidified, and, on crystallisation from benzene–ligroin, yielded colourless prisms, m. p. 56—57° (Found: C, 57·5; H, 5·9. $C_{10}H_{12}O_3N_2$ requires C, 57·7; H, 5·8%).

Aceto-p-*nitrobenzylmethylamide*, prepared similarly, separated from benzene–ligroin in colourless prisms, m. p. 80—81° (Found: C, 57·6; H, 6·0%).

(x) *Acetodibenzylamide*, $(C_6H_5\cdot CH_2)_2N\cdot CO\cdot CH_3$.—This substance was prepared by boiling dibenzylamine for a few minutes with acetic anhydride and decomposing the excess of the reagent with water. It was extracted from alkaline solution by means of ether, and, after distillation, was obtained as a rather viscous oil, b. p. 194—195°/3 mm. (Found: C, 79·9; H, 7·0. $C_{16}H_{17}ON$ requires C, 80·0; H, 7·1%). It was also prepared by treating a pyridine solution of dibenzylamine with acetyl chloride and extracting with ether after adding excess of dilute hydrochloric acid. It is easily soluble in concentrated hydrochloric acid, but only sparingly soluble in dilute acid. On boiling for 6 hours with 20% hydrochloric acid, hydrolysis of the acetyl group took place, and the solution on cooling deposited crystals of dibenzylamine hydrochloride.

Nitration with Different Concentrations of Nitric Acid.—(*a*) The acetyl compound (2·5 g.) was added in about 15 portions during 1½ hours to 15 g. of 95% nitric acid at about − 5°. At each addition a deep red colour was formed which vanished after a few seconds. The product was kept for a further hour at 0°, and at the ordinary temperature for the same period, and then mixed with ice. The oily precipitate slowly solidified and after crystallising from alcohol yielded 1·5 g. of crystals, m. p. 175°. After complete purification, these had m. p. 183° and were identified as aceto-*pp'*-dinitrodibenzylamide by direct comparison with a specimen of this substance, and by converting them by hydrolysis (boiling for 6 hours with 20% hydrochloric acid) into *pp'*-dinitrodibenzylamine which, along with its hydrochloride, was similarly identified. The alcoholic mother-liquors were evaporated and the residue was fractionally crystallised from alcohol, when aceto-*mm'*-dinitrodibenzylamide was readily isolated in a pure condition and identified by direct comparison with an authentic specimen (below). The ultimate residues yielded (besides a further quantity of the *pp'*-compound) a very small amount of the *oo'*-isomeride, which was obtained from gummy residues by seeding with a pure specimen. The quantities isolated were: *para* 45%; *meta* 20%; *ortho* 3%.

(*b*) The dibenzylamide was treated at 30—50° with 80% nitric acid, and the product isolated and separated as described above. Yields: *para* 30%; *meta* 40%; *ortho* trace.

(*c*) The dibenzylamide was boiled with 70% nitric acid for 15

minutes, and the products were isolated and separated. Yields *para* 20%; *meta* 55%.

Aceto-oo′-dinitrodibenzylamide, $(NO_2 \cdot C_6H_4 \cdot CH_2)_2N \cdot CO \cdot CH_3$, was prepared from the corresponding base by acetylation with boiling acetic anhydride. After decomposing the acetic anhydride by boiling with water, sufficient additional acetic acid was added to complete the solution of the acetyl compound. On cooling, clusters of very pale yellow needles separated, m. p. 154° (Found: C, 58·6; H, 4·4. $C_{14}H_{15}O_5N_3$ requires C, 58·4; H, 4·5%).

Aceto-mm′-dinitrodibenzylamide, prepared in exactly the same way, crystallised in small, pale yellow prisms, m. p. 146° (Found: C, 58·5; H, 4·5%).

Aceto-pp′-dinitrodibenzylamide, obtained likewise, separated in colourless needles, m. p. 183—184° (Found: C, 58·3; H, 4·5%).

(xi) *Diacetylbenzylamine*, $C_6H_5 \cdot CH_2 \cdot N(CO \cdot CH_3)_2$.—Benzylamine (5 g.) was boiled with acetic anhydride (20 c.c.) for 3 days, after which the solution was cooled and shaken with water until the excess of acetic anhydride had decomposed. The solution was then made alkaline and extracted with ether. The residue from the ether evidently consisted of a mixture of mono- and di-acetyl derivatives, since some of the former compound crystallised on keeping for a few days in an evacuated desiccator. To isolate the diacetyl compound the mixture was dissolved in ether and the monoacetyl derivative removed by shaking with 5% hydrochloric acid. On evaporation of the ether an oil was obtained which refused to solidify and was therefore purified by distillation. Di-acetylbenzylamine is a colourless, rather viscous liquid, b. p. 176—178°/30 mm. (Found: C, 69·1; H, 7·2. $C_{11}H_{13}O_2N$ requires C, 69·2; H, 6·9%). It is completely hydrolysed to benzylamine hydrochloride on boiling for 16 hours with 20% hydrochloric acid.

The substance was allowed to flow through a fine capillary tube into 10 parts of 95% nitric acid at — 20°, and the resulting solution mixed with crushed ice. The oily product thus obtained was extracted with ether after the addition of sodium hydroxide, and as it did not solidify after evaporation of the ether, was hydrolysed by boiling for 12 hours with 20% hydrochloric acid. On evaporating the solution so obtained, a solid residue remained, consisting of *m*-nitrobenzylamine hydrochloride, which was readily isolated in the pure condition by crystallisation from alcohol, and identified by direct comparison with a genuine specimen. No by-product could be recognised.

Some of the analyses recorded in this paper were carried out by Mr. Arthur Rumfit, to whom the authors acknowledge their

ndebtedness. They also desire to record their thanks to the Chemical Society for a grant wherewith part of the expense of this esearch has been defrayed.

THE UNIVERSITY, LEEDS. [*Received, May 2nd,* 1925.]

CCXLI.—*Syntheses of Disulphoxides.*

By DAVID TEMPLETON GIBSON, CECIL JAMES MILLER, and SAMUEL SMILES.

FOUR general methods of obtaining the disulphoxides are at present available, but the very simple synthesis from a mercaptan and a sulphonyl chloride, although frequently attempted, has not yet been successfully accomplished. Blomstrand (*Ber.*, 1870, **3**, 962)

$$(a)\ RSO_2Cl + R'SH = HCl + RSO_2{\cdot}SR'$$

claimed to have obtained tolyl amyl disulphoxide from amyl mercaptan and toluenesulphonyl chloride, but his product was ill-defined and apparently not analysed; thus Otto, after further investigation of the reaction, was fully justified in doubting this result (*Ber.*, 1882, **15**, 121). Otto also attempted to obtain diphenyl and ditolyl disulphoxides (*Ber.*, 1876, **9**, 1636; 1878, **11**, 2070) by this method, but was unsuccessful, isolating instead the corresponding disulphide and sulphinic acid. He represented the completed reaction as follows:

$$(b)\ RSO_2Cl + 2RSH = HCl + RSO_2H + (RS)_2.$$

Many other observers have since met with Otto's experience and agree with his representation of the process.

The circumstance that the disulphoxides apparently cannot be obtained in this manner has been utilised by Hinsberg (*Ber.*, 1903, 36, 109) and by Fromm and Seixas Palma (*Ber.*, 1906, **39**, 3310) as evidence against the thiolsulphonate structure of these substances. Conclusive evidence in favour of this constitution has been obtained (J., 1924, **125**, 176; this vol., p. 224). Hence it seemed necessary to find an explanation of this discrepancy, and a further examination of the reaction between mercaptans and sulphonyl halides has now been made. In the reaction between disulphoxides and mercaptans the former undergo fission, yielding a sulphinic acid whilst the thioaryl group appears as disulphide (*loc. cit.*):

$$(c)\ RSO_2SR' + R'SH = RSO_2H + (R'S)_2.$$

Since this decomposition of the disulphoxides takes place very easily, it seemed probable that the reaction between sulphonyl halide and mercaptan may proceed in two stages, the disulphoxide

at first formed (according to *a*) being rapidly decomposed (compar *c*) by the mercaptan. According to this hypothesis it should b possible to obtain disulphoxides by the method if experimenta conditions are adopted in favour of (*a*) and unfavourable to (*c* In one set of experiments these have been attained by slowly addin the mercaptan to a large excess of the heated sulphonyl chloride thus completing (*a*) as rapidly as possible and avoiding the exces of mercaptan necessary to (*c*). In other experiments the mor reactive sulphonyl iodides were used, the secondary action of th mercaptan being to a great extent avoided by the use of silve mercaptides. With these modified conditions the method ma be used for the synthesis of disulphoxides and, as shown below the somewhat inaccessible class of disulphoxides containing dis similar aromatic nuclei are readily obtained. Of the two method described, that involving the use of the sulphonyl iodides is usuall to be preferred, but owing to the tendency of these substances t liberate iodine some disulphide may be formed from the mercaptide The success of this method is therefore more easily attained b using the more stable of the sulphonyl iodides and by choosin mercaptans which generate the soluble disulphides. The latte condition facilitates separation of the impurity from the required disulphoxide.

It is now evident that the failure to obtain disulphoxides from these reagents under ordinary conditions can no longer be used as objection to the thiolsulphonate structure; on the contrary, the results now described give further evidence in support of this.

Experimental.

(a) *Syntheses from Mercaptans and Sulphonyl Chlorides.*—The conditions adopted were as follows. A solution of the mercaptan in benzene containing a small quantity of pyridine was slowly added to a boiling solution of excess of the sulphonyl chloride in the same solvent. When the liquid had cooled, any sulphinic acid pyridine, and the excess of acid chloride present were removed The solvent was evaporated and the residue was examined.

Di-*p*-tolyl disulphoxide was obtained in 25% yield from 2 mols of the mercaptan and 5 mols. of *p*-toluenesulphonyl chloride. It was isolated and identified in the usual manner.

2 : 5 : 2′ : 5′-Tetrachlorodiphenyl disulphoxide was obtained (5% yield) from 2 : 5-dichlorothiophenol (1 mol.) and 2 : 5-dichlorobenz enesulphonyl chloride (7 mols.). The product (m. p. 127°) was identified in the usual manner.

4-*Tolyl* 3-*nitrobenzenethiolsulphonate*, $C_6H_4Me{\cdot}S{\cdot}SO_2{\cdot}C_6H_4{\cdot}NO_2$ was isolated (30% yield) from the reaction between 3-nitrobenzene

sulphonyl chloride (8 mols.) and 4-tolyl mercaptan (1 mol.). The substance, isolated as usual, formed colourless needles, m. p. 109° (Found: C, 50·4; H, 3·6; N, 4·9. $C_{13}H_{11}O_4NS_2$ requires C, 50·5; H, 3·5; N, 4·5%).

The ascribed constitution was confirmed by treating the substance in warm alcohol with 2 : 5-dichlorothiophenol (1 mol.). 3-Nitrobenzenesulphinic acid and 2 : 5-dichloro-4′-methyldiphenyl disulphide were isolated (J., 1924, **125**, 182).

(b) *Syntheses from Sulphonyl Iodides and Silver Mercaptides.*—The sulphonyl iodides (Otto and Tröger, *Ber.*, 1891, **24**, 478) were prepared by slowly adding an alcoholic solution of the theoretical amount of iodine to a cold solution of the sodium sulphinate containing about 20 g. of the salt in 2—3 litres of water. The crystalline material was washed and dried (yield, under the best conditions, generally over 80%).

2 : 5-*Dichlorobenzenesulphonyl iodide*, $C_6H_3Cl_2{\cdot}SO_2I$, separated from light petroleum in golden-yellow needles, m. p. 100° (Found: Cl + I, 58·7; S, 9·35. $C_6H_3O_2Cl_2IS$ requires Cl + I, 58·7; S, 9·6%).

Naphthalene-2-sulphonyl iodide, $C_{10}H_7{\cdot}SO_2I$, separated from benzene–light petroleum in yellow needles, m. p. 96—97° (decomp.). This sulphonyl iodide was more stable in solution than any other encountered in these experiments (Found: I, 40·0; S, 10·0. $C_{10}H_7O_2IS$ requires I, 39·9; S, 10·0%).

The silver mercaptides used were obtained from silver nitrate, the mercaptan, and sodium acetate (1 mol.) in alcoholic solution.

The dry silver mercaptide (rather more than 1 mol.) was gradually added with thorough shaking to a dry solution of the sulphonyl iodide in ether or benzene. Owing to the tendency of solutions of the iodides spontaneously to liberate iodine, the duration of the process was kept within certain limits—generally about ½ hour—which varied with different sulphonyl iodides. The silver halide was then removed and the solution was treated with a little dilute aqueous sodium carbonate and, if necessary, with sufficient sodium sulphite to remove free iodine. After the solvent had been removed the residue was purified in the usual manner. In this way the following thiolsulphonates were obtained.

2 : 5-Dibromophenyl 2 : 5-dichlorobenzenethiolsulphonate,

$$C_6H_3Br_2{\cdot}S{\cdot}SO_2{\cdot}C_6H_3Cl_2,$$

from 2 : 5-dichlorobenzenesulphonyl iodide and 2 : 5-dibromophenyl mercaptan (88% yield). The product (m. p. 124°) was identified with that obtained from silver dichlorobenzenesulphinate and dibromophenylsulphur bromide (this vol., p. 230) (Found: S, 13·3. Calc., S, 13·4%).

4-*Tolyl* 2 : 5-*dichlorobenzenethiolsulphonate*, $C_6H_4Me{\cdot}S{\cdot}SO_2{\cdot}C_6H_3Cl_2$, was obtained (80% yield) from 2 : 5-dichlorobenzenesulphonyl iodide and silver 4-tolyl mercaptide. The subtance separated from aqueous alcohol in small, colourless needles, m. p. 74° (Found: S, 19·2; Cl, 21·4. $C_{13}H_{10}O_2Cl_2S_2$ requires S, 19·25; Cl, 21·2%).

6-*Methoxy*-3-*tolyl* 2-*naphthalenethiolsulphonate*, $OMe{\cdot}C_6H_3Me{\cdot}S{\cdot}SO_2{\cdot}C_{10}H_7$, was prepared (about 85% yield) from 2-naphthalenesulphonyl iodide and 4-methoxytoluene 3-mercaptan (J., 1923, **123**, 2390). After purification from hot alcohol the substance formed colourless prisms, m. p. 113—114° (Found: C, 62·6; H, 4·7; S, 18·5. $C_{18}H_{16}O_3S_2$ requires C, 62·7; H, 4·6; S, 18·6%).

2 : 4-*Xylyl* 2-*naphthalenethiolsulphonate*, $C_6H_3Me_2{\cdot}S{\cdot}SO_2{\cdot}C_{10}H_7$, was obtained (about 85% yield) from 2-naphthalenesulphonyl iodide and 2 : 4-xylylthiol. It separated from benzene–ligroin in colourless prisms, m. p. 80—81° (Found: C, 65·5; H, 4·9; S, 19·2. $C_{18}H_{16}O_2S_2$ requires C, 65·8; H, 4·9; S, 19·5%).

We are indebted to the Chemical Society for a grant which partly defrayed the cost of these experiments.

CCXLII.—*Studies of Electrolytic Polarisation. Part III. The Diffusion Layer.*

By SAMUEL GLASSTONE.

SINCE Noyes and Whitney (*Z. physikal. Chem.*, 1897, **23**, 689) first put forward the view that diffusion plays the chief part in the rate of a heterogeneous process such as solution, and Nernst *et al.* (*ibid.*, 1904, **47**, 52; 1905, **53**, 235) extended the idea to chemical and electrochemical reactions in heterogeneous systems, most authors have accepted the idea of the existence of a layer of liquid of different concentration from that of the bulk of the solution at the surface of the reacting solid or the electrode in the case of an electrolytic process. The thickness of this layer has been presumed to be independent of the concentration of the liquid, and even to vary only slightly with the nature of the two phases involved in the reaction. Further, in the case of electrolytic reduction Jahn ("Grundriss der Elektrochemie," 1905, p. 519 *et seq.*) quotes results from the work of Haber *et al.* (*Z. physikal. Chem.*, 1900, **32**, 193, 271; 1904, **47**, 257) and from that of Akerberg (*Z. anorg. Chem.*,

902, **31**, 161) which indicate that the thickness of the diffusion ayer for a given electrode and electrolyte is also independent of he current density under such conditions that very little or no gas s being evolved. The results obtained by Nernst and Merriam *Z. physikal. Chem.*, 1905, **53**, 235) and by Wilson and Youtz *J. Ind. Eng. Chem.*, 1923, **15**, 603), as well as unpublished measure- nents by the present author, all lead to the same conclusion. When a heterogeneous reaction involves the liberation of gas, as in he dissolution of metals in acid, the results of Palmaer (*Z. physikal. Chem.*, 1906, **56**, 689) and of Prins (*Proc. K. Akad. Wetensch. Amsterdam*, 1921, **23**, 1449) indicate that it is very probable that he thickness of the diffusion layer does not remain constant; no work, however, appears to have been done in connexion with the iffusion layer in an electrolytic process involving free evolution of as, but the results described below have an important bearing on his problem. These results were obtained in the course of experi- nents on lead and mercury cathodes in various electrolytes, some f the results of which have already been published (J., 1924, **125**, 414, 2646). An examination of the figures given in these papers vill show that under a variety of conditions the difference between he direct and the extrapolated overvoltage, which is presumably lue to the resistance at the electrode surface, is not nearly pro- ortional to the magnitude of the current. This indicates that the alue of the resistance alters with the current as long as gas bubbles re being evolved; actually the resistance decreases as the current s increased. A large part of this resistance is believed to be due o the presence of a thin layer of dilute electrolyte—the diffusion ayer—which is in immediate contact with the electrode; it thus ppears that the resistance, and probably the thickness, of this ayer decreases as the current density is increased. This is no loubt due to the fact that the rapid evolution of gas at the high urrent densities causes a stirring of the electrolyte which results n a reduction of the thickness of the diffusion layer. Further onfirmation of this view has been obtained by experiments with a nercury cathode in dilute solutions of sulphuric acid containing otassium sulphate, and with various electrodes in hydrochloric cid solution.

The experimental results have thrown further light on the factors nfluencing the rate of fall of the back *E.M.F.* of a polarised elec- rode; in the previous work on the mercury cathode (*loc. cit.*) it vas shown that the diffusion of oxygen from the anode can affect he back *E.M.F.* and it is now found that the thickness of the liffusion layer may also influence the rate of fall.

Experimental.

The apparatus used in this work was the same as that describe in previous communications (*loc. cit.*); unless otherwise stated, th experiments were carried out at room temperature (about 15°) an anode and cathode compartments were not separated.

Sulphuric Acid and Potassium Sulphate Solutions.—During th course of the measurements of the overvoltage at the mercur cathode in *N*/16-sulphuric acid containing potassium sulphate (se J., 1924, **125**, 2651) it was found that, although the back *E.M.F* of the electrode decreased normally for the first 0·012 sec. afte the polarising current was switched off, yet in certain cases, afte this period had elapsed, an abnormal condition set in which wa independent of the nature of the electrode vessel, and of the separ ation or not of the anode and cathode compartments. The followin typical result will make this abnormality clear:

Back *E.M.F.* after:	C.D. (amp./cm.²)	0·003	0·006	0·012	0·024
0·012 sec.		0·91	0·92	0·92	0·92
0·018 „		0·89	0·89	0·85	0·85

After a certain interval of time, instead of the normal decrease o the back *E.M.F.* there was a sudden, more rapid, fall of potentia This fall was first observed at the highest current densities used but after increasing time intervals it was found to occur at lowe current densities. At a higher temperature the sudden fall o potential took place after a shorter interval of time for any par ticular current density. This curious behaviour was noted in al cases where the electrolyte contained an excess of potassium ion and where the potentials indicated that the normal hydroge discharge was not the only cathodic process. Similar experiment in which sodium sulphate was used instead of the potassium sal gave similar results.

The potential measurements suggest that the hydrogen-ion con centration in the vicinity of the electrode in these solutions i impoverished, probably owing to the fact that the presence of a large excess of potassium ions prevents the hydrogen ions fron diffusing up to the electrode as fast as they are discharged; the potential of the electrode becomes more negative and potassium ions are discharged to form an amalgam. When the polarising current is switched off, the hydrogen ions can diffuse through the impoverished layer of electrolyte without being discharged and s react with the amalgam, causing its rapid decomposition (see Klein *Z. anorg. Chem.*, 1924, **137**, 39) and a consequent fall of potential the thinner the diffusion layer the sooner will this sudden fall o potential occur. The results given above show that this fall occurs

ponest at the highest current densities, and hence we may conclude hat under conditions of gas evolution the diffusion layer is thinnest t high current densities. An increase of temperature causes the ate of diffusion to increase, even if it does not appreciably influence he thickness of the diffusion layer, and so the time interval between witching off the current and the sudden fall of back *E.M.F.* is iminished. These conclusions regarding the diffusion layer in the pecial case under discussion are in agreement with those arrived t from a consideration of the difference between the direct and ic extrapolated overvoltage measurements.

If the above views are correct it is to be expected that rapid irring of the electrode and electrolyte will have some influence on ie fall of the back *E.M.F.* In these circumstances the diffusion ayer would cease to exist the instant that the polarising current as switched off, and so a more rapid fall of potential right from ie beginning would be expected at all current densities, but no idden fall after an interval of time. These forecasts have been onfirmed; up to 0·03 sec. after the polarising circuit was broken ie rate of fall of the back *E.M.F.* was still normal at all the current ensities used in the previous experiments; this rate of fall was reater initially than in a similar experiment in which the electrolyte as not stirred. The following figures illustrate the effect of irring.

Back *E.M.F.* after :	C.D. amp./cm.^{2}	0·002	0·004	0·008	0·016	
0·002 sec.		0·98	1·00	1·02	1·04	
0·006 ,,		0·95	0·97	0·99	1·01	Not stirred.
0·018 ,,		0·88	0·90	0·91	0·89	
0·002 ,,		0·92	0·94	0·96	0·99

Hydrochloric Acid Solutions.—In the course of experiments with -hydrochloric acid as electrolyte, chlorine gas was always evolved the anode. If the anode and cathode compartments were parated, no special precautions were taken before making measure-ents; in other cases the polarising current was passed for some me so that the electrolyte dissolved a considerable amount of ilorine gas. In the latter circumstances no hydrogen could be erated at the cathode unless a high current density was applied, ., 0·24 amp. per 10 sq. cm., but once gas evolution had commenced ie current could be reduced by gradual stages to 0·015 amp. and ie evolution of gas would continue. If the current was reduced ddenly, gas evolution ceased. In making measurements it was ual to determine the potential by the direct method first, and en to measure the back *E.M.F.* at certain definite times after the

polarising current was switched off, first with decreasing and the with increasing current densities. The results quoted below a the mean of those obtained with increasing and decreasing current the actual values for the same current density did not va appreciably.

The following table contains the results obtained with a mercu cathode of 10 sq. cm. exposed area in N-hydrochloric acid; t anode and cathode compartments were not separated.

C.D.	Overvoltage.		Back $E.M.F.$ after :						
(amp./cm.^{2}).	Direct.	Extrap.	0·002	0·004	0·006	0·008	0·012	0·018	sec.
0·0015	1·03	1·01	0·98	0·96	0·94	0·91	0·89	0·84	
0·003	1·07	1·03	1·00	0·98	0·96	0·91	0·89	0·84	
0·006	1·11	—	0·99	0·97	0·95	0·89	0·84	*0·74	
0·012	1·15	—	0·97	0·94	0·89	0·80	*0·67	0·50	
0·024	1·19	—	0·93	0·89	0·83	*0·67	0·49	0·28	

These results show that there are two distinct abnormalities i the fall of the back $E.M.F.$ after the polarising current is switche off. In the first place, although the direct overvoltage increas regularly, yet the back $E.M.F.$ after 0·002 sec. at first increas and then decreases as the current density is increased. Th suggests that immediately the current is switched off at the hig current densities there is a very rapid fall of potential which cann be detected directly. Following this the rate of fall of potenti is fairly regular until after a certain interval of time there is anoth sudden fall in the back $E.M.F.$ at the points marked with a asterisk in the above table. The period of time that elapses befo this second fall of potential occurs decreases as the current densit is increased. This fall of potential is not due to the failure of th electrode to reach its equilibrium condition when the current switched on, since measurements have shown that at these hig current densities almost the same potential is reached while th current is flowing whether the commutator is working or not.

In the next experiments the anode and cathode compartment were separated by placing the mercury in a porous pot; the platinu anode was placed in the liquid which surrounded the pot. Th same electrolyte, N-hydrochloric acid, was used throughout. Th results were as follows.

C.D.	Overvoltage.		Back $E.M.F.$ after			
(amp./cm.^{2}).	Direct.	Extrap.	0·002	0·004	0·006	0·012 sec.
0·0015	1·03	1·01	0·98	0·96	0·94	0·89
0·003	1·07	1·03	0·99	0·97	0·95	0·89
0·006	1·11	1·04	1·00	0·98	0·96	0·90
0·012	1·15	1·05	1·01	0·99	0·97	0·91
0·024	1·19	1·06	1·02	0·99	0·97	0·91

These figures appear to be quite normal in every way, and hen it may be concluded that the abnormal fall of the back $E.M.$

bserved in the previous experiment is due to the action of the hlorine gas liberated at the anode; in all cases where the chlorine as prevented from diffusing to the cathode the fall of potential as normal, but in other cases it was abnormal. In order to etermine the influence, if any, of the material of the electrode essel on the abnormal results, the platinum anode was placed inside he porous pot containing the mercury; the potentials were almost he same as those obtained with the mercury in a glass beaker, nd hence the experiment did not yield any decisive result. Using glass beaker which had been standing with concentrated alkali or about a week, the following back *E.M.F.*'s were measured at ·002 sec. after the polarising current was switched off :—

C.D.	0·0015	0·003	0·006	0·012	0·024
Back *E.M.F.*	0·96	0·97	0·95	0·91	0·80

The inside of the beaker was then coated with paraffin wax and he following measurements were then recorded at the same series f current densities :—

Back *E.M.F.*	0·96	0·97	0·98	0·97	0·95

The initial fall in the back *E.M.F.* at high current densities is thus nfluenced to some extent by the material of the electrode vessel, nd different results were obtained from time to time with different glass beakers. The sudden fall that occurred after the lapse of an nterval of time was always observed, provided the anode and athode compartments were not separated.

Discussion.

Applying the suggestions that have been put forward to explain he abnormal back *E.M.F.* of the mercury cathode in dilute ulphuric acid solutions (see Part II, *loc. cit.*), it appears that the irst rapid fall of potential at the high current densities is to be ttributed to the concentration of the electromotively active material t the circumference of the electrode owing to the action of surface ension forces. As soon as the polarising current is switched off his active substance appears to be rapidly attacked by the chlorine n solution, and the material of the electrode vessel may influence he rate of reaction; there is thus a rapid initial fall of potential. f the mercury was in such a condition that the surface forces were o longer operative, then this rapid fall of potential should not be bserved; some experiments were therefore made with an amal- amated lead electrode, which in most cases gives overvoltages hat are not very different from those given by pure mercury. The electrodes used had an exposed area of 7·5 sq. cm. and the irect overvoltages were almost the same as those observed with a

pure mercury surface of the same area. The back *E.M.F.* measured at 0·002 sec. after the polarising current was switched off increased regularly as the current density increased independently of whether the anode and cathode compartments were separated or not, and showed no signs of abnormality.

C.D. (amp./cm.²)	0·004	0·008	0·016	0·032
Direct overvoltage	1·07	1·11	1·15	1·18
Back *E.M.F.* after 0·002 sec.	0·87	0·88	0·90	0·93

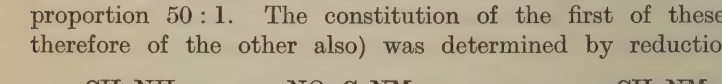
The subsequent rate of fall of the back *E.M.F.* was too great to make extrapolation possible, and so the actual overvoltages can only be inferred from the direct measurements. The decrease of back *E.M.F.*, although rapid, was quite regular in those cases in which the anode and cathode compartments were separated, but when this was not the case a sudden fall of potential was observed after an interval of time had elapsed; first at the higher current densities, and after increasing periods at the lower current densities. It appears therefore that the initial sudden fall of potential observed with the mercury cathode in the presence of dissolved chlorine is connected with the surface tension forces that are operative when the current is flowing, but the subsequent rapid fall after an interval of time is due to another cause.

According to the views expressed in connexion with the abnormal results obtained with the mercury cathode in sulphuric acid containing potassium sulphate, the sudden fall of potential that is observed some time after the polarising current is switched off is apparently due to the diffusion of chlorine through the layer of electrolyte in immediate contact with the electrode. Judging by the difference between the direct and the extrapolated overvoltages this layer should be thinnest at the highest current densities, and consequently under these conditions chlorine will take the least time to diffuse through. By removing the active hydrogen very rapidly, the chlorine causes a sudden fall of potential, which will occur soonest at the high current densities; the two tables given above show that the time which elapses between switching off the current and the commencement of this rapid fall of potential is roughly proportional to the resistance which is the cause of the difference between the direct and the extrapolated overvoltages. Since this rapid fall of potential could not be connected in any way with the material of the electrode or of the cell, but should depend simply on the existence of a diffusion layer, it should occur with other electrodes in hydrochloric acid. Experiments with lead and copper electrodes have shown that this is actually the case, although neither of them showed the very rapid initial fall of the back *E.M.F.* that occurred with the mercury cathode, yet in both

ases there was a sudden fall of potential after a certain interval f time; this interval was shortest at the highest current densities. Where the anode and cathode compartments were separated before he electrolyte had dissolved any chlorine gas this rapid fall of potential was not observed in any case investigated hitherto.

Since both types of abnormal back *E.M.F.* are connected in ome way with the chlorine gas dissolved in the electrolyte, but in ne case the fall takes place almost the instant the current is witched off, whilst in the other only after an appreciable interval f time, it is clear that in the former case the diffusion layer must e extremely thin. This means that the layer of solution containing dissolved chlorine must be almost in direct contact with he mercury at its circumference, since it is considered that it is here that the first rapid removal of active material occurs immediately the current is switched off. It is possible that the forces cting at the electrode–electrolyte interface under the influence of he current cause fresh electrolyte containing dissolved chlorine to e drawn continuously towards the circumference of the electrode, nd so no appreciable time elapses for the chlorine to diffuse in. When the current is off, the surface forces are no longer operative, nd so fresh electrolyte is no longer drawn to the circumference of he mercury, neither is there such a large concentration of active aterial in this vicinity; hence the subsequent fall of potential s not very rapid until chlorine diffuses up to the main portion of he electrode surface.

Summary.



An examination of the difference between the direct and the xtrapolated overvoltages at lead and mercury cathodes in various lectrolytes has led to the conclusion that the thickness of the iffusion layer at an electrode from which gas is being liberated eely decreases as the current density is increased; this is probably ue to the stirring caused by the rapid evolution of bubbles. This iew has been confirmed by an analysis of the abnormal fall in the ack *E.M.F.* of a mercury cathode in a dilute solution of sulphuric cid containing an excess of alkali sulphate, and of various cathodes n *N*-hydrochloric acid saturated with chlorine. In previous work has been found that oxygen diffusing from the anode may influence he initial fall of the back *E.M.F.* of a mercury cathode in a manner hich depends on the material of the electrode vessel and the urrent density; a similar abnormality has been observed as the sult of the diffusion of anodic chlorine towards a mercury cathode n hydrochloric acid solution.

University College, Exeter. [*Received, May 16th*, 1925.]

CCXLIII.—*The* 4- *and* 5-*Nitro*-1 : 2-*Dimethylglyoxaline*

By Vinayak Keshav Bhagwat and Frank Lee Pyman.

In the methylation of 4(5)-nitroglyoxaline (Hazeldine, Pyman, a Winchester, J., 1924, **125**, 1431) and 4(5)-nitro-5(4)-meth glyoxaline (Pyman, J., 1922, **121**, 2616) by methyl sulphate, 3 and 233 times respectively as much of the isomerides wi NO_2 : (*N*)Me in the 5 : 1-positions were isolated as of those wi NO_2 : (*N*)Me in the 4 : 1-positions. Under similar conditio 4(5)-nitro-2-methylglyoxaline (I) yields 5-*nitro*-1 : 2-*dimethylg oxaline* (II) and 4-*nitro*-1 : 2-*dimethylglyoxaline* (III) in the relati proportion 50 : 1. The constitution of the first of these (a therefore of the other also) was determined by reduction a

(I.) (II.) (III.)

fission, as in the investigations cited above, when ammonia, meth amine, and glycine were identified, but here a small quantity of unidentified base, $C_5H_{10}N_2$, was also obtained. On nitrati 1 : 2-dimethylglyoxaline, the 4- and 5-nitro-derivatives w isolated in the relative proportion 2 : 1, this result being similar that obtained by the nitration of 1-methylglyoxaline (Hazeldi Pyman, and Winchester, *loc. cit.*). The 5-nitro-compound gave picrate and is thus a stronger base than the 4-isomeride, from wh no picrate could be prepared. Moreover, the 5-isomeride combi with methyl iodide at 100°, whereas the 4-isomeride does not re with methyl iodide at 100°, although it does so at 150°. T methiodides of the two isomerides are identical, being 4(5)-nit 1 : 2 : 3-trimethylglyoxalinium iodide, which yields on distillat 4-nitro-1 : 2-dimethylglyoxaline. The properties of the isomeri are thus generally similar to those of the 5- and 4-nitro-1-meth glyoxalines.*

The reactivity of the 2-methyl group in these compounds b been examined. Since the bromine atom in 2-bromo-5-nit 1 : 4-dimethylglyoxaline can be replaced by the sulphonic a residue (Pyman and Timmis, J., 1923, **123**, 494), it was thou that 5-nitro-1 : 2-dimethylglyoxaline might react with benzaldeh to yield 5-nitro-2-styryl-1-methylglyoxaline under the conditi used by Windaus and Langenbeck (*Ber.*, 1923, **56**, 683) for conve ing 4(5)-nitro-5(4)-methylglyoxaline into 4(5)-nitro-5(4)-styrylg

* It is shown in the experimental part that the behaviour of the pai isomerides 4(and 5)-nitro-1 : 5(and 1 : 4)-dimethylglyoxalines is similar.

oxaline, but neither 4- nor 5-nitro-1 : 2-dimethylglyoxaline reacted with benzaldehyde, and the result calls to mind an unsuccessful attempt to condense 2-methylglyoxaline-4(5)-sulphonic acid with benzaldehyde (Forsyth, Moore, and Pyman, J., 1924, **125**, 919).

5(4)-Bromo-4(5)-nitro-2-methylglyoxaline (IV) is very easily converted into the ammonium salt of 4(5)-*nitro*-5(4)-*thiol*-2-*methylglyoxaline* (V) by means of ammonium sulphide.

Experimental.

The 4- *and* 5-*Nitro*-1 : 2-*dimethylglyoxalines.*

(A) *Preparation by Nitration of* 1 : 2-*Dimethylglyoxaline.*—Concentrated sulphuric acid (6 c.c.) was added to 1 : 2-dimethylglyoxaline (3 g.) in nitric acid (6 c.c.; *d* 1·4) at 0°, the product heated for 4 hours at 100°, cooled, and aqueous sodium hydroxide added, when nearly pure 4-nitro-1 : 2-dimethylglyoxaline (0·5 g.) separated. Chloroform extracted from the filtrate a mixture of bases which was separated by ether into sparingly soluble and readily soluble fractions (0·9 and 2·0 g.), the latter consisting largely of 1 : 2-dimethylglyoxaline. After fractional crystallisation as picrate or base, there were isolated in almost pure condition 4-nitro-1 : 2-dimethylglyoxaline (yield 20% *), 5-nitro-1 : 2-dimethylglyoxaline (yield 10%), and unchanged 1 : 2-dimethylglyoxaline (yield 22%).

(B) *Preparation by Methylation of* 4(5)-*Nitro*-2-*methylglyoxaline.*—4(5)-Nitro-2-methylglyoxaline (20 g.) and methyl sulphate (16 c.c.) were heated for 1 hour at 100°, and the products worked up as in analogous cases described previously (*e.g.*, J., 1922, **121**, 2616), when 2·0 g. of 4(5)-nitro-2-methylglyoxaline were recovered, whilst 5-nitro-1 : 2-dimethylglyoxaline was isolated as picrate (33 g., pure, yield 57%), and 4-nitro-1 : 2-dimethylglyoxaline as base (0·25 g., pure, yield 1·1%).

4-*Nitro*-1 : 2-*dimethylglyoxaline* (III) crystallises from alcohol in glistening needles, m. p. 182—183° (corr.). It is easily soluble in alcohol, somewhat sparingly soluble in cold water, and sparingly soluble in ether (Found: C, 42·4; H, 5·0. $C_5H_7O_2N_3$ requires C, 42·6; H, 5·0%).

The *hydrochloride* is obtained on spontaneous evaporation of a solution of the base in concentrated hydrochloric acid in long needles which on rapid heating sinter at about 175° and melt with

* The compounds described in this paper were colourless, and yields are given in percentage of the theoretical, except where it is stated to the contrary.

effervescence at about 215°. It dissociates on heating at 100° or on treatment with water, giving the base. The base did not yield a picrate.

5-*Nitro*-1 : 2-*dimethylglyoxaline* (II) crystallises from water in long, stout needles, m. p. 138—139° (corr.). It is easily soluble in alcohol, and somewhat sparingly soluble in cold water or ether (Found : C, 42·4; H, 5·1. $C_5H_7O_2N_3$ requires C, 42·6; H, 5·0%). The *hydrochloride* crystallises from dilute hydrochloric acid in large prisms, m. p. 195° (decomp.; corr.) after sintering earlier. It is very easily soluble in water or alcohol, but sparingly soluble in acetone. It is not dissociated by water, and remains unchanged in m. p. after prolonged heating at 100°, but the salt is slowly volatilised. The *picrate* crystallises from water or alcohol in yellow needles, m. p. 162—163° (corr.). It is very sparingly soluble in these solvents when cold (Found : C, 35·8; H, 3·0. $C_5H_7O_2N_3,C_6H_3O_7N_3$ requires C, 35·7; H, 2·7%).

4(5)-*Nitro*-1 : 2 : 3-*trimethylglyoxalinium iodide* is formed on heating methyl iodide with 5-nitro-1 : 2-dimethylglyoxaline at 100° (but not on heating under reflux), or with 4-nitro-1 : 2-dimethylglyoxaline at 150° but not at 100°. It crystallises from alcohol in bright yellow needles, m. p. 195—196° (decomp.; corr.). It is soluble in water and rather less so in cold acetone (Found : I, 44·8. $C_6H_{10}O_2N_3I$ requires I, 44·9%). On heating this salt (3 g.) over a free flame under 33 mm. until distillation began, and crystallising the combined distillate and residue from alcohol, 4-nitro-1 : 2-dimethylglyoxaline (1·0 g., m. p. 179—180°, yield 67%) was obtained.

Attempted Condensations with Benzaldehyde.—Both 4- and 5-nitro-1 : 2-dimethylglyoxalines were recovered to the extent of 90% unchanged after heating 1 g. with benzaldehyde (2 c.c.) and piperidine (0·2 c.c.) for 2 hours at 155—160° under reflux.

Reduction of 5-*Nitro*-1 : 2-*dimethylglyoxaline.*—To a solution of the base (14 g.) in concentrated hydrochloric acid (50 c.c.), a solution of hydrated stannous chloride (68 g.) in concentrated hydrochloric acid (150 c.c.) was added below 10°. After keeping over-night, tin was removed by hydrogen sulphide, when partly crystalline hydrochlorides were obtained. On extraction with absolute alcohol, ammonium chloride (6 g.) remained undissolved; the extract was then added to a solution of picric acid (25 g.) in hot water (1 l.), when picrates were deposited from which after repeated crystallisation from water and alcohol, 1·5 g. of a *picrate*, m. p. 142·5° (corr.), were obtained (Found : C, 39·7, 39·4, 39·1, 39·1; H, 3·7, 4·0, 3·9, 3·8. N, 21·7, 21·7, 21·4. $C_5H_{10}N_2,C_6H_3O_7N_3$ requires C, 40·4; H, 4·0; N, 21·4%). The mother-liquor was extracted with ether to remove

picric acid, and evaporated to dryness, when about 7 g. of partly crystalline hydrochlorides were obtained. These were separated by the method used by Hazeldine, Pyman, and Winchester (*loc. cit.*, p. 1435) into ammonium chloride (1·0 g.), crude methylamine hydrochloride (1·6 g. containing 54·0% Cl) and the hydrochloride of glycine ethyl ester (0·8 g., m. p. 136—140°), yielding the pure substance, m. p. 143—144° (corr.; alone or mixed with a synthetic specimen).

4(5)-*Nitro*-5(4)-*thiol*-2-*methylglyoxaline* (V).—Hydrogen sulphide was passed through a warm solution of 5(4)-bromo-4(5)-nitro-2-methylglyoxaline (2 g.) in 5*N*-ammonia (15 c.c.) for $\frac{1}{4}$ hour, when the *ammonium* salt of 4(5)-nitro-5(4)-thiol-2-methylglyoxaline separated in deep yellow prisms * (1·7 g., yield almost theoretical). It is readily recrystallised from water, and both the crude and the purified material darken from 190°, being quite black by 210° (corr.). This salt is anhydrous, and yields ammonia when boiled with aqueous sodium hydroxide (Found: C, 27·6; H, 5·0; N, 31·9; S, 18·3. $C_4H_8O_2N_4S$ requires C, 27·3; H, 4·5; N, 31·8; S, 18·2%). On rendering its aqueous solution faintly acid with hydrochloric acid, 4(5)-*nitro*-5(4)-*thiol*-2-*methylglyoxaline* is obtained as a yellow, crystalline precipitate, m. p. *ca.* 260° (corr.; decomp.) crude or after crystallisation from alcohol (Found: C, 30·3, 29·8; H, 3·5, 3·2. $C_4H_5O_2N_3S$ requires C, 30·2; H, 3·1%). It is sparingly soluble in alcohol or hot water, and readily soluble in alkalis, ammonia, and sodium carbonate, giving bright yellow solutions, whilst sodium hydroxide gives an orange-yellow solution, which reddens on keeping. It dissolves in 5*N*-hydrochloric acid, but the solution soon deposits pale buff crystals of the hydrochloride, m. p. *ca.* 260° (corr.; decomp.), which dissociate on treatment with water.

4(5)-*Nitro*-1 : 3 : 5(4)-*trimethylglyoxalinium iodide* is formed on heating methyl iodide with 5-nitro-1 : 4-dimethylglyoxaline under reflux or with 4-nitro-1 : 5-dimethylglyoxaline at 100° (but not under reflux). It crystallises from acetone in bright yellow, prismatic needles, m. p. (of material dried at 100°) 134—135° (corr.), and is readily soluble in water or alcohol, but sparingly soluble in cold acetone (Found: loss in a vacuum, 2·9. $C_6H_{10}O_2N_3I,\frac{1}{2}H_2O$ requires H_2O, 3·1. Found, in dried salt: I, 44·9. $C_6H_{10}O_2N_3I$ requires I, 44·9%). After heating the air-dried salt (6 g.) under diminished pressure until all methyl iodide was removed, and crystallising the residue from water, 4-nitro-1 : 5-dimethylglyoxaline (2·42 g., pure, yield 83%) was obtained, whilst the mother-liquors, after being mixed with picric acid and seeded with 5-nitro-1 : 4-dimethylglyoxaline picrate, deposited a minute quantity of a crystal-

* The formation of crystals in this way was first observed by Mr. L. Light, B.Sc.Tech.

line picrate. 4-Nitro-1 : 5-dimethylglyoxaline dissolves in concentrated hydrochloric acid, but after spontaneous evaporation in the air the base remains. On adding water to the solution of the base in concentrated hydrochloric acid, the base is precipitated.

5-*Nitro*-1 : 4-*dimethylglyoxaline hydrochloride* crystallises from dilute hydrochloric acid in prisms, which, after drying at 100°, melt and decompose at 188° (corr.). It slowly volatilises at 100°. After evaporation with water it can be recovered unchanged.

One of us (V. K. B.) desires to thank the University of Bombay for a Sir Mangaldas Nathubai Technical Scholarship which has enabled him to take part in the investigation.

CCXLIV.—*Some Physical Properties of Aniline and its Aqueous Solutions.*

By MALCOLM PERCIVAL APPLEBEY and PERCIVAL GLYN DAVIES.

IN the course of work on the osmotic properties of aniline solutions (see following paper) the authors have had occasion to prepare this liquid in a pure condition and to make some measurements of its principal properties, as well as to investigate the effect of water upon those properties.

The aniline, purified from thiophen compounds by the method of Hantzsch and Freese (*Ber.*, 1894, **27**, 3), was finally dried over solid potash and fractionated in an apparatus shielded from atmospheric moisture and carbon dioxide by soda-lime tubes. It showed no brown colour, but had a bright blue fluorescence and boiled well within half a degree. The fluorescence disappeared in the course of a few days, even when the liquid was kept in closed brown stoppered bottles in a desiccator in a dark cupboard.

The physical properties of purified aniline have been measured by Timmermans (*Proc. Roy. Soc. Dublin*, 1912, **13**, 326), Knowles (*J. Ind. Eng. Chem.*, 1920, **12**, 881), Schwers (*J. Chim. Phys.*, 1911, **9**, 15), and Tyrer (J., 1911, **99**, 872; 1912, **101**, 84). Their values are compared with ours in the following table :—

	Applebey and Davies.	Timmermans.	Knowles.	Schwers.	Tyrer.
F. p.	−5·98°	−6·2°	−6·24°	—	—
B. p.	184° (appx.)	184·40°	184·32—184·39°	—	—
$d_4^{t°}$	1·02315 (20°)	1·03909 (0°)	1·0268 (15°)	1·02479 (17·6°)	1·02840 (12·87°) 1·02225 (21·89°)
$n_D^{20°}$	1·58685	—	1·5850	—	—

The freezing points recorded by other workers are in each case lower than that observed by us. The differences are in our opinion due in all probability to the care we have taken to exclude water. Aniline, like many other organic liquids, takes up small quantities of water with extreme avidity. Our value for the freezing point is confirmed by the work of Ampola (*Gazzetta*, 1895, **27**, i, 35), who obtained — 5·96°, and our value for the refractive index is somewhat supported by the determinations of Brühl and Weegman (compare Landolt-Börnstein, "Tabellen"), both of whom obtained values of $n_D^{20°}$ considerably higher than that of Knowles. The lower freezing point recorded by Knowles would correspond to about 0·1% of water, the refractive index to about 0·7%, assuming the values now obtained to be the correct ones. The various values recorded in the above table for the relative density, though they differ considerably among themselves, lie upon a fairly smooth curve when plotted against the temperature of determination. This is not surprising, since the relative density, while much affected by changes of temperature, is hardly altered by the addition of water as will be shown later.

Density.—Density measurements were made in pyknometers of about 10 c.c. capacity, weighed against sealed counterpoises in the manner described by Hartley and Barrett (J., 1911, **99**, 1072). The pyknometers were filled by slow suction so as to avoid air bubbles, any filling which showed signs of air bubbles or dust being discarded. The filling with aniline occupied about 15 minutes, so that the possibility of absorption of water vapour from the air during filling had to be considered. By filling at rates varying from 10 to 40 minutes, however, no variation of density of the same sample could be detected. It may therefore be assumed that the water absorbed in this time has a negligible effect on the density. Further, careful determinations with a specific gravity bottle, which can be filled much more quickly, gave results in close agreement with the pyknometer determinations. The value obtained for pure aniline was $d_{20°}^{20°} = 1·02315$ or $d_{4°}^{20°} = 1·02136$.

The density of a saturated solution of water in aniline at 20° was found to be $d_{20°}^{20°} = 1·02393$. (The solution used for this determination was prepared in a thermostat, left to settle for several days, and kept at 25° during filling in order to avoid separation of phases.) Thus about 5% of water produces a density-change of only 0·00078.

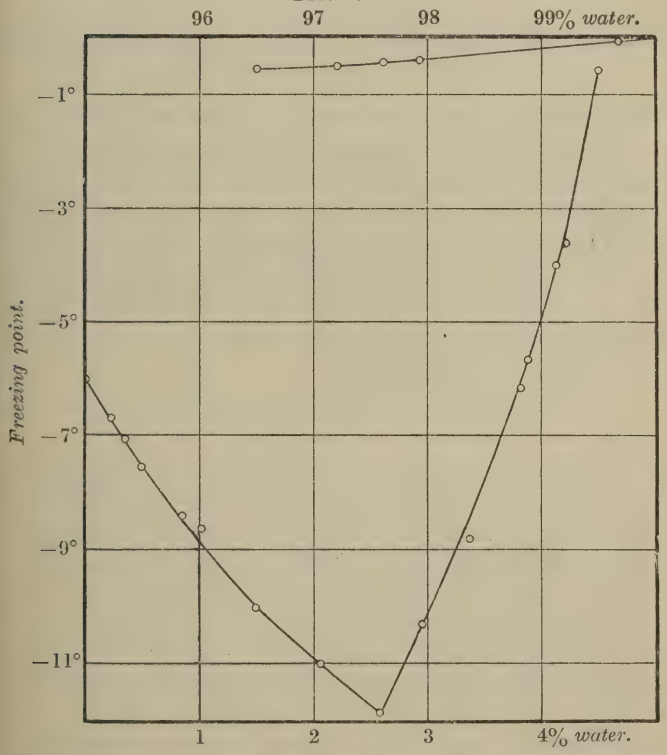
Refractive Index.—The refractive indices of pure aniline and of some solutions were determined for sodium light by means of a Pulfrich instrument. The liquids were warmed to about 25° and determinations were made during subsequent cooling. The refrac-

tive indices at 20° were read off the resulting refractive index-temperature curves. These curves were all nearly linear, the temperature coefficient in each case being very near to — 0·00030 per degree.

% Water	0·0	1·0484	2·1232	3·0571
$n_D^{20°}$ obs.	1·58685	1·58396	1·58114	1·57861
$n_D^{20°}$ calc.	—	1·58402	1·58112	1·57860

The refractive index is a linear function of the percentage composition, as is seen from the last column, which is calculated from the equation $n_D^{20°} = 1{\cdot}58685 - 0{\cdot}00270p$, where p is the percentage of water. The change of refractive index with composition is, however, quite small.

Viscosity.—The viscosities of aniline and of some solutions were measured in three viscosimeters. One, which had a time of flow of about 60 minutes with pure aniline, had been standardised by the method previously described by one of us (J., 1910, **97**, 2000) and found to obey Poiseuille's law accurately. The others, which had times of flow of 45 and 15 minutes respectively, gave the same values for the ratio Time of flow for aniline/Time of flow for water as the standard instrument and therefore were in accord with Poiseuille's law. Using freshly distilled aniline for each determination, values for the time ratio were found varying about a mean value of 4·309. Using Thorpe and Rodger's value for the viscosity of water at 20°, this gives the absolute viscosity of aniline as 0·04468, a value almost identical with that obtained by Poiseuille (0·04467) but considerably higher than the later determinations by Faust (0·433 at 18°) (*Z. physikal. Chem.*, 1912, **79**, 99). No great weight can, however, be attached to these determinations, since it was found that the viscosity of pure aniline is not a constant quantity. The variability of the results obtained and the fact, which further investigation brought to light, that freshly distilled aniline suffers appreciable change in viscosity when kept, even when it is stored in a desiccator in the dark, show that some change takes place after distillation. As an example, aniline kept for a week after distillation had a viscosity of 0·04439, nearly 1% less than that of the freshly distilled sample. The change was not due to absorption of water, since the freezing point showed no depression. The aniline was still fluorescent, though it should be noted that the action of light does produce a further slight change of viscosity.



The viscosities of two solutions were measured; they were made up with freshly distilled aniline and gave the following results :—

% Water	0·227	0·344
$\eta^{20°}$	0·0441	0·0438

Freezing Points.—The freezing points were measured in a Beckmann apparatus. The temperatures were in each case determined with different amounts of supercooling, and the accurate freezing points (with no supercooling) estimated from the resulting curve.

% Water.	F. p.	% Water.	F. p.
0	— 5·980°	3·372	—8·80°
0·227	— 6·675	3·820	—6·15
0·344	— 7·050	3·880	—5·65
0·489	— 7·550	4·127	—4·00
0·848	— 8·400	4·219	—3·60
1·015	— 8·625	(congruent	
1·490	—10·000	solutions)	—0·60
2·059	—11·000	97·203	—0·50
2·575 (eutectic)	—11·85	97·608	—0·43
2·952	—10·30	97·928	—0·38

FIG. 1.

The results are plotted in Fig. 1. It will be seen that the eutectic is on the aniline side, the solid separating from solutions containing more than 2·575% of water being ice. The determinations on the ice side of the eutectic were confirmed and extended by Miss E. M. O. Tarrow, to whom our best thanks are due. They are necessarily

somewhat uncertain, since in this region a small separation of soli brings about a relatively large change of concentration.

Taking 58·7 as the cryoscopic constant for aniline (Ampola Rimatori, *Gazzetta*, 1897, **27**A, 35), the calculated molecular weigh of water rises from 22·9 in very dilute solution to 25·1 in a solutio in the neighbourhood of the eutectic. There is thus clear evidenc of association of water in aniline solution. The freezing points c the dilute solutions of aniline in water also indicate association c the solute, the molecular weight calculated being about 105 instea of 93.

CCXLV.—*Osmotic Pressure by the Solubility Method in Concentrated Solutions.*

By MALCOLM PERCIVAL APPLEBEY and PERCIVAL GLYN DAVIES

THE changes which are produced in the solubility relations of tw partially miscible liquids when a solute is added which is solubl in only one of the liquids have been studied by Nernst and others Nernst has shown that, when the quantities of solute added are s small as to enable the dilute solution relations to be used, th lowering of solubility of the solvent A (which dissolves the solute in the second solvent B is an osmotic property, connected with th osmotic pressure by the relation

$$P = \frac{L - L'}{L'} \cdot \frac{0{\cdot}0819T \,.\, 1000d}{M_0}$$

in which P is the osmotic pressure (through a membrane permeabl to solvent A), L is the solubility of solvent A in solvent B, L' th altered value of L when the solvent A contains the solute, while d and M_0 are the density and molecular weight of solvent A. Th correctness of this expression and its usefulness as a method o molecular-weight determination have been sufficiently proved b Nernst's experiments (*Z. physikal. Chem.*, 1890, **6**, 16) and by thos of Tolloczko (*ibid.*, 1896, **20**, 389) and Küster (*Ber.*, 1894, **27**, 324) These experiments, however, throw no light on the behaviour o strong solutions. The osmotic relations of such solutions can a present only be investigated by means of the direct method or by means of vapour-pressure measurements and the application o Porter's relation (*Proc. Roy Soc.*, 1907, A, **79**, 519). Of these the direct method is not only costly, but also is only applicable fo the very limited range of substances for which a suitable membran

an be found. The vapour-pressure method, on the other hand, is borious and also requires for the solution of the integral terms of orter's equation far more information as to the specific volumes nd compressibilities of solution, solvent, and vapour than is sually available. It therefore seemed worth while to investigate he phenomenon of solubility lowering in strong solutions in the ope of opening up another way of approach to the osmotic relations strong solutions.

The osmotic behaviour of sucrose in aqueous solution has been much more thoroughly studied than that of any other substance hat any experiments on other osmotic properties must begin with his system. The problem of choice of materials accordingly resolves self into finding a second solvent which can be obtained pure, hich dissolves fairly large (and therefore determinable) quantities water and in which sucrose itself is insoluble. The solvent which est fulfils these requirements is aniline, which may be obtained a standard and highly purified condition. It dissolves about % of water at 20° and has no appreciable solvent effect on sucrose. he aniline, which was obtained from Kahlbaum or Merck, was urified in the manner described in the preceding paper. In all ases, however, the aniline was redistilled not more than 3 days efore use. Its purity was frequently tested by determining its eezing point. The freshly distilled aniline froze at $-5{\cdot}98°$; any amples which showed a lower freezing point than $-6{\cdot}1°$ were ried over potash and redistilled.

The water used was twice redistilled from a well-steamed-out ass still and collected in a receiver protected from dust and other mospheric contamination. The sucrose was Kahlbaum's purest roduct, powdered and dried in a sulphuric acid desiccator before use.

The solutions were prepared by stirring weighed quantities of queous solutions of sucrose of known content with measured uantities of aniline in a mercury-sealed stirring bottle of brown ass. The bottle was immersed in a thermostat maintained at $0° \pm 0{\cdot}01°$. The stirring was continued for a day and the solutions ere then left over-night in the thermostat to settle. The aniline hase was removed by means of a dry pipette in experiments where constituted the upper layer, or by a syphon tube when its density as greater than that of the aqueous phase. In the latter case the ifficulty of introducing the syphon without entrapping some of the pper layer was overcome by having the end of the syphon blown ut into a thin closed bulb which could be broken against the ottom of the vessel after the syphon was in position. The solutions ere then centrifuged in a room the temperature of which never iffered by more than a degree from 20°, so as to remove the last

particles of aqueous phase remaining. The method of centrifugin carried out at temperatures differing from the exact experiment temperatures is clearly only permissible when the amount o aqueous phase remaining is negligibly small. It is obvious als that it cannot be used for aniline phases in equilibrium with pur water or very dilute solutions. Other methods have to be use in these cases to obtain complete separation.

Determination of Concentration of Equilibrium Solutions.—It wa hoped that some one of the physical properties of aniline might b sufficiently sensitive to the addition of water to enable the com position of solutions to be estimated by careful measurement o the property. Accordingly the variations of density, refractiv index, viscosity, and freezing point produced by the addition o water were determined. For one cause or another, all thes measurements proved unsuitable. The effect of water on th density and refractive index of aniline is too small; the viscosity i untrustworthy owing to changes occurring with time; and th freezing point is inaccurate as a measure of concentration over th range of the present experiments, since the solid phase separatin consists of the component present in small concentration. Detail of these measurements will be found in the preceding paper.

In these circumstances recourse was had to direct solubilit measurements. Weighed quantities of the solutions, freed fron the aqueous phase by centrifuging, were sealed up in glass tube either alone or with weighed quantities of water added. The tube were shaken in well-stirred water of slowly changing temperature and the temperatures at which turbidity occurred on cooling an disappeared on heating were determined. These temperature differed by not more than 0·2° and the mean was taken to be th temperature of saturation. As there is difficulty in deciding upon a safe criterion of transparency, and as our experience showed tha the results depend to a certain extent upon the conditions of lightin of the tubes, it was thought advisable first to construct a solubilit curve by measuring the temperatures of saturation of known mixture of aniline and water, and to use this curve in interpreting our result rather than the determinations of Sidgwick, Pickford, and Wilsdo (J., 1911, **99**, 1122). The following results were obtained, t being th temperature of saturation :

% Water	4·534	4·659	4·815	4·926	4·950	5·398	5·899	6·104
$t°$	15·9	18·3	20·5	21·15	22·6	34·1	43·5	47·5

A smoothed curve was drawn representing these measurements and used in the subsequent determinations. The saturated solution at 20° from the curve appears to contain 4·835% of water, whereas

idgwick, Pickford, and Wilsdon give 5·123%. The discrepancy ıay be due in part to difference in the aniline used, but is more robably to be ascribed to differences in the conditions of deter- ıining the saturation temperatures. It is of no great moment for ur purpose, as only comparative measurements are in question. .s an example of the consistency of the results obtained in measuring ıe amount of water in the equilibrium solutions, details are given f the analysis of the aniline phase in equilibrium with a solution f 420 g. of sucrose in 1000 g. of solution.

Wt. of solution (g.).	Water added (g.).	Temp. of satn.	% Water in original soln.
—*	0·0	9·5°	4·57
2·1163	0·0241	39·9	4·53
1·6367	0·0098	27·8	4·56
			Mean 4·55

* The solution in this experiment was not weighed and the temperature as determined in an open tube. The agreement with the other experiments ıows that losses during sealing are of no importance.

The method was also tested on two occasions by shaking pure ıiline and water in the thermostat at 20°, allowing to stand in ıe thermostat for a fortnight (the method of centrifuging cannot e used in this case), and determining the temperature of saturation f the aniline layer in unsealed bulbs. The two experiments gave 0·2° and 20·5°, temperatures sufficiently near to 20° to show that ıe method was satisfactory; if complete separation by centrifuging ad been possible, no doubt an even better agreement could have een obtained.

The equilibrium experiments are summarised in the following ıble :

Conc. of sugar soln.		Conc. of water.		Osmotic press. (atm.).		
g./1000 g. of solution.	g./litre.	g./g. of solution.	Mol. fraction.	From Nernst.	Detd.	Calc.
0	0	0·04835	0·2078	—	7·4	5
300	348·1	0·0466	0·2016	50	40	43
420	498·4	0·0455	0·1976	83	69	67
540	676·1	0·0439	0·1917	135	119	103
660	872·8	0·0407	0·1797	250	218	180

'he values for the osmotic pressures in the sixth column are derived ·om the determinations of Berkeley and Hartley (*Phil. Trans.*, 906, **206**, A, 481; 1919, **218**, A, 344), allowance being made for he difference of temperature and for the presence of aniline in he aqueous phase.

It will be noted that the Nernst dilute solution formula soon egins to diverge from the experimental values when the concen- ration becomes fairly large. In the following pages an attempt is

made to relate the solubility lowering to the osmotic pressure solutions outside the range of the dilute solution law.

Since the two solutions, of sugar in water and of water in aniline are in equilibrium, they must have the same osmotic pressure through a membrane permeable to water. Now the aniline phase is an extremely concentrated solution of aniline in water of the osmotic pressure of which we know nothing. There is, however an exact relation between the osmotic pressure of a solution measured by a membrane permeable to one of its constituents and the conjugate osmotic pressure measured by a membrane permeable to the other constituent. This relation, deduced by Berkeley and Burton (*Phil. Mag.*, 1909, **17**, 598), takes the form of a differential equation

$$\frac{dP_1}{dc_2} = \frac{c_2 u_2}{c_1 u_1} \frac{dP_2}{dc_1},$$

in which P_1 = ordinary osmotic pressure–water membrane; P_2 = conjugate osmotic pressure–aniline membrane; c_1 = g. of solvent (water) per g. of solution; c_2 = g. of solute (aniline) per g. of solution; u_1 and u_2 = specific volumes of solvent and solute respectively.

Now the solutions in question, though they are concentrated solutions of aniline in water, are dilute solutions of water in aniline and it might therefore be supposed that they would obey the dilute solution law $P_2 = RTc_1$ and therefore $dP_2/dc_1 = RT$, in which case Berkeley and Burton's expression can be integrated, giving

$$P_1 = -RT\frac{u_2}{u_1}(\log c_1 + c_2),$$

the constant of integration being zero, since $P_1 = 0$ when $c_2 = 0$ and $c_1 = 1$. This method of interpreting the solubility results was suggested to us by the late Dr. C. V. Burton, and gives at once a value for the osmotic pressures of the sugar solutions. Unfortunately, however, the calculations give results which are widely at variance with the known osmotic pressures of these solutions, and the only conclusion which can be drawn is that the assumption that the conjugate osmotic pressures obey the dilute solution law is very far from being true for saturated solutions of water in aniline. The true value of dP_2/dc_1 must in fact be very much less than RT. The same conclusion may be clearly drawn from many experiments on the freezing points of systems consisting of partially miscible liquids. For example, the curves found by Sidgwick and Turner (J., 1922, **121**, 2257) for the temperatures of separation of *o*- and *m*-chlorophenol in presence of increasing quantities of water bend very definitely upward and appear to meet

ıe liquid–liquid line almost horizontally, *i.e.*, with a very small ılue of dT/dc and therefore of dP/dc. The same upward curvature ay be observed in the curve for the separation of solid aniline om aqueous solutions (see preceding paper), but not so clearly this case, since the eutectic intervenes before the curvature has ecome very pronounced.

Although this method of treatment, in the form suggested by urton, has proved inadequate to represent the solubility results, has been found that the application of van Laar's well-known uation for concentrated solutions in place of the dilute solution w gives much more satisfactory results. Assuming that this uation represents the conjugate osmotic pressures, we have $_2 = -RT \log (1 - c_1) + \alpha c_1^2$. Differentiating and substituting the Berkeley–Burton equation,

$$\frac{dP_1}{dc_2} = \frac{c_2 u_2}{c_1 u_1}\left(\frac{RT}{1 - c_1} + 2\alpha c_1\right)$$

hich, since $c_2 = 1 - c_1$, becomes

$$\frac{dP_1}{dc_2} = \frac{u_2}{u_1}\left(\frac{RT}{1 - c_2} + 2\alpha c_2\right),$$

ı expression which on integration gives

$$P_1 = u_2/u_1(-RT \log \overline{1 - c_2} + \alpha c_2^2).$$

he integration constant is again zero.)

This expression is not without interest, since it shows that if the dinary osmotic pressure of a solution can be represented by van aar's expression, so also can the conjugate osmotic pressure, and ith the same value for the constant α, which according to van Laar connected with the mutual attraction of solvent and solute.*

* Mr. D. L. Chapman has pointed out to us that the argument may be ıt more generally thus. If the product of the osmotic pressure of a solution ıd the specific volume of the solvent is a function $f(c)$ of its concentration, en the equation of Berkeley and Burton may be written $(1 - c)\frac{df(c)}{dc} = \frac{f(1 - c)}{d(1 - c)}$, where c is written for c_2 and $1 - c$ for c_1. This is a differential uation which has many solutions, of which, however, the only simple ones e $f(c) = k \cdot \log (1 - c)$ and $f(c) = k'c^2$, k and k' being constants. Putting $= -RT$ in the first solution, we have van Laar's equation $P = -RT \log (1-c)$, duced thermodynamically; taking both solutions together and putting $= \alpha$, we have van Laar's second expression $P = -RT \log (1 - c) + \alpha c^2$, which the second term had a somewhat empirical basis. It is of some portance that this second term is now shown to be a solution of the thermo- namic equation of Berkeley and Burton. We may note also that the lute solution law $P = RTc$ does not satisfy the requirements of this method deduction, and this law accordingly has no validity except as an approxima- on to the true law in conditions of extreme dilution.

The application of the new integration to the foregoing solubili results can only be performed in a somewhat approximate manne since the evaluation of the constant α requires a systematic stud of the osmotic pressures of aniline solutions. A preliminary valu for α can, however, be obtained by assuming the correctness of th osmotic pressure of a saturated solution of water in aniline, whic was calculated (from the lowering of the freezing point) by th usual formulæ as 7·4 atmospheres. The value of R in the expressio is not the usual value, since concentrations are expressed in gram per gram of solution, but may be obtained by assuming that $N/1000$-solution has an osmotic pressure of 0·0224 atm. at 0°; fo such a solution the α term is negligible. With the values thu obtained, *viz.*, $R = 4{\cdot}76$, and $\alpha = 4661$, the values tabulated i the last column of the table were obtained. It will be seen tha the agreement with the direct determinations of Berkeley an Hartley is fairly satisfactory up to a concentration of 420 g. pe 1000 g. of solution, but considerable divergence occurs at high concentrations. Better agreement can be obtained by adjustment o the constants, but since in any case the osmotic pressure is given a the rather small difference of two large terms, such adjustments hav no value except in providing what then becomes a purely empiric equation to express the results.

For the practical determination of osmotic pressures in con centrated solutions the solubility method is not yet capable of givin direct results accurately, though the van Laar integration is a ste towards that end. On the other hand, comparative results ma be obtained without undue experimental difficulty. By findin the percentage of water in the aniline phase in equilibrium with solution of unknown osmotic pressure and reading off from ou results the concentration of the sucrose solution which is in equil brium with the same aniline solution we may at once equate th osmotic pressure of the unknown solution to that of the sucros solution. The method is of course only applicable to solutions o substances the solubility of which in aniline is very slight.

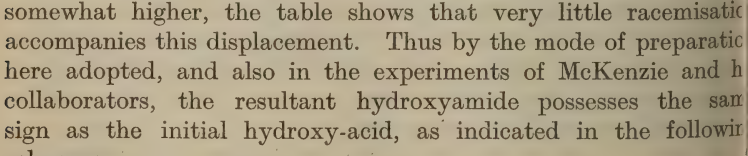
CXLVI.—*Studies on the Walden Inversion. Part IX. The Influence of the Solvent on the Sign of the Product in the Conversion of β-Bromo-β-phenylpropionic Acids into β-Hydroxy-β-phenylpropionamides.*

By George Senter and Allan Miles Ward.

the reaction between concentrated aqueous ammonia and bromo-β-phenylpropionic acid, no β-amino-β-phenylpropionic acid obtained, but the products consist of β-hydroxy-β-phenylopionamide, styrene, ammonium bromide, and ammonium rbonate (Posner, *Ber.*, 1905, **38**, 2316). The yield of β-hydroxyphenylpropionamide is, however, not good, but is the better the gher the concentration of ammonia employed. These results ould lead to the view that this reaction proceeds *via* the correonding lactone, thus :

In the present experiments the reaction of ammonia in ethyl cohol, in acetonitrile, and also of liquid ammonia with *r*-β-bromophenylpropionic acid have been investigated, and in each case e hydroxyamide (III) was produced, together with styrene, but no amino-β-phenylpropionic acid was isolated. These reactions in n-aqueous solvents are in accordance with the mechanism given ove. The reaction of β-bromo-β-phenylpropionic acid with mmonia in dry ethereal solution yields a precipitate of (I), and is appears to be the first salt of this acid to be isolated. It is ry unstable, dissolving in water to a clear solution, shortly llowed by a pronounced turbidity due to the production of styrene, d decomposing fairly rapidly in the dry state at room temperature, t the lactone (II) could not be isolated from the products of dry composition. The *diethylammonium* salt underwent similar composition, but with greater ease.



In spite of the failure to isolate the lactone, the mechanism suming its intermediate formation still seems probable from the actions of β-bromo-β-phenylpropionic acid, and also from the haviour of related substances. The view that β-phenyl-β-opionolactone has a transitory existence was first put forward by lenmeyer (*Ber.*, 1880, **13**, 305) to account for the observation of

Fittig (*Annalen*, 1879, **195**, 131) that β-bromo-β-phenylpropio acid reacting with aqueous sodium carbonate yields styrene almo quantitatively. The lactones of all three β-bromo-β-mononitr phenylpropionic acids have been prepared as stable crystalline soli (Einhorn, *Ber.*, 1883, **16**, 2208; Basler, *ibid.*, p. 3001; Prausnit *ibid.*, 1884, **17**, 595). The products of decomposition of these lacton by heat, and also by reaction with ammonia, are of the same typ as those obtained from β-bromo-β-phenylpropionic acid, the on differences being in the relative proportions of the products.

Not only did liquid ammonia, ethyl-alcoholic ammonia, acet nitrile ammonia and aqueous ammonia solutions yield the hydrox amide in each case from the *r*-bromo-acid, but with an optical active bromo-acid as initial material, the hydroxyamide produc by reaction in the above solvents was opposite in sign to the brom acid used, as shown in the following table:

Solvent.	[α] of bromo-acid.	α of amide.	[α] of amic
Liquid ammonia	+74·6°	−1·88°	−27·5°
Ethyl alcohol	−75·1	+1·35	+24·3
Acetonitrile	+81·7	−1·93	−28·2
Water	−85·0	+1·68	+27·8

d-β-Hydroxy-β-phenylpropionamide with [α] + 38·4° in ethy alcoholic solution has been prepared by McKenzie, Rule, ar Martin (J., 1914, **105**, 1588) by the esterification of *d*-β-hydrox β-phenylpropionic acid, followed by reaction with ammoni whilst the *l*-isomeride with [α] − 39·5° was similarly prepared b McKenzie and Smith (J., 1922, **121**, 1359). β-Bromo-β-pheny propionic acid has not been prepared in a state of optical purit McKenzie and Humphries (J., 1910, **97**, 121) obtained an ac with $[\alpha]_D$ + 96·2° by recrystallisation of a bromo-acid with [α + 32·2° from chloroform, whilst in the present experiments an ac with $[\alpha]^{13°}$ + 110° for $c = 1·079$, $l = 2$, was obtained as a final cr by fractional precipitation of the bromo-acid from chlorofor solution by means of ligroin (b. p. 40—60°). This acid being take as optically pure, although possibly the activity of the pure acid somewhat higher, the table shows that very little racemisatio accompanies this displacement. Thus by the mode of preparatio here adopted, and also in the experiments of McKenzie and h collaborators, the resultant hydroxyamide possesses the sam sign as the initial hydroxy-acid, as indicated in the followi scheme:

Walden inversion is not here detected by solvent variation, and e only examples yet obtained of either isomeride being produced preponderating amount by solvent variation alone is in the single stance in which phenyl and carboxyl are both attached to the ymmetric carbon atom.

Experimental.

β-Bromo-β-phenylpropionic Acids.—The inactive acid was prepared by Senter and Ward (J., 1924, **125**, 2137), and the active bromo-ids by the conversion of *d*- and *l*-β-hydroxy-β-phenylpropionic ids with hydrogen bromide in glacial acetic acid at 25°, followed y one recrystallisation of the product from chloroform.

Ammonium β-Bromo-β-phenylpropionate.—To 25 c.c. of dry ether reviously saturated with ammonia, 2 g. of finely powdered β-bromo-phenylpropionic acid were added, and shaken for a few minutes. he solid was washed with dry ether and rapidly dried over con-ntrated sulphuric acid. The bromine was estimated by heating weighed sample with aqueous sodium carbonate until styrene as expelled, followed by precipitation as silver bromide (Found : r, 32·1. $C_9H_{12}O_2NBr$ requires Br, 32·5%). This salt undergoes irly rapid decomposition in the dry state at room temperature, and pid decomposition without melting at 60°, the products being mmonium bromide, carbon dioxide, styrene, and a small amount cinnamic acid.

Diethylammonium β-bromo-β-phenylpropionate was prepared by lding diethylamine (1 mol.) to the bromo-acid (1 mol.) in ethereal lution (2—3%), when white, compact crystals soon commenced to parate. The salt was isolated after 15 minutes as in the case of e ammonium salt, and the bromine estimated in the same way ound : Br, 26·6. $C_{13}H_{20}O_2NBr$ requires Br, 26·5%). This salt osely resembles the ammonium salt in properties, but is even more nstable, the temperature of rapid decomposition in the dry state ing 44—45°.

Conversion of β-Bromo-β-phenylpropionic Acids into β-Hydroxy-phenylpropionamides.—The reactions were first carried out with e *r*-bromo-acid, and as in each case β-hydroxy-β-phenylpropion-mide resulted (m. p. 121—122°), together with styrene and mmonium bromide as main products, these experiments are not scribed. The method of experiment with the active acids was follows : The solvent was added to the bromo-acid (5 g.), and ter a definite period the solvent was evaporated on the water-bath (except in 1). The residual solid was extracted with dry ether in Soxhlet apparatus for 10 hours, and the ether evaporated; the oduct consisted of crude β-hydroxy-β-phenylpropionamide. The

insoluble residue in the extractor was analysed for bromine in eac case; the results are shown under (*a*), the theoretical value f ammonium bromide being Br, 81·6%. Under (*b*) are given th yield of crude hydroxyamide, the observed rotation, the specif rotation, and the percentage of nitrogen (determined by dire distillation into standard acid of the ammonia evolved on decon position of the amide by heating with excess of aqueous caustic soda In each case the percentage of nitrogen was appreciably lower tha the theoretical (8·5), and the hydroxyamide was markedly acid i reaction. This acidity was removed by shaking a solution of th crude amide in some 125 c.c. of ether with dilute aqueous caust soda until the aqueous layer was alkaline. The ethereal layer wa separated, the alkaline aqueous solution extracted four times wit ether, the ethereal solutions were combined, and the solvent wa evaporated, when the purified amide remained. Its rotation an analysis are given under (*c*). The remaining aqueous solution in a cases yielded on acidification a small precipitate of cinnamic aci All measurements of rotation were made in ethyl-alcoholic solutio in a 2-dcm. tube with the yellow mercury line.

(1) *Liquid ammonia.* Liquid ammonia (50 c.c.) was added to th *d*-bromo-acid with $[\alpha]^{18^\circ} + 74{\cdot}6^\circ$, when a clear solution quick resulted. This was left in the solid carbon dioxide–ether freezin mixture for ½ hour, when considerable solid had separated. Th solvent was then allowed to evaporate.

(*a*) Br, 81·4%.
(*b*) 0·8 g.; $\alpha^{16^\circ} - 1{\cdot}69^\circ$, $c = 3{\cdot}528$; $[\alpha]^{16^\circ} - 24{\cdot}0^\circ$; N, 8·1%.
(*c*) $\alpha^{22{\cdot}5^\circ} - 1{\cdot}88^\circ$, $c = 3{\cdot}422$; $[\alpha]^{22{\cdot}5^\circ} - 27{\cdot}5^\circ$; N, 8·3%.

(2) *Ethyl alcohol.* Ethyl alcohol (75 c.c.) at − 15°, dried b distillation over lime and saturated with ammonia at − 14°, wa added to the *l*-bromo-acid with $[\alpha]^{15^\circ} - 75{\cdot}1^\circ$. The acid rapid dissolved to a clear solution, and the temperature was allowed t rise slowly. At the end of an hour a considerable precipitate o ammonium carbamate had separated. The solvent was evaporate after 3 hours.

(*a*) Br, 77·5%.
(*b*) 1·6 g.; $\alpha^{15^\circ} + 1{\cdot}60^\circ$, $c = 3{\cdot}644$; $[\alpha]^{15^\circ} + 22{\cdot}0^\circ$; N, 7·3%.
(*c*) $\alpha^{20^\circ} + 1{\cdot}35^\circ$, $c = 2{\cdot}776$; $[\alpha]^{20^\circ} + 24{\cdot}3^\circ$; N, 8·2%.

(3) *Acetonitrile.* Acetonitrile (75 c.c.) at − 18°, saturated wit ammonia at − 13°, was added to the *d*-bromo-acid with $[\alpha]^{1}$ $+ 81{\cdot}7^\circ$. The acid dissolved to a clear solution, from which a heav precipitate of ammonium bromide rapidly separated. The tem perature was allowed to rise slowly, and the solvent was evaporate after 3 hours.

) Br, 71·1%.
) 1·4 g.; $\alpha^{16°} - 2·07°$, $c = 3·868$; $[\alpha]^{16°} - 26·8°$; N, 7·8%.
) $\alpha^{24°} - 1·93°$, $c = 3·422$; $[\alpha]^{24°} - 28·2°$; N, 8·6%.

(4) *Water*. Aqueous ammonia (35 c.c.) saturated at − 10° was ded to the *l*-bromo-acid with $[\alpha]^{12°} - 85·0°$, and kept at − 10° r ½ hour. The acid dissolved to a turbid solution and a con-lerable layer of styrene separated. The solvent was evaporated ter 3 hours.

) Br, 75·9%.
) 1·3 g.; $\alpha^{15°} + 1·55°$, $c = 3·322$; $[\alpha]^{15°} + 23·3°$; N, 7·4%.
) $\alpha^{24°} + 1·68°$, $c = 3·028$; $[\alpha]^{24°} + 27·8°$; N, 8·3%.

One of us (A. M. W.) desires to express his indebtedness to the epartment of Scientific and Industrial Research for a maintenance ant during the course of this investigation.

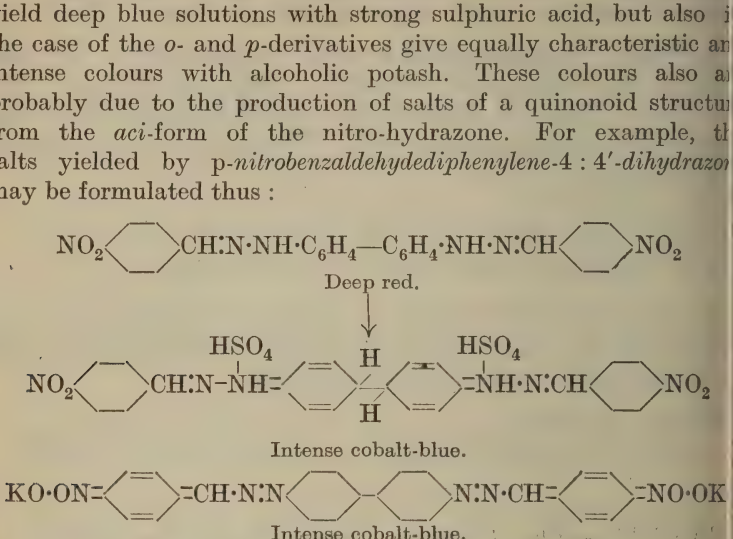
CXLVII.—*The Colours Produced by the Action of Sulphuric Acid upon Some Hydrazones.*

y Frederick Daniel Chattaway, Stanley John Ireland, and Arthur John Walker.



ost hydrazones when dissolved in strong sulphuric acid give loured solutions (Bülow, *Annalen*, 1886, **236**, 194; Pechmann, *er.*, 1893, **26**, 1045; Troeger and Puttkammer, *J. pr. Chem.*, 1908, **3**, 450). These colours are not as a rule very characteristic, or nspicuous, but those given by many of the hydrazones of di-ienylene-4 : 4′-dihydrazine, of *p*-iodophenylhydrazine, and of iodo-2-methylphenylhydrazine are of a peculiarly intense shade cobalt-blue.

These colours are probably due to the formation of salts of a inonoid structure similar to that suggested by Wieland (*Ber.*, 1907, **0**, 4260) to account for the brilliant blue colour produced when tra-*p*-tolylhydrazine is dissolved in sulphuric acid (Chattaway and gle, J., 1895, **67**, 1090). For example, in the case of *benzalde-dediphenylene*-4 : 4′-*dihydrazone*, this salt formation may be repre-nted :

Pale yellow. Intense cobalt-blue.

The *hydrazones* which with *o*, *m*, and *p*-nitrobenzaldehyde for these hydrazines are of special interest, for not only do the yield deep blue solutions with strong sulphuric acid, but also i the case of the *o*- and *p*-derivatives give equally characteristic an intense colours with alcoholic potash. These colours also a probably due to the production of salts of a quinonoid structu from the *aci*-form of the nitro-hydrazone. For example, t salts yielded by p-*nitrobenzaldehydediphenylene*-4 : 4′-*dihydrazo* may be formulated thus :

The nitro-group not being concerned in the production of t salt by sulphuric acid, its position scarcely affects the intensity the character of the colour, all the three isomeric nitrobenzaldehyd hydrazones of diphenylene-4 : 4′-dihydrazine, of *p*-iodopheny hydrazine, and of 4-iodo-2-methylphenylhydrazine giving the san intense cobalt-blue.

In the production of colour by alcoholic potash, however, t nitro-group is involved, and, as with other nitrobenzaldehyd hydrazones, its character depends on the position occupied by th group. Intense colour is produced only by the *o*- and *p*-isomeride these alone yielding salts of the necessary quinonoid configuratio The colour produced follows the rule established for *o*-, *m*-, an *p*-nitrobenzaldehydehydrazones in general (Chattaway and Clem J., 1923, **123**, 3041), that is, the *o*-nitro-hydrazone gives a brig green, the meta- a brown, and the para- an intense blue colour.

It is worth noting that the colours produced by the *p*-nitr benzaldehydehydrazones of these hydrazines with sulphuric ac are practically indistinguishable from the intense blue colours whic they yield with alcoholic potash.

Experimental.

The diphenylene-4 : 4′-dihydrazones (formulæ as I) were prepare by adding a hot acetic acid solution of the appropriate aldehyc

r ketone (2 mols.) to a hot acetic acid solution of diphenylene-
: 4′-dihydrazine (1 mol.). On cooling, the hydrazone separated
s a rule as a microcrystalline powder. Nearly all are so
)aringly soluble in ordinary organic solvents that they cannot
e recrystallised from them. In boiling nitrobenzene, however,
ıey are moderately easily soluble, and separate on cooling in well-
eveloped crystals.

When these hydrazones are added to a large excess of strong
ılphuric acid, intensely coloured solutions are produced. In
)me cases the salts to which the colour is due are comparatively
:able and the colours persist at the ordinary temperature for
)urs or even days with but little change; in others, however,
ecomposition soon occurs and the colour alters in character or
isappears.

After a description of the crystals, the melting point, and the
ıalytical data of the individual hydrazone, the colour produced
ith strong sulphuric acid is given and then the colour produced by
:rong alcoholic potash.

Benzaldehydediphenylene-4 : 4′-*dihydrazone* (I).—Pale yellow
:edles, m. p. 283° (decomp.) (Found : N, 14·6. $C_{26}H_{22}N_4$ requires
, 14·4%). Brilliant cobalt-blue, which slowly fades, leaving after
)me hours only a yellowish-brown liquid. It gives no colour with
coholic potash.

Salicylaldehydediphenylene-4 : 4′-*dihydrazone*.—Pale yellow plates,
. p. 264° (decomp.). Indigo blue, which on warming, or on long
anding becomes green and finally yellow. With alcoholic potash
: gives a brownish-yellow solution.

Anisaldehydediphenylene-4 : 4′-*dihydrazone*.—Pale yellow needles,
. p. 248° (decomp.) (Found : N, 12·4. $C_{28}H_{26}O_2N_4$ requires
., 12·4%). Bright green. With alcoholic potash it gives no
olour.

Cinnamaldehydediphenylene - 4 : 4′ - *dihydrazone*. — Long, yellow
:edles, m. p. 253° (decomp.) (Found : N, 12·6. $C_{30}H_{26}N_4$ requires
., 12·7%). Deep sap-green. With alcoholic potash it yields no
olour.

Acetophenonediphenylene-4 : 4′-*dihydrazone*.—Pale yellow, irregular
jates, m. p. 250° (decomp.). Heliotrope.

Benzophenonediphenylene-4 : 4′-*dihydrazone*.—Yellow plates, m. p.
)5° (decomp.). Brilliant violet, which soon changes on standing
t a dirty, blackish tint.

Pyruvic Acid Diphenylene-4 : 4′-*dihydrazone*.—Yellow, micro-
crystalline powder, m. p. 225° (decomp.). Dark orange-red, which
i a few seconds changes to an intense magenta colour, which
(rkens on standing. Pale yellow solution in alcoholic potash.

o-*Nitrobenzaldehydediphenylene*-4 : 4′-*dihydrazone*.—Dark re needles, appearing almost black by reflected light, m. p. 24 (decomp.) (Found : N, 17·6. $C_{26}H_{20}O_4N_6$ requires N, 17·5% Intense brilliant cobalt-blue indistinguishable in shade from th given by the benzaldehydediphenylenedihydrazone. This colo changes more rapidly than those given by the *m*- and *p*-isomeride and after 15–20 minutes becomes of a greenish or peacock-bl shade, the green shade becoming more marked as time passe until after 1–2 hours the liquid is olive-green, which finally becom yellowish-brown. Deep green solution in warm strong alcohol potash.

m-*Nitrobenzaldehydediphenylene*-4 : 4′-*dihydrazone*.—Compac dark red, octahedral crystals, m. p. 257° (decomp.) (Found : 17·4%). Intense brilliant cobalt-blue solution indistinguishab from that given by its isomerides. The colour changes less readi that than given by its *o*-isomeride, the peacock-blue shade beir developed after about 30 minutes, and changing very little f several hours. Brown solution in alcoholic potash.

p-*Nitrobenzaldehydediphenylene*-4 : 4′-*dihydrazone*.—Deep re slender plates, m. p. 275° (decomp.) (Found : N, 17·65%). Inten blue solution, indistinguishable in shade from that given by its and *m*-isomerides, and by benzaldehydediphenylene-4 : 4′-d hydrazone. It dissolves in alcoholic potash giving a brillia cobalt-blue solution, practically indistinguishable from that give by it and its isomerides with strong sulphuric acid.

Behaviour of the p-*Iodophenylhydrazones with Sulphuric Acid*.—Benzaldehyde-*p*-iodophenylhydrazone dissolves in strong sulphur acid, giving a deep peacock-blue solution. *o*-, *m*-, and *p*-Nitr benzaldehyde-*p*-iodophenylhydrazones when added to stron sulphuric acid give at the moment of contact a yellow or oran colour, which very quickly changes to green, and then again rapid to an intense cobalt-blue, indistinguishable from the colour give by the corresponding diphenylenedihydrazones.

With strong alcoholic potash the benzaldehydehydrazone giv a yellow solution, the *o*-nitrobenzaldehydehydrazone a dee brilliant green, the *m*-nitrobenzaldehydehydrazone a deep cle brown, and the *p*-nitrobenzaldehydehydrazone a brilliant cobal blue, indistinguishable from that given with sulphuric acid.

The o-, m-, and p-*nitrobenzaldehyde*-4-*iodo*-2-*methylpheny hydrazones* behave similarly with strong sulphuric acid. A yello colour momentarily develops, which quickly changes to an inten cobalt-blue. The blue colours are indistinguishable from on another, and from those developed by the corresponding diphenylen dihydrazones.

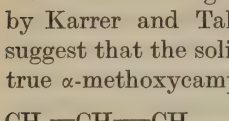
With strong alcoholic potash similarly the *o*-nitrobenzaldehydehydrazone gives a brilliant green colour, the meta- a clear brown, and the para- a brilliant cobalt-blue, indistinguishable from that given with sulphuric acid.

It is worthy of note that the corresponding hydrazones derived from o- and m-*iodophenylhydrazines* give no intense colours with strong sulphuric acid, only yellow or orange-coloured solutions being obtained. With alcoholic potash, the *o*-nitrobenzaldehydehydrazone gives a deep green, and the *p*-nitrobenzaldehydehydrazone a brilliant cobalt-blue solution.

The Queen's College, Oxford. [*Received, July 9th*, 1924.]

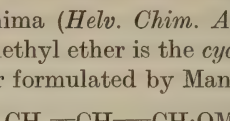
CCXLVIII.—*Studies in the Camphane Series. Part XL. Constitution of Manasse's Hydroxycamphor.*

By Martin Onslow Forster and Prajaram Prabhashanker Shukla.



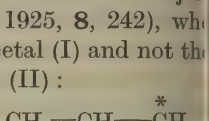
Following his initial description of hydroxycamphor (*Ber.*, 1897, **30**, 659), Manasse further characterised the material formed on reducing camphorquinone (*Ber.*, 1902, **35**, 3811) and claimed to recognise two isomeric substances, indistinguishable in appearance and optical activity; the "α"-modification melted at 203—205° with $[\alpha]_D$ 12·8°, whilst the "β"-modification, produced by hydrolysing the solid methyl ether, melted at 212—213° with $[\alpha]_D$ 12·3°.

It is unfortunate that Manasse denominated his materials in this perplexing manner, because it was already known that replacement of hydrogen in the camphor molecule might occur elsewhere than at the α-position; αβ-dibromocamphor, originally called β-dibromocamphor, was first prepared in 1866 by Swarts and reinvestigated many times after 1881, whilst β-bromocamphor was isolated in 1901. Hence, at the time of publishing his experiments, Manasse might well have been aware that a substance called β-hydroxycamphor would correspond in orientation with β-bromocamphor; confusion with the true β-hydroxycamphor subsequently described (Forster and Howard, J., 1913, **103**, 63) might thus have been avoided.



Manasse supported his belief in the existence of two distinct modifications by the production of two oximes, m. p. 86—87° (α) and 83—84° (β), two phenylhydrazones, m. p. 137·5° (α) and 111—113° (β), two semicarbazones, m. p. 182—183° (α) and 202—204° (β) and two benzenesulphonyl derivatives, m. p. 95—96° (α) and 111—113° (β). Excepting the last-named, however, these pairs might have arisen from a single hydroxycamphor, and in view of the

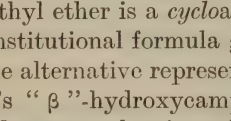
slender distinction between the two parents, one of us (M. O. F.) with Dr. A. Zimmerli began in 1911 an inquiry which was interrupted and could not be resumed until eighteen months ago.

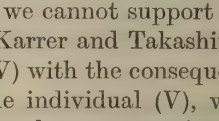


Simultaneous light and shadow have now been cast on the subject by Karrer and Takashima (*Helv. Chim. Acta*, 1925, **8**, 242), who suggest that the solid methyl ether is the *cyclo*acetal (I) and not the true α-methoxycamphor formulated by Manasse (II) :

(I.)

(II.)



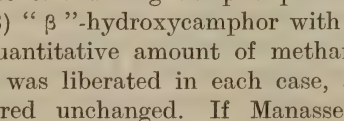


(III.)

Thereupon they propose for Manasse's α-and β-hydroxycamphor the representation (III), ascribing to configuration-change in one of the asterisked carbon atoms the respective divergence in properties.

Our experiments amply confirm the above suggestion that the solid methyl ether is a *cyclo*acetal, but we cannot support the complete constitutional formula given by Karrer and Takashima. We prefer the alternative representation (IV) with the consequence that Manasse's " β "-hydroxycamphor is the individual (V), whilst his " α "-hydroxycamphor is probably that substance associated with a variable amount of the stereoisomeride in which the hydroxyl group and hydrogen atom both occupy the alternate plane.

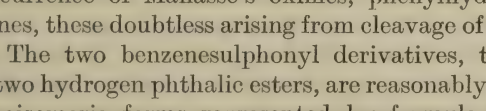
(IV.)



(V.)

With Karrer and Takashima, we agree that the solid methyl ether does not reveal a carbonyl group; we failed to produce an oxime and recovered the substance unchanged by treatment with magnesium methyl iodide. Moreover, on treating separately (1) the crude product of reducing camphorquinone, (2) " α "-hydroxycamphor and (3) " β "-hydroxycamphor with excess of the Grignard agent the quantitative amount of methane required by one hydroxy group was liberated in each case, and the original product was recovered unchanged. If Manasse's hydroxycamphor had the conventional constitution (VI), it could scarcely escape at least partial conversion into the secondary-tertiary diol (VII), in view

(VI.)



(VII.)

of the readiness with which camphorquinone is transformed into the dimethyldiol by magnesium methyl iodide (Forster, J., 1905, **87**, 241).

Our reason for questioning the transference of the hydroxyl group rom the true α-position (in V) to the adjacent carbon atom (in III), s represented by Karrer and Takashima, is the one familiar to all hemists who have closely studied the members of this family, amely, the greatly superior activity of the α-carbon atom to that of ts ketonic neighbour. The comparative behaviour of camphor and f camphorquinone towards aniline, phenylhydrazine, hydroxyl- mine, semicarbazide, nitromethane, ethyl cyanoacetate, and phenyl- cetonitrile may be recalled in this connexion: and finding that Ianasse's hydroxycamphor is readily formed by reducing a cold thereal solution of camphorquinone with aluminium amalgam, we annot believe that in this reaction alone the diketone has belied tself.

Aside from the question of orientation, however, the above iagnosis by Karrer and Takashima has, in our judgment, clarified situation which has been hitherto most obscure, and harmonises /ith the occurrence of Manasse's oximes, phenylhydrazones and emicarbazones, these doubtless arising from cleavage of the ethylene xide-ring. The two benzenesulphonyl derivatives, to which we ave added two hydrogen phthalic esters, are reasonably attributable o the stereoisomeric forms represented by formula V, because, lthough tertiary alcohols do not generally incur the formation of ydrogen phthalic esters, even limited occurrence of the equilibrium,

/ould account for the result observed. Moreover, the irregular ourse of ester-hydrolysis revealed by the polarimeter indicates the peration of concurrent mutarotation in the hydroxycamphor egenerated.

Experimental.

Reduction of Camphorquinone.—(a) Zinc and acetic acid. Cam- horquinone (40 g.) dissolved in hot glacial acetic acid (70 c.c.) /as precipitated by hot water (500 c.c.), and zinc dust (40 g.) added ı small quantities to the continuously shaken suspension. The lear, pale green liquid was heated to coagulate undissolved zinc, ıe filtrate from which was saturated with salt and allowed to cool. [ydroxycamphor was removed by filtration; after treating the ltrate with just sufficient sodium hydroxide (20%) to redissolve ıe zinc hydroxide, more was extracted by ether (three times), in hich the separated portion was then dissolved. Dried with ılcium chloride, the ether was distilled and left a very pale ellow, camphoraceous residue (32·5 g.; yield 80%).

(*b*) *Aluminium amalgam.* Camphorquinone dissolved in undried ether was left in contact with freshly amalgamated aluminium during 12 hours. The colour faded to very pale green, and the decanted liquid with ether-washings having been dried and distilled deposited a colourless residue (yield 85%).

After crystallisation from petroleum the material prepared by each of the above methods melts at 203—205°; the less readily fusible product described by Manasse has been obtained only by hydrolysing the solid methyl ether. This compound crystallises in colourless plates from a solution of the initial product in methyl alcohol containing hydrogen chloride (6%); it melts at 149—150° (Found: MeO, 15·9. Calc., MeO, 17·0%) and has $[\alpha]_D$ 182·8° (1% in chloroform). The methyl ether is not affected by boiling alcoholic potassium hydroxide (10%), but is rapidly hydrolysed by cold hydrochloric acid, from which sodium carbonate precipitates the less readily fusible form of hydroxycamphor; this melts at 215°, and in all other respects is indistinguishable from the material arising directly on reduction of camphorquinone.

The Hydroxyl Value of Hydroxycamphor. —At one time it seemed possible that the peculiar behaviour of hydroxycamphor might be due to its representing the equilibrium mixture,

but this is now precluded by several indications. In the first place, hydroxycamphor in chloroform does not decolorise bromine, and in ether does not develop a coloration with ferric chloride; moreover, the aqueous solution does not give a precipitate with copper acetate, and the methyl ether is equally indifferent to all these agents. When the action of bromine is pressed by heating hydroxycamphor with the halogen in acetic acid which has dissolved sodium acetate, a very slow action occurs; but this leads to camphoric anhydride without any indication of addition or substitution. The same treatment converts the solid methyl ether also into camphoric anhydride, and in both cases a considerable proportion of unchanged hydroxycamphor is recovered, having survived this attack during several hours.

Conclusive evidence against the above possibility, however, was given by the behaviour of hydroxycamphor towards magnesium methyl iodide, from which the quantitative amount of methane for one hydroxyl group was liberated equally by the crude product of reducing camphorquinone and by specimens of hydroxycamphor melting at 203—205° and at 215°, whilst the methyl ether also

remains unaltered by the Grignard agent without liberating methane. These experiments were conducted in phenetole, and appeared remarkable in view of the observations by Bredt-Savelsberg and others (*J. pr. Chem.*, 1924, **107**, 65) relating to enolisation of camphor by the Grignard agent, which may exceed 40%; but they now receive their explanation in the *cyclo*acetal representation of Karrer and Takashima.

The Camphoryl Hydrogen Phthalates.—A mixture of phthalic anhydride and hydroxycamphor (m. p. 215°) in equal weights, and therefore containing a slight molar excess of the anhydride, was heated at 110—120° during 8 hours and kneaded in a solution of sodium carbonate. On extracting the filtered liquid with ether, about 15% of the hydroxycamphor was recovered unchanged, whilst the hydrogen phthalate was precipitated along with phthalic acid by neutralising the solution of sodium salts; it was separated by dissolution in chloroform, which deposited crystals on evaporation. Recrystallisation from benzene–petroleum gave *camphoryl hydrogen phthalate* in rectangular plates, m. p. 164—165° (Found: C, 68·2; H, 6·6. $C_{18}H_{20}O_5$ requires C, 68·3; H, 6·3%). The $[\alpha]_D$ in aqueous alcohol (1 : 1) was 53·7°.

On repeating this operation with hydroxycamphor melting at 203—205°, or with a specimen recovered unchanged by the methylation process, the proportion of unconverted hydroxycamphor was about the same, and the first crop of crystals melted at 152—156°; this was ultimately resolved into a mixture of the foregoing substance with an isomeric *camphoryl hydrogen phthalate* crystallising in slender needles, m. p. 147° (Found: C, 68·1; H, 6·4%). The $[\alpha]_D$ in aqueous alcohol (1 : 1) was 42·2°.

Thus there appear to be two definite hydrogen phthalates, but it has not been possible to decide whether hydrolysis leads to the respective parents. In fact, on following the hydrolysis polarimetrically, there is an indication of the result being an equilibrium system.

A clear solution prepared by mixing equal volumes of alcohol (97·5%) and aqueous potassium hydroxide (20%) was used. When dissolved in this, the higher-melting hydrogen phthalate passed from the initial $[M]_D$ 102·7° to 61·6° during 200 hours, whilst the isomeride changed from $[M]_D$ 55·0° to 64·4°. Intermediate stages were various, however, the higher-melting form having sunk to $[M]_D$ 60·3° when the isomeride was at 98·6° (after 50 hours), and rising again to $[M]_D$ 73·0° when the isomeride had fallen to 78·3° (after 145 hours). These changes are probably due to varying rates of hydrolysis overlapping unequal mutarotation of the resulting hydroxycamphor, because, in the same alcoholic alkali, higher-melting hydroxycamphor

with initial $[M]_D$ 34·2° reaches a maximum of 82·6° in 26 hours and begins to fall after 48 hours, whilst the lower-melting form has initial $[M]_D$ 50·9°, reaches its maximum of 69·0° at about the same time as the other, and then remains constant. The later observations are only approximate because the liquids, although initially colourless, develop a brown tint which increases in depth with passage of time: moreover, the hydroxycamphor recovered from such solutions melts lower and more indefinitely than the original materials.

BANGALORE, S. INDIA. [*Received, June 29th*, 1925.]

CCXLIX.—*A New Synthesis of Arylazoaldoximes.*

By THOMAS KENNEDY WALKER.

THE interaction of aryldiazonium salts and malonic acid does not always produce formazyl compounds; thus Busch and Wolbring (*J. pr. chem.*, 1905, **71**, 366) obtained phenylhydrazones of glyoxylic acid from certain ortho-substituted diazonium salts and *o*-chlorobenzeneazoformaldoxime from diazotised *o*-chloroaniline, and the present author found (J., 1923, **123**, 2775) that the interaction of diazotised *p*-nitroaniline and allylmalonic acid produced a mixture of a formazyl derivative with an acidic substance the instability of which precluded its examination. As it seemed probable that this anomalous behaviour might be due to the presence of adventitious nitrous acid, a study was made of the simultaneous action of an aryldiazonium salt and nitrous acid on monoalkylated malonic acids. This resulted in a new synthesis of arylazoalkylformaldoximes, *e.g.*, *benzeneazobenzylformaldoxime* and *benzeneazoallylformaldoxime*. The course of the reaction is probably as follows,

$$CHR(CO_2H)_2 + N_2Ph\cdot OH \xrightarrow[-H_2O]{-CO_2} CO_2H\cdot CR{:}N\cdot NHPh \xrightarrow{+HNO_2} OH\cdot N{:}CR\cdot N{:}NPh + CO_2 + H_2O,$$

since an almost quantitative yield of benzeneazobenzylformaldoxime was obtained by the action of nitrous acid on the phenylhydrazone of phenylpyruvic acid, whereas no condensation occurred when diazobenzene was brought into contact with its oxime.

EXPERIMENTAL.

Benzeneazobenzylformaldoxime.—(*a*) To a diazo-solution (aniline 1·86 g., glacial acetic acid 6 g., concentrated hydrochloric acid 6 c.c.; sodium nitrite 1·38 g., ice-water 35 c.c.) were added benzyl-

malonic acid (3·8 g. dissolved in a little ice-water), crystalline sodium acetate (10·8 g.), and, 5 minutes later (this condition is essential for successful preparation), a cooled 2% aqueous solution of nitrous acid (1·5 mols.) The mixture was filtered and kept cold for 30 hours, during which carbon dioxide was evolved. A solution of the bulky, spongy, yellow product in dilute aqueous caustic potash was filtered from a small quantity of benzylformazyl. The *oxime*, precipitated by 5% acetic acid, was crystallised from 80% acetic acid (in small, deep yellow needles) and then from benzene (in paler, silky needles) by the addition of light petroleum; m. p. 144° (yield, nearly quantitative) (Found: C, 70·0; H, 5·4; N, 17·8. $C_{14}H_{13}ON_3$ requires C, 70·3; H, 5·43; N, 17·56%). It is easily soluble in ether, alcohol, chloroform, or ethyl acetate. When boiled with moderately dilute hydrochloric acid, it yields phenylacetaldehyde (which is partly oxidised to the acid), hydroxylamine, and benzenediazonium chloride which, as it is formed, is converted into phenol.

(*b*) A solution of ethyl benzylacetoacetate (14·6 g.) in alcohol (120 c.c.) was mixed at −5° with a solution of diazotised aniline (1 mol.) and the requisite quantity of sodium acetate. The product, which separated as a pale red, viscous oil in quantitative yield after 16 hours, was hydrolysed by warming with 10% aqueous alcoholic caustic potash (3 mols.) for 30 minutes and the solution diluted, filtered, and acidified; the phenylpyruvic acid phenylhydrazone, which separated as an oil and solidified, melting at 161° after recrystallisation (Wislicenus, *Ber.*, 1887, **20**, 592). A solution of the hydrazone in alcohol and 80% acetic acid (equal vols.) was filtered at room temperature and treated with finely-powdered sodium nitrite (3 mols. in one lot); evolution of carbon dioxide occurred. After 30 minutes, when the addition of water to a sample ceased to precipitate any of the original acid, the solution was gradually diluted with cold water. The oxime, which separated in yellow needles (yield quantitative) was recrystallised from benzene–light petroleum; it melted at 144°, alone or mixed with the oxime obtained by method (*a*) (Found: C, 69·9; H, 5·6%).

The *phenylcarbamate*, obtained quantitatively in slender, glistening, orange-red prisms by keeping a mixture of the oxime (3 g.) and phenylcarbimide (1·5 g.) in dry ether (40 c.c.) at 0° for 3 hours, crystallised from acetone in large, scarlet prisms, m. p. 154° (Found: N, 15·8. $C_{21}H_{18}O_2N_4$ requires N, 15·6%). The *benzoyl* derivative, prepared from benzoyl chloride (1 mol.) and the potassium salt of the oxime (1 mol.) in ethereal solution, crystallised from acetone in large, elongated, ruby prisms, m. p. 144—145° (frothing).

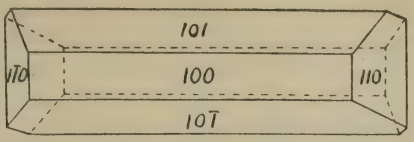
p-*Tolueneazoallylformaldoxime.*—A solution of *p*-toluenediazonium

sulphate (6 g.) in a little ice-water was treated with crystalline sodium acetate (10 g.), followed by a chilled aqueous solution containing allylmalonic acid (4·24 g.) and sodium acetate (7·2 g.). The subsequent addition of nitrous acid and the other operations were carried out as described above under (*a*). The product crystallised from warm benzene in slender, yellow needles, m. p. 93° (shrinking at 90°), and also crystallised well from light petroleum or aqueous alcohol, but not from other solvents. Yield, 25% (Found: C, 65·0; H, 6·5; N, 20·9. $C_{11}H_{13}ON_3$ requires C, 65·0; H, 6·4; N, 20·7%).

Attempts to prepare benzeneazopropaldoxime from ethylmalonic acid by this method resulted only in the production of resinous, uncrystallisable material.

p-*Tolueneazobenzylformaldoxime from Phenylpyruvic Acid* p-*Tolylhydrazone.—Ethyl phenylpyruvate* p-*tolylhydrazone*, obtained in nearly quantitative yield from ethyl benzylacetoacetate and *p*-toluidine by the method used in preparing the corresponding phenylhydrazone, crystallises in glistening, orange prisms, m. p. 72° (Found: N, 9·5. $C_{18}H_{20}O_2N_2$ requires N, 9·46%). It is fairly soluble in cold alcohol, more soluble in cold acetone, and very soluble in hot benzene. On hydrolysis, *phenylpyruvic acid* p-*tolylhydrazone* was obtained, which crystallises from alcohol in slender, yellow, felted needles and from acetone in slender prisms, m. p. 158° (frothing). (Found: C, 71·4; H, 6·1. $C_{16}H_{16}O_2N_2$ requires C, 71·5; H, 6·0%).

A solution of this acid (10 g.) in 50 c.c. of 80% acetic acid and 150 c.c. of alcohol was treated with powdered sodium nitrite (3 mols.) and kept for 30 minutes, after which the product was isolated as described above under (*b*). Successive recrystallisations from benzene and from acetone–light petroleum gave the pure *oxime*, m. p. 144° (slight decomp.). Yield, over 80% (Found: C, 70·0; H, 6·1. $C_{15}H_{15}ON_3$ requires C, 70·1; H, 5·9%).



When light petroleum is added to a dilute solution of this oxime in acetone and the liquid allowed to evaporate slowly, the substance separates in transparent, orange-red crystals. Through the kindness of Sir Henry Miers, F.R.S., it has been possible to obtain measurements of these crystals, and the author takes this opportunity of thanking Mr. G. Greenwood, M.Sc., who kindly undertook the crystallographic examination. His report is as follows:—

Crystal symmetry: Monoclinic holohedral.

Axial constants: $a : b : c = 1{\cdot}352 : 1 : 1{\cdot}216$; $\beta = 83° 17'$.

Forms developed and Habit.—The crystals are usually elongated in the direction of the *b* axis and form prisms often 15 mm. long by

about 1·5 mm. thick (see Fig.). The forms present are {100}, {101}, {10$\bar{1}$}, and {110}.

Crystallographic angles.

Angle.	No. of measurements.	Limits.	Mean obs.	Mean calc.
(100) : (101)	11	44° 9′ —44° 30′	44° 20′	—
(100) : (110)	13	53° 9′ —53° 42′	53° 19′	—
(110) : (10$\bar{1}$)	10	67° 55′—68° 34′	68° 18′	—
(100) : (10$\bar{1}$)	17	51° 43′—52° 5′	51° 50′	51° 46′
(110) : (101)	9	64° 30′—65° 7′	64° 49′	64° 42′

The *phenylcarbamate*, obtained quantitatively by keeping a mixture of the oxime and phenylcarbimide (equal mols.) in much dry ether for 2 hours, is difficultly soluble in the usual organic media, but crystallises from much hot acetone in slender, vivid orange-red prisms, m. p. 152—153° (decomp.) (Found : N, 15·1. $C_{22}H_{20}O_2N_4$ requires N, 15·0%).

Benzeneazobenzaldoxime from Phenylglyoxylic Acid Phenylhydrazone.—Ethyl phenylglyoxalate phenylhydrazone was prepared by the general method described above and hydrolysed. The acid, m. p. 163°, obtained could not be converted into the oxime so smoothly as in the other two cases. It proved necessary to keep the mixture cold, avoid excess of sodium nitrite, and work up the product immediately Yield, about 25%.

This work arose out of a previous investigation undertaken at the suggestion of Prof. A. Lapworth, F.R.S., LL.D., to whom the author has pleasure in acknowledging his indebtedness. The author's thanks are also due to the Department of Scientific and Industrial Research for a grant in aid of the work.

The University, Manchester. [*Received, October 18th*, 1924.]

CCL.—*Angles of Contact and Polarity of Solid Surfaces.*

By Neil K. Adam and Gilbert Jessop.

From Dupré's equation

$$W = T_{SV} + T_{LV} - T_{SL} \quad . \quad . \quad . \quad . \quad . \quad . \quad (1)$$

which relates the free surface energies (surface tensions) at the interfaces of three phases S, V, L, with the work, W, done in separat-

ing S from L across the surface of separation, is combined with the equation of equilibrium of a liquid, L, resting on a solid surface, S, at an angle θ

$$T_{SV} - T_{SL} = T_{LV} \cos\theta \quad . \quad . \quad . \quad . \quad . \quad . \quad (2)$$

we obtain

$$W = T_{LV} \ (1 + \cos\theta) \quad . \quad . \quad . \quad . \quad . \quad . \quad (3)$$

thus eliminating the quantities T_{SL} and T_{SV} which cannot be determined. Equation (3) has been deduced by Pockels (*Physikal. Z.*, 1914, **15**, 39) and Edser (4th Report on Colloid Chemistry, 1922, p. 310), and an equivalent equation is deducible from Laplace's theory of capillarity (Poincaré, " Capillarité," 1895, 35). It appears to have been very little used. W being the adhesion of the liquid for the solid, and $2T_{LV}$ the cohesion of the liquid, equation (3) shows that zero angle of contact indicates an attraction of liquid for solid at least as great as that of liquid for liquid, 90° shows that this adhesion is half the cohesion of the liquid, and 180° would indicate no adhesion. Clearly measurements of angles of contact against water will give a quantitative measure of the polarity of a solid surface.

We have attempted to use the values of W for solid surfaces of long-chain aliphatic compounds as an indication of the orientation of the surface molecules. If many polar groups are at the free surface, the angle of contact should be low; if the surface consists solely of the hydrocarbon ends of the chains, the angle should be approximately the same as for paraffin wax.

In measuring the angle of contact, we have used a plate of the solid, held in an adjustable holder, which could be set at any angle with the surface, and also raised or lowered by rack and pinion. The water was contained in a glass vessel, preferably rectangular with plate glass sides, filled to the brim; the sides were several millimetres thick and were covered with paraffin on the top; the water surface was cleaned as necessary by scraping with strips of paraffined glass. The plate was set by trial at such an angle that the water surface remained horizontal right up to the edge of the plate, this being determined either by inspection from the side, or by observation of the reflexion of a source of light in the water surface very close to the plate. The angle between the plate and the water surface was then measured by a protractor.

These rather crude arrangements were adequate for this work, as the plates varied in angle of contact, in different parts, by several degrees; there would be little difficulty in improving the optical arrangements, but we would point out that it is of little use to employ accurate optical devices in the measurement of angle of contact

less both a proper means of obtaining a freshly cleaned water rface and a means of moving the plate relative to the water rface are provided. If contamination is present to an extent fficient to affect the surface tension of the water, the angle of ntact will be too low; the method of cleaning by *paraffined* rriers working on a fairly wide *paraffined* surface at the level the water has been exhaustively tested in recent work on thin ms and found simple and effective. Ablett's most accurate work paraffin wax (*Phil. Mag.*, 1923, **46**, 244) has probably given a good sult, although no means of frequently cleaning the surface was ailable, because paraffin wax practically does not contaminate water surface; nevertheless his apparatus would probably not satisfactory for the majority of substances. An ideal apparatus ight combine his method of rotating the cylinder of the solid th the method of cleaning by paraffined barriers.

The principal difficulty in measurement of contact angles is the ect of motion of the solid in dragging the liquid along with it. extreme cases, the angle when the liquid is advancing over the lid may be 60° greater than when it is receding. It is not necessary at there should be actual motion, for a force on the liquid tending move it has the same effect. The phenomenon is obvious on spection of a drop of water on a slightly dirty glass plate; it pears to have been first described in detail by Pockels (*loc. cit.*) d has been accurately measured in one case by Ablett. In the se of some surfaces, when the motion ceases, the line of contact liquid and solid slips back to give a true equilibrium contact gle, the same whether the motion was advancing or receding. is was only observed with one or two mechanically smooth surfaces, such as a scraped paraffin-wax surface. Ablett's results (n surfaces turned in a lathe) indicate that he obtained a true "stationary" angle of contact. In nearly all cases, including me with paraffin wax, when advancing motion ceased the liquid rse to an angle of contact which was greater than that to which fell after cessation of receding motion. The angle usually became nstant after motion, in less than a minute. So far as our servations go, it is indicated that the rougher the surface is, echanically, the greater is the difference between the advancig and receding angles; but it is not yet proved that there is ways a relation between mechanical roughness and the dragging ect.

The cause of this dragging effect (often called "hysteresis" of te angle of contact) seems to us to lie, not in any absorption of te liquid by the solid, but in a simple friction of the liquid on the rface. Let F be the force of friction which just prevents motion,

then, when the liquid is on the point of advancing, equation (3) becomes

$$T_{SV} - T_{SL} = T_{LV}\cos\theta_A + F \quad . \quad . \quad . \quad . \quad . \quad (4)$$

and when just receding,

$$T_{SV} - T_{SL} = T_{LV}\cos\theta_R - F \quad . \quad . \quad . \quad . \quad . \quad (5)$$

θ_A and θ_R are the angles of contact when the force is just sufficient to move the liquid forwards or backwards, and are therefore the angles measured after moving the plate a short distance and waiting till the angle becomes constant after the motion has ceased.

For the calculation of W by equation (3) the equilibrium angle is required. By adding (4) and (5), and eliminating $T_{SV} - T_{SL}$ by (2),

$$2\cos\theta = \cos\theta_A + \cos\theta_R \quad . \quad . \quad . \quad . \quad . \quad (6)$$

and when (as with the aliphatic substances here considered) the angles are between 45° and 135°, no error greater than 2° arises by substituting

$$2\theta = \theta_A + \theta_R \quad . \quad . \quad . \quad . \quad . \quad . \quad (7)$$

By raising the plate of solid vertically by means of the rack and pinion, and taking the mean of the angles after advancing and after receding motion, the following values of the equilibrium angle of contact have been measured. The error is probably of the order 5° in most cases; the angle for a scraped paraffin-wax surface is probably correct to 1°, and agrees with other published determinations.

Surface.	Angle of contact.	Work of adhesion in ergs per sq. cm.
Paraffin wax:		
Scraped surface	105°	54
Solidified in air	105	54
Solidified in contact with water	85 to 100	79·4 to 60·4
Octadecyl iodide:		
Solidified in air	100	60·4
Scraped	95	66·5
Pure hexadecyl alcohol:		
Solidified in air	95	66·5
Scraped surface	50 to 75	123 to 92
Crystal flake	85	79·4
Kahlbaum's "cetyl alcohol" (not crystalline)	20 to 50*	—
Palmitic, stearic, and eicosanic acids, also commercial "stearic":		
Solidified in air	100 to 105	60·4 to 54
Scraped	50 to 105	123 to 54
Crystal flake	95	66
Octadecylamine and eicosylamine hydrochlorides:		
Flakes	45	128

* The "cetyl" alcohol contaminated the water surface very quickly, and possibly the surface tension of the water was lowered sufficiently to render these angles decidedly too low.

There is a strong tendency for the surfaces which have solidified
om a melt, in air, to approach the value for paraffin wax. This
dicates that the normal orientation of molecules is with the paraffin
ains outwards.

Paraffin wax and octadecyl iodide, which contain no groups
ving a strong affinity for water, give practically the same angle
a surface cut from the interior as at the natural surface. The
bstances which contain polar groups at one end of the molecule,
ids and alcohols, give very varying results for surfaces cut from
e interior. These may be as low as 50°, or have practically the
me value as the natural surface. It is known from the *X*-ray
idies of Müller and Shearer that these substances crystallise in
kes, the unit of which is a layer 2 mols. thick, which has the polar
oups in the interior and the hydrocarbon chains outwards. A
t surface which runs parallel to the direction of these flakes in
e solid mass will expose very few, if any, polar groups; but one
right angles will expose the maximum number. Hence the
riation in the results.

An attempt was made to produce a surface of hexadecyl alcohol
ntaining a very high concentration of polar groups, by solidifying
te mass in contact with water, so that the layer of molecules nearest
te water might be oriented with polar groups outwards. This
as not successful, probably because this outermost layer sticks
ore closely to the water, to which it is attracted by polar groups,
an to the solid plate, to which it is attracted only by the smaller
traction between methyl groups; surfaces crystallised in contact
th water were of two kinds, some having a small angle of about
°, others giving about 100°. Frequently both types of surface
re present on the same mass. It was observed that the surface
th low angle of contact had a fine structure and did not flake off,
te appearance indicating that the crystal flakes were nearly per-
ndicular to the water; those with high angle easily flaked off,
owing that the crystal flakes were parallel to the water.

The table also indicates a tendency of the crystalline flakes
rmed from alcoholic or benzene solutions) to have a lower angle
contact than the mass solidified from the melt. The difference
perhaps too small to be trustworthy in the case of the alcohols
d acids, but the amine hydrochlorides (which could not be examined
er solidification from a melt, as they decompose on melting)
ve a very low angle of contact in the flakes. It is very probable,
m the similarity of constitution and of the appearance of the
kes, that these flakes have the same molecular structure as those
the acids and alcohols. Thus the very strongly polar groups
the interior *appear* to exercise an appreciable attraction on the

water over a distance equal to the length of an octadecyl chain-about 22 Å.U. Owing to the fact that a layer of closely packe hydrocarbon chains is undoubtedly permeable to water molecule this cannot be taken as a proof that the attraction of the interi polar groups does actually extend to a distance 22 Å.U., still retai ing a considerable fraction of its intensity. The interchange water between the internal polar groups and the exteri may result in something approaching chains of water molecul in among the hydrocarbon chains, and this would render the exteri surface polar. The flakes of these amine hydrochlorides, immerse in water for some hours, swell, and form a colloidal solutio eventually.

THE SORBY RESEARCH LABORATORY,
UNIVERSITY OF SHEFFIELD. [*Received, July 9th*, 1925.]

CCLI.—*The Parachor and Chemical Constitution. Part II. Geometrical Isomerides.*

By SAMUEL SUGDEN and HENRY WHITTAKER.

WHILST many physical properties of geometrical isomerides hav been investigated and correlated with configuration, no systemati study of the surface tensions of such substances appears to have bee made. The work now described was commenced about two yea ago with the object of collecting data for pairs of isomerides c known configuration which might provide a basis for a method c determining configuration when the chemical evidence was nc conclusive. Meanwhile it was found by one of us (Sugden, J 1924, **125**, 1178) that the parachor, a quantity involving surfac tension and density, can be expressed as a simple additive functio of certain atomic and structural constants; from these constant it is possible to calculate the theoretical parachor for all the sul stances studied and, by comparison of this with the observed figur to detect the existence of any anomalies.

The determination of the parachor of geometrical isomerides i also of interest, since it has been found (Sugden, Reed, and Wilkin this vol., p. 1525) that by means of this constant a distinction ca be drawn between the two types of double bond which are predicte by the " octet " theory of valency as developed by Lewis, Langmui and Lowry. The non-polar double bond, consisting of two coval encies, adds 23·2 units to the parachor, whilst the semipolar doubl bond, which is made up of one covalency and one electrovalency lowers the molecular parachor by 1·6 units. It is therefore an eas

atter to determine experimentally the type of linking present in a rticular compound. Lowry has suggested that the "activated" olecule of an ethylene derivative may contain a semipolar double nd; this may not, of course, persist in the resting state and ngmuir (*loc. cit.*) assumes that carbon–carbon double bonds are n-polar, so that each carbon atom possesses a complete octet. rther it has been suggested by one of us (Sugden, J., 1923, **123**, 64), that there must be free rotation about a semipolar double nd; hence it would be expected that compounds which exhibit ometrical isomerism would possess a linking of the non-polar pe. It may be stated at once that all the ethylene derivatives so r examined, including those discussed in the present paper, have en found to contain non-polar double bonds.

The substances which have been measured are all methyl esters unsaturated acids. Esters were used to avoid the complication troduced by association of the free acids, and methyl esters were osen so that the loading of the molecule, which might obscure nall differences between isomeric substances, should be as small possible.

The results obtained are shown in the accompanying table. Since e calculated value of the parachor includes the effect of a non-olar double bond, the good agreement between the figures in the st two columns shows that all these compounds contain this type linking. If a semipolar double bond were present the molecular rachor would be 24·8 units lower, and whilst deviations of a few nits are present in the observed figures none of them is large enough suggest the occurrence of this type of bond.

[1] *Ber.*, 1890, **23**, 2511. [2] *Ibid.*, p. 2130. [3] *Ibid.*, 1886, **19**, 1378. [4] "Die agerung der Atome im Raume," Braunschweig, 1877, 21.

There is a small but systematic difference between the values of ie parachor for each pair of isomerides; the *cis*-compounds, in hich two bulky groups are adjacent, give values for the parachor

closely approximating to the theoretical figure, whilst the *trans*-compounds give rather lower values. The difference is small and varies from one unit in the case of maleic and fumaric esters to four units for the mesaconic and citraconic esters. It is therefore little greater than the experimental error; but it appears systematically in each of the pairs of compounds examined, so that configuration does seem to have a real although small effect upon the molecular parachor.

Isomeric substances, *e.g.*, the esters of the formula $C_6H_{12}O_2$ and the three xylenes, have very nearly the same parachor (Sugden, *loc. cit.*, 1180, 1185). Since the atomic constants do not vary in different classes of substances, any differences between the parachors of isomerides must be due to marked differences in structure. The structural constants so far evaluated range from 46·6 for the triple bond to 6·1 for a six-membered ring and appear to depend chiefly upon the degree of unsaturation, or rather upon the crowding of the orbits of shared electrons. The semipolar double bond with a constant of −1·6 fits in with this conception, since, for example, in sulphates and phosphates there is no chemical evidence of unsaturation. Thus a marked difference between the parachors of isomerides would be expected to occur only with a marked difference in structure and in degree of unsaturation, as, for instance, in benzene, for which $[P]$ calc. = 207·1, and dipropargyl, for which $[P]$ calc. = 224·6. It is therefore not surprising that the configuration of geometrical isomerides has only a small influence upon the molecular parachor.

Experimental.

The isomerides of the cinnamic series were prepared by Sudborough's methods (J., 1903, **83**, 666, 1153). Cinnamic acid was converted into ethyl αβ-dibromo-β-phenylpropionate, the latter treated with alcoholic caustic potash, and the resulting mixture of α-bromocinnamic and α-bromo*allo*cinnamic acids separated by means of the barium salts. Phenylpropiolic acid was prepared by heating bromocinnamic acid with aqueous caustic potash. Sudborough recommends the use of a 20% solution of potash and gently heating on the water-bath, but a better conversion resulted by heating more vigorously with 30% potash. Even under these conditions the reaction was not complete, and difficulty was experienced in the purification of the phenylpropiolic acid until it was found that its barium salt was soluble in dilute ammonia and so could be readily separated from the insoluble barium bromocinnamate. The β-bromo-acids were prepared by the addition of phenylpropiolic acid to saturated aqueous hydrobromic acid, and the isomerides separated by means of their barium salts. *allo*Cinnamic acid was obtained

by reducing β-bromo*allo*cinnamic acid with zinc dust and 96% alcohol; the directions given by Michael (*Ber.*, 1901, **34**, 3651) for the preparation of *iso*cinnamic acid were followed, but the results confirmed the conclusions of Sudborough (*loc. cit.*) that the product is nearly pure *allo*cinnamic acid.

With one exception the methyl esters were prepared from the free acids by the Fischer-Speier method. Maleic acid under this treatment gave a mixture of fumarate and maleate which contained very little maleate; this ester was therefore made by the action of methyl iodide on the silver salt.

The surface tensions of the purified esters were determined by the method of maximum bubble pressure (J., 1922, **121**, 860; 1924, **125**, 27). Seven bubblers were used in the course of the work and in general each substance was measured on two instruments. The constants for these are tabulated below. The densities over a suitable temperature range were determined by means of the

App.	3b.	4a.	4c.	4d.	5b.	6.	6a.
r_2 cm.	0·159	0·139	0·139	0·139	0·140	0·156	0·156
A ...	0·004664	0·003708	0·004790	0·007767	0·009655	0·004439	0·009109

U-shaped pyknometer previously described (J., 1924, **125**, 1171). In the tables below, t is the corrected temperature, P the difference in pressure in dynes/cm.^{2} required to liberate bubbles from the two tubes, D the density in gm./c.c., ϕ the correction factor, and γ the surface tension in dynes/cm. The parachor is calculated by the formula $[P] = \gamma^{1/4}M/D$, where M is the molecular weight.

Methyl cinnamate was recrystallised from ligroin and melted sharply at 33·5° (corr.), M 162·1. Densities determined: 1·078 at 36°, 1·069 at 47°, 1·058 at 61°, 1·046 at 76°, 1·035 at 90°; whence $D_{4^\circ}^{t^\circ} = 1{\cdot}107 - 0{\cdot}000795\ t$.

This substance was measured by Walden and Swinne (*Z. physikal. Chem.*, 1912, **79**, 730) and by Morgan and Chazal (*J. Amer. Chem. Soc.*, 1913, **35**, 1821). They used the density data of Weger (*Annalen*, 1883, **221**, 75), which are 4% lower than ours. Calculated with the aid of our densities, the surface tensions found by Walden and Swinne agree well with our measurements, whilst those of Morgan and Chazal are still low. The latter workers give no criteria by which the purity of their specimen can be judged.

Summary.

(1) The surface tension and the density of five pairs of geometrical isomerides have been measured over a range of temperatures.

(2) All the substances examined contain a non-polar double bond adding 23·2 units to the molecular parachor.

(3) The *cis*-compounds, in which two bulky groups are adjacent, have slightly higher parachors than the corresponding *trans*-compounds.

One of us (S. S.) wishes to express his thanks to the Research Fund Committee of the Chemical Society for a grant which has partly defrayed the cost of this investigation.

FETTER LANE, E.C. 4. [*Received, July 9th*, 1925].

CCLII.—*A New Synthesis of Aldehydes.*

By HENRY STEPHEN.

THE basis of this new method is the conversion of a nitrile through the imino-chloride (which need not be isolated) into an aldehyde with the same number of carbon atoms. The most suitable reducing agent is anhydrous stannous chloride * dissolved in ether saturated with hydrogen chloride. Finely powdered, anhydrous stannous chloride (1½ mols.) is suspended in dry ether, which is then saturated with dry hydrogen chloride until the mixture separates into two layers, the lower viscous layer consisting of stannous chloride dissolved in ethereal hydrogen chloride. The nitrile (1 mol.) is now added with vigorous shaking and, after a few minutes, separation begins of a white, crystalline aldimine stannichloride,

$$(R{\cdot}CH{:}NH,HCl)_2,SnCl_4.$$

The course of the formation and reduction of the imino-chloride is therefore as follows: $R{\cdot}CN + HCl \longrightarrow R{\cdot}CCl{:}NH$; $R{\cdot}CCl{:}NH + SnCl_2 + 2HCl \longrightarrow R{\cdot}CH{:}NH,HCl + SnCl_4$. After removal of this

* The anhydrous stannous chloride for these reactions was prepared by heating the crystalline variety until the temperature reached 180°. The product contained some stannous oxide, but this appears to be insoluble in ether saturated with hydrogen chloride. A convenient and rapid method for preparing pure anhydrous stannous chloride is to dissolve the fused mass obtained as above in pyridine. Solution takes place with evolution of heat and the insoluble stannous oxide is then filtered off. The filtrate deposits fine, white needles of a *double* compound, $SnCl_2,2C_5H_5N$ (Found: $SnCl_2$, 53·2; C_5H_5N, 46·4. $SnCl_2,2C_5H_5N$ requires $SnCl_2$, 53·2; C_5H_5N, 46·8%). When the double compound is heated under diminished pressure the pyridine is removed; the residue is anhydrous stannous chloride.

salt the ether may be again employed for another preparation. The salt is readily hydrolysed by warm water, and the aldehyde formed may be removed by distillation with steam or extraction with a solvent.

The method is applicable to aliphatic and aromatic nitriles, and the yields are usually almost quantitative. As the rate of deposition of the stannichloride varies in different cases, it is advantageous to allow at least two hours for completion of the reaction.

3 : 4 : 5-Trimethoxybenzonitrile and other nitriles which are only sparingly soluble in cold ether may be dissolved in chloroform and the solution added to the reducing agent.

o-Toluonitrile and α-naphthonitrile give only small yields of the respective aldehydes. This is no doubt due to steric hindrance, of which the two nitriles form well-known examples; both, for instance, fail to give imino-ethers (Pinner, " Die Imidoäther und ihre Derivate," 1892, pp. 4, 81), for the formation of which an imino-chloride is essential.

A special application of the method is the formation of indole by reduction of *o*-nitrophenylacetonitrile; sufficient reducing agent is employed to reduce both the imino-chloride and the nitro-group :

$$C_6H_4\langle\begin{matrix}CH_2\cdot CN\\NO_2\end{matrix} \rightarrow C_6H_4\langle\begin{matrix}CH_2\cdot CHO\\NH_2\end{matrix} \rightarrow C_6H_4\langle\begin{matrix}CH\\NH\end{matrix}\rangle CH$$

(compare Pschorr, *Ber.*, 1910, **43**, 2543).

Experimental.

n-*Octaldehyde*.—Octonitrile was prepared by warming a solution of octoamide in thionyl chloride on the water-bath for 30 minutes and removing the excess of thionyl chloride under diminished pressure. The residue of nitrile (b. p. 87°/10 mm.) was almost pure and the yield quantitative. The method has been applied to the amides of myristic, palmitic, and stearic acids with equally good results.

Octonitrile (25 g.) was brought into reaction with stannous chloride (57 g.) in dry ether (200 c.c.), saturated with hydrogen chloride as described above. The aldehyde produced by hydrolysis of the stannichloride was isolated by distillation with steam and extraction with ether. It was obtained as a colourless oil, b. p. 65°/11 mm., having a strong lemon-like odour. Prepared by the usual methods and crystallised from methyl alcohol, the oxime was obtained in fine, silky needles, m. p. 60°, the semicarbazone in needles, m. p. 98°, and the *p-nitrophenylhydrazone* in bright yellow needles, m. p. 80° (Found : N, 15·8. $C_{14}H_{21}O_2N_3$ requires N, 15·9%).

Myristaldehyde was prepared from the corresponding nitrile, but being only slightly volatile in steam it was extracted with warm ether after hydrolysis of the stannichloride. It was obtained as thin, colourless laminæ, m. p. 23°, b. p. 155°/10 mm., and rapidly polymerised to a white solid, m. p. 65°. The oxime and semicarbazone crystallised from methyl alcohol in needles, m. p. 82·5° and 106·5°, respectively (compare Le Sueur, J., 1905, **87**, 1900). The p-*nitrophenylhydrazone* is a bright yellow, crystalline powder, m. p. 95° (Found: N, 12·4. $C_{20}H_{33}O_2N_3$ requires N, 12·1%).

Palmitaldehyde formed thin plates with nacreous lustre (from ether), m. p. 34°; the polymeride had m. p. 73—74°. The oxime and semicarbazone crystallised from methyl alcohol in needles, m. p. 88° and 107°, respectively (Le Sueur, *loc. cit.*). The p-*nitrophenylhydrazone* formed yellow needles, m. p. 96·5°, from alcohol (Found: N, 11·3. $C_{22}H_{37}O_2N_3$ requires N, 11·2%).

Stearaldehyde has m. p. 38°, not 63·5° as stated by Krafft (*Ber.*, 1880, **13**, 1417). It rapidly polymerises to a white solid, m. p. 80° The oxime and semicarbazone crystallise in needles, m. p. 89° and 108—109°, respectively. The p-*nitrophenylhydrazone* forms yellow needles, m. p. 101°, from methyl alcohol (Found: N, 10·6. $C_{24}H_{41}O_2N_3$ requires N, 10·4%).

Benzaldehyde.—Benzonitrile is rapidly and almost quantitatively converted into benzaldehyde by the new method. The *stannichloride* was obtained in white needles from alcohol (Found: Sn, 21·2. $C_{14}H_{16}N_2Cl_6Sn$ requires Sn, 21·8%). The salt, if dry, may be preserved indefinitely. It dissolves in water, but is rapidly hydrolysed when the solution is warmed.

3 : 4 : 5-*Trimethoxybenzaldehyde.*—The corresponding nitrile is readily obtained by the action of thionyl chloride on the amide (yield 90%), and without further purification melts at 93° as stated by Harding (J., 1911, **99**, 1594). A solution of the nitrile (9 g.) in 20 c.c. of chloroform is added to anhydrous stannous chloride (9 g.) in ether (150 c.c.) saturated with hydrogen chloride. After an hour the yellow stannichloride is filtered off, hydrolysed by boiling water, and the solution filtered. 3 : 4 : 5-Trimethoxybenzaldehyde crystallises from the filtrate in shimmering leaves, m. p. 74—75°. The oxime has m. p. 88°; the semicarbazone, m. p. 218°; and the *p*-nitrophenylhydrazone, m. p. 201° (compare Mauthner, *Ber.*, 1908, **41**, 923).

Indole.—*o*-Nitrophenylacetonitrile (3 g.) is added to a solution of anhydrous stannous chloride (16 g.) in ether (100 c.c.) saturated with hydrogen chloride. After remaining 2 hours, the stannichloride is filtered off, dissolved in water, the solution made alkaline with sodium hydroxide. and the indole removed in a current of

steam. The product, m. p. 52° (yield 1·2 g.), shows all the characteristic properties of indole.

The following aldehydes have been prepared by the new method, and except in the cases marked * the yields were almost quantitative. *o*-Tolualdehyde,* b. p. 94°/10 mm.; p-*nitrophenylhydrazone*, red needles, m. p. 222°, from alcohol (Found: N, 16·2. $C_{14}H_{13}O_2N_3$ requires N, 16.4%). *p*-Tolualdehyde, b. p. 106°/10 mm.; p-*nitrophenylhydrazone*, similar to the above, m. p. 200·5° (Found: N, 16·5%). *o*- and *p*-Chlorobenzaldehydes, phenyl-, *p*-chlorophenyl-, and *p*-tolyl-acetaldehydes (p-*nitrophenylhydrazone* of the last, yellow needles from alcohol, m. p. 144·5°. Found: N, 15·3. $C_{15}H_{15}O_2N_3$ requires N, 15·6%), cinnamaldehyde and β-phenylpropaldehyde, α-naphthaldehyde * (m. p. 33—34°; oxime, m. p. 39°; semicarbazone, m. p. 222°; p-*nitrophenylhydrazone*, orange needles, m. p. 234°. Found: N, 14·4. $C_{17}H_{13}O_2N_3$ requires N, 14·4%). The investigation is being continued.

In conclusion, the author has to thank Professors Lapworth and Robinson for their interest in the research.

THE UNIVERSITY, MANCHESTER. [*Received, June 26th*, 1925.]

CCLIII.—*ββ′-Dichloro- and ββ′-Dibromo-diethyl Selenides and their Simple Halogen Derivatives.*

By HUGH CHESTER BELL and CHARLES STANLEY GIBSON.

IN studying the reaction between ethylene and selenium monochloride, Bausor, Gibson, and Pope (J., 1920, **117**, 1453) showed that ββ′-dichlorodiethyl selenide dichloride (m. p. 122·5°) is formed and that the reaction proceeds according to the equation $2CH_2{:}CH_2 + 2Se_2Cl_2 = (CH_2Cl{\cdot}CH_2)_2SeCl_2 + 3Se$. Heath and Semon (*Ind. Eng. Chem.*, 1920, **12**, 1100) suggested that the final product is *s*-tetrachlorodiethyl selenide, $(CHCl_2{\cdot}CH_2)_2Se$, m. p. 118°.† On the other hand, Boord and Cope (*J. Amer. Chem. Soc.*, 1922, **44**, 395) agree that the final product is ββ′-dichlorodiethyl selenide dichloride, but they advance arguments to prove that the reaction goes in two stages:

(*a*) $2C_2H_4 + Se_2Cl_2 = (C_2H_4Cl)_2Se + Se$.
(*b*) $(C_2H_4Cl)_2Se + Se_2Cl_2 = (C_2H_4Cl)_2SeCl_2 + 2Se$.

In their paper Boord and Cope do not give any indication that they have investigated the reaction between ethylene and selenium

† These authors state that hydrogen chloride is evolved during the reaction. We have found that this is not so if precautions are taken to exclude moisture.

monochloride and did not isolate ββ′-dichlorodiethyl selenide which, the present work has further proved, was described by Bausor, Gibson, and Pope for the first time (compare Boord, *Ind. Eng. Chem.*, 1919, **11**, 101). The argument advanced by Boord and Cope is based on the results of experiments on the reaction between selenium monochloride and propylene, butylene, and amylene, respectively, and they show in each case that when selenium monochloride is added to the olefine the ββ′-dichlorodialkyl selenide is produced (reaction *a*). The only case of the formation of a selenide dichloride found by Boord and Cope was when they carried out the reaction between selenium monochloride and propylene, substantially under the conditions maintained by Bausor, Gibson, and Pope in the case of ethylene, and they obtained ββ′-dichlorodipropyl selenide dichloride. If the reaction between the olefines and selenium monochloride is a general one and occurs in two stages as stated by Boord and Cope, then that between the selenide and selenium monochloride (*b*) must be quantitative and proceed under the ordinary conditions of the experiment. In only one case apparently did the authors try this; they found that when equimolecular quantities of selenium monochloride and ββ′-dichlorodibutyl selenide were mixed the selenide dichloride was not obtained. The work of Boord and Cope indicates that the selenide dichlorides from butylene and amylene are difficult to prepare and may not have been obtained, but it affords little evidence that the reaction between ethylene and selenium monochloride takes place in two stages.

When selenium monochloride in chloroform is added to a chloroform solution of ββ′-dichlorodiethyl selenide at the ordinary temperature the formation of ββ′-dichlorodiethyl selenide dichloride is, we find, instantaneous and selenium separates at once. Although it may be convenient to regard the formation of the selenide as a phase in the reaction, it is clear that it cannot exist in the presence of selenium monochloride for any appreciable time. We describe below a highly satisfactory method for the preparation of ββ′-dichlorodiethyl selenide from the dichloride in which the possibility of its contamination with selenium is avoided and since the preparation of the dichloride can be carried out so readily we have not investigated the possibility of the preparation of the somewhat toxic selenide directly from selenium monochloride which, at the best, would involve the separation of the product from selenium.

ββ′-Dichlorodiethyl selenide dichloride can be prepared not only by the action of ethylene on selenium monochloride, but also in quantitative yield from selenium tetrachloride,

$$2C_2H_4+SeCl_4=(CH_2Cl\cdot CH_2)_2SeCl_2,$$

and the separation of the product from selenium is thereby avoided. It is possible to chlorinate selenium in the presence of benzene (very little chlorination of the latter takes place) or other suitable solvents to the tetrachloride and to convert this quantitatively into the final product, the same vessel being used throughout. In an analogous manner, ββ′-*dibromodiethyl selenide dibromide* is obtained, starting with selenium.

Bausor, Gibson, and Pope suggested that the colourless, crystalline substance, m. p. 23—25°, obtained in small quantity by reducing a cold aqueous solution of ββ′-dichlorodiethyl selenide dichloride with sulphur dioxide is probably ββ′-dichlorodiethyl selenide (*loc. cit.*). This is the fact. It can also be prepared by reducing the dichloride with hydrogen sulphide or, best, with potassium metabisulphite. It has a characteristic and persistent garlic-like odour and its toxicity appears to be very much less than that of ββ′-dichlorodiethyl sulphide. The corresponding ββ′-*dibromodiethyl selenide* is prepared in an analogous manner by reduction of the corresponding dibromide.

On treatment under appropriate conditions with either chlorine or bromine, the selenides combine with two atomic props. of the halogen. Apart from the dichloride and the dibromide already mentioned, we have prepared in this way ββ′-*dichlorodiethyl selenide dibromide* and ββ′-*dibromodiethyl selenide dichloride*. Since chlorine combines with ββ′-dichlorodiethyl selenide to give the product obtained by the reaction of ethylene with selenium monochloride, these compounds afford additional evidence of the correctness of the constitution given to ββ′-dichlorodiethyl selenide dichloride by Bausor, Gibson, and Pope. ββ′-Dichlorodiethyl selenide dichloride is precipitated from its aqueous solution by hydrochloric acid, and similarly the corresponding dibromide is precipitated by hydrobromic acid. The product obtained by adding hydrochloric acid to an aqueous solution of ββ′-dibromodiethyl selenide dibromide was proved to be the dichloride by its yielding ββ′-dibromodiethyl selenide on reduction with potassium metabisulphite. Under similar conditions, ββ′-dichlorodiethyl selenide dibromide is converted into ββ′-dichlorodiethyl selenide. It is interesting to compare the instability of ββ′-dichlorodiethyl sulphide dibromide (Gibson and Pope, J., 1920, **117**, 277) with the great stability of the analogous compounds of selenium now described.*

* Propylene reacts with selenium tetrachloride in a precisely similar manner to ethylene, and a quantitative yield of ββ′-dichlorodipropyl selenide dichloride results. This compound, reduced by potassium metabisulphite, is converted quantitatively into ββ′-dichlorodipropyl selenide (compare Boord and Cope, *loc. cit.*).

So far, all attempts to prepare direct oxidation products of ββ′-dichlorodiethyl selenide have failed. Although part of it is destroyed in the process, ββ′-dichlorodiethyl selenide dichloride can be recrystallised from concentrated nitric acid. Under the conditions for converting ββ′-dichlorodiethyl sulphide into the corresponding sulphoxide (Gibson and Pope, *loc. cit.*), ββ′-dichlorodiethyl selenide is partly destroyed and the dichloride crystallises out from the solution. Although the dichloride in aqueous solution behaves like the chloride of a bivalent metal, we have not been able to isolate either the corresponding hydroxide or oxide. An attempt to prepare the oxide by the action of ethylene on selenium oxychloride resulted in the formation of the dichloride and selenium dioxide, the following reaction presumably taking place :

$$2SeOCl_2+2C_2H_4=SeO_2+(C_2H_4Cl)_2SeCl_2.$$

Experimental.

ββ′-Dichlorodiethyl Selenide Dichloride.—Some quantity of this compound was prepared by the original method from selenium monochloride and the previous results were confirmed in all respects. When an excess of dry ethylene was passed into a dry benzene solution of selenium monochloride, hydrogen chloride was not evolved for the issuing gas produced no change in the alkalinity of standard sodium hydroxide. In an actual experiment, dry ethylene was passed into a rapidly stirred solution of 42 g. of selenium monochloride in dry benzene, cooled in running water. The yields of ββ′-dichlorodiethyl selenide dichloride and of precipitated selenium obtained were 24 g. and 19 g., respectively; according to the equation, they should be 25·4 g. and 21·7 g.

The preparation from selenium tetrachloride is, however, much more convenient, since all contamination with selenium is avoided. A rapid stream of chlorine is passed into a cooled, well-stirred suspension of finely divided selenium (1 part) in a convenient amount of benzene (carbon tetrachloride, chloroform or ether may be used). Selenium tetrachloride is formed with evolution of heat and separates rapidly as a pale yellow powder. The chlorine supply is then cut off, finely divided selenium (3 parts) added, and stirring continued for some time, during which the selenium tetrachloride is converted into the monochloride and almost complete solution is effected. The somewhat diluted benzene solution is filtered in a dry atmosphere, and chlorination is continued rapidly under the same conditions as before until the solution is completely decolorised and the selenium tetrachloride separates as a pale yellow powder, almost insoluble in most organic solvents. After

freeing the solution from excess of chlorine by passing dry air, ethylene is passed in until complete solution of the selenium tetrachloride is effected in the warm solvent, which should become quite colourless when the reaction is finished. The dichloride crystallises as the solution cools and the small amount remaining in solution can be recovered in the usual manner. In this way, from a total amount of 20 g. of selenium, 60—65 g. of ββ′-dichlorodiethyl selenide dichloride can be prepared conveniently in the course of about 8 hours including the preparation of the necessary ethylene. That the reaction between selenium tetrachloride and ethylene takes place according to the equation $2C_2H_4+SeCl_4=(C_2H_4Cl)_2SeCl_2$ was proved by passing ethylene into dry benzene in which 10 g. of the tetrachloride was suspended. Twelve grams of the resulting compound was obtained (theory requires 12·5 g.).

The identity of the compound prepared from selenium tetrachloride with that prepared from the monochloride was proved by its melting point (122·5°), by its crystalline form, and by its behaviour with sodium hydroxide in cold aqueous solution (Found : titratable Cl, 25·9; *M*, cryoscopic in hexachloroethane,* 276. Calc. for $C_4H_8Cl_4Se$: titratable Cl, 25·6%; *M*, 277·2). The compound is best purified by recrystallisation from chloroform. It can be almost quantitatively recovered from its aqueous solution by addition of concentrated hydrochloric acid and this is also a convenient method of purification. Its aqueous solution decomposes above 35°, and rapidly when boiled, with evolution of ethylene.

When concentrated hydrobromic acid was added to a cold aqueous solution of ββ′-dichlorodiethyl selenide dichloride, a yellow, crystalline precipitate was obtained which, after recrystallisation from chloroform, had m. p. 117° (decomp.) and was proved by its constants and by analysis to be *ββ′-dichlorodiethyl selenide dibromide*, obtained also in another way (see p. 1883).

In attempts to isolate ββ′-dichlorodiethyl selenide dihydroxide, careful addition of sodium hydroxide (2 equivs.) to the aqueous solution of the dichloride gave negative results. Similarly, in attempting to prepare ββ′-dichlorodiethyl selenide oxide by the action of dry silver oxide on a benzene solution of the dichloride, selenium was deposited and no oxide-like substance could be isolated.

ββ′-Dibromodiethyl Selenide Dibromide, $(CH_2Br{\cdot}CH_2)_2SeBr_2$, is prepared in an analogous manner to the dichloride. Finely divided selenium is suspended in pure carbon tetrachloride and bromine is added to the rapidly stirred suspension until the whole of the

* The use of hexachloroethane for the determination of molecular weights has not yet been described but, as soon as its general applicability has been determined, an account will be submitted for publication.

bromine is converted into the tetrabromide. The excess of bromine is removed either by boiling or by passing a current of dry air. Dry ethylene is then passed into the rapidly stirred suspension of the tetrabromide until the solution becomes clear; the ββ′-dibromodiethyl selenide dibromide dissolves in the warm solvent and crystallises on cooling. One crystallisation from chloroform is sufficient for complete purification, well-formed, bright yellow prisms, m. p. 118°, being obtained (Found : Br, 71·1. $C_4H_8Br_4Se$ requires Br, 71·6%).

ββ′-*Dichlorodiethyl Selenide*, $(CH_2Cl{\cdot}CH_2)_2Se$.—The substance, m. p. 23—25°, originally prepared by Bausor, Gibson, and Pope (*loc. cit.*) by passing sulphur dioxide into a cold aqueous solution of ββ′-dichlorodiethyl selenide dichloride, was prepared again by the same method and proved to be ββ′-dichlorodiethyl selenide identical with the product obtained more conveniently by a slightly different procedure.

ββ′-Dichlorodiethyl selenide dichloride may be reduced in boiling benzene solution by dry hydrogen sulphide. Sulphur separates and the reaction is finished when hydrogen chloride ceases to be evolved. On distilling off the benzene from the filtered solution, a product is obtained, m. p. about 24°, which is extremely difficult to obtain free from adhering sulphur. On extraction with dry ether, some sulphur is left undissolved, but the melting point of the product is scarcely affected. Fractional freezing of the material to free it from sulphur is not very satisfactory and even after repeating this process several times analysis shows that the resulting material is not quite pure (Found : Cl, 33·2%).

After many experiments the following method was finally adopted for preparing ββ′-dichlorodiethyl selenide conveniently in a state of purity. A solution of pure ββ′-dichlorodiethyl selenide dichloride (10—15 g.) in cold water is shaken with cold aqueous potassium metabisulphite (calc. quantity) and at once extracted with ether. The ethereal solution is washed with water, dried with calcium chloride, and evaporated; the selenide crystallises easily (yield almost theoretical). It is convenient to purify it by pressing on to clean unglazed porcelain and subsequent fractional freezing. It crystallises in colourless needles, m. p. 24·2° (Found : Cl, 34·7; Se, 38·6; *M*, cryoscopic in benzene, 196. Calc. for $C_4H_8Cl_2Se$: Cl, 34·4; Se, 38·4% : *M*, 206). Unlike the corresponding sulphide, it cannot be distilled in a water-pump vacuum without considerable decomposition. The distillate, however, contains some unchanged selenide which is identified by conversion into the dibromide (see below).

ββ′-Dichlorodiethyl selenide combines with chlorine (1 mol.) to

give the dichloride and with bromine (1 mol.) in chloroform solution. The reaction is quantitative: 0·3915 g. decolorised 0·315 g. bromine, the theoretical quantity being 0·303 g. bromine. The compound so formed is therefore ββ′-*dichlorodiethyl selenide dibromide*, $(C_2H_4Cl)_2SeBr_2$, which crystallises from chloroform in pale yellow prisms, m. p. 117° (decomp.). This compound, on reduction with potassium metabisulphite in the manner already described, yields ββ′-dichlorodiethyl selenide. It has been mentioned that when hydrobromic acid is added to a cold aqueous solution of ββ′-dichlorodiethyl selenide dichloride this dibromide is precipitated (see p. 1881) and the facts now brought forward prove that when ββ′-dichlorodiethyl selenide dichloride is dissolved in water the halogen atoms attached to the selenium are hydrolysed.

When a chloroform solution of selenium monochloride is added to a similar solution of ββ′-dichlorodiethyl selenide, selenium is at once precipitated and the filtered solution yields a quantitative amount of ββ′-dichlorodiethyl selenide dichloride. The reaction takes place with evolution of heat and proceeds according to the equation $Se_2Cl_2+(C_2H_4Cl)_2Se=(C_2H_4Cl)_2SeCl_2+2Se$.

When ββ′-dichlorodiethyl selenide is oxidised with nitric acid, the only product which has up to the present been isolated is ββ′-dichlorodiethyl selenide dichloride (identified by its melting point and crystalline form), part of the selenide being destroyed. An attempt to prepare the oxide by the action of ethylene on selenium oxychloride resulted in the formation of selenium dioxide and ββ′-dichlorodiethyl selenide dichloride, the selenium oxychloride reacting as an equimolecular mixture of selenium dioxide and selenium tetrachloride.

ββ′-*Dibromodiethyl Selenide*, $(CH_2Br{\cdot}CH_2)_2Se$.—This compound is prepared by reduction of ββ′-dibromodiethyl selenide dibromide by means of potassium metabisulphite under the conditions already described. It crystallises from ethyl alcohol in yellow needles, m. p. 44·2°, and is much more easily handled than the corresponding chloro-compound (Found: Br, 53·5. $C_4H_8Br_2Se$ requires Br, 54·2%).

It combines with chlorine in chloroform solution to give ββ′-*dibromodiethyl selenide dichloride*, $(C_2H_4Br)_2SeCl_2$, pale yellow prisms, m. p. 98—99°, from chloroform (Found: Cl+Br, 62·8. $C_4H_8Cl_2Br_2Se$ requires Cl+Br, 63·0%). This compound has a greater solubility in organic solvents than the analogous compounds already mentioned. The same compound is precipitated by adding a concentrated solution of hydrochloric acid to a cold aqueous solution of ββ′-dibromodiethyl selenide dibromide, but it has to be separated from some unchanged dibromide which is precipitated with it. As was expected, the melting point of the

product so obtained was somewhat low (96°), but, on reduction, it gave ββ′-dibromodiethyl selenide identical with an authentic specimen.

Addendum.

The reaction between propylene and selenium tetrachloride has also been carried out. ββ′-Dichlorodipropyl selenide dichloride, m. p. 76·5° (Boord and Cope, *loc. cit.*, give 81°), was obtained in almost theoretical yield. It is conveniently purified by dissolving in cold water, in which it is readily soluble, and reprecipitating with hydrochloric acid (Found: Cl, 46·7; calc., Cl, 46·5%). When reduced with potassium metabisulphite under the usual conditions, it was converted into ββ′-dichlorodipropyl selenide, which has not yet been obtained crystalline (Found: Cl, 30·1; calc., Cl, 30·3%).

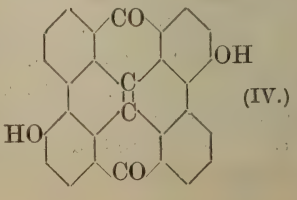
CCLIV.—*Reduction Products of the Hydroxyanthraquinones. Part VI.*



By ARTHUR GEORGE PERKIN and GEN YODA.

HALLER and PERKIN (J., 1924, **125**, 239) showed that when 3 : 6′-dihydroxydianthranol (I), but curiously enough not the corresponding dianthrone, is oxidised with alkaline permanganate or, better, with ferricyanide, a mixture of the helianthrone (III) and naphthadianthrone (IV) is obtained. These compounds are also produced in minute amount by the glucose–alkali fusion of 2-hydroxyanthraquinone (Bradshaw and Perkin, J., 1922, **121**, 913).

It appeared likely that the first product of the oxidation would be the dihydroxydianthraquinone (II) and it was actually found by Perkin and Haller (*loc. cit.*) that by the more gentle action of ferricyanide a product was obtained which seemed to consist of this substance in an impure condition. Experiment has now shown that this dihydroxydianthraquinone can be prepared in good yield by the action of iodine on a pyridine solution of tetra-acetyldihydroxydianthranol at about 80°, diacetoxydianthrone remaining unchanged under these conditions. This substance, apparently the first hydroxydianthraquinone to be prepared, consists of pale yellow leaflets, blackens about 280°, and does not appear to have a definite melting point. Though two formulæ are applicable to this compound, in which hydroxyls occupy either the 3 : 6′-* or 3 : 3′-positions, it evidently consists in the main of a single substance, because on oxidation with alkaline ferricyanide an excellent yield of the dihydroxyhelianthrone (III) is produced. On the other hand, whereas the melting point of the diacetyldianthraquinone, after crystallisation from acetic anhydride, is 293—295°, and this can be raised by repeated fractionation from tetrachloroethane to about 314—316° without apparent alteration in the character of the substance, it is possible that a small amount of a second variety is also produced. The melting points given of the dibenzoyl compound, 301—302°, and the dimethyl ether, 290—292°, vary to some extent with the rapidity of heating, but on the whole there is no definite evidence that the new dihydroxydianthraquinone consists of two isomerides. 3 : 3′-Dihydroxydianthraquinone (m. p. 293—295°) is easily reduced by zinc dust and ammonia to 3-hydroxyanthranol, but is unaffected by long treatment with sulphur dioxide in the presence of alcohol. By digestion with 3-hydroxyanthranol in boiling acetic acid solution 3 : 3′-dihydroxydianthrone is slowly produced, whereas acetyldihydroxydianthraquinone with chromic acid in the same solvent gives 2-acetoxyanthraquinone. Dihydroxydianthraquinone is more quickly affected by light than the corresponding helianthrone (*loc. cit.*), the pale yellow crystals rapidly becoming orange-coloured, evidently with production first of the latter compound; this change even occurs to some extent during crystallisation from much boiling acetone. Though the diacetyl and dimethyl compounds are less sensitive in the solid condition to light than the corresponding dihydroxy-derivative, after 5 weeks' exposure to light their

* Experiments in progress render it uncertain as to whether the dihydroxydianthranol reacts in these cases as the 3 : 6′-compound as was suggested (*loc. cit.*), but as the work is incomplete such formulæ are still employed for the present.

solutions in benzene had deposited diacetoxynaphthadianthrone and dimethoxynaphthadianthrone containing a little dimethoxyhelianthrone, respectively. It is thus evident that in these circumstances the helianthrone formation precedes that of the naphthadianthrone.

Experimental.

Tetra-acetyldihydroxydianthranol (0·5 g.) dissolved in pyridine (5 c.c.) was treated with a solution of iodine (0·5 g.) in pyridine (5 c.c.) and kept at 80° for 1½ hours. The reddish-brown liquid was poured into a freshly-acidified solution of sodium bisulphite, and the greenish-yellow precipitate collected and dried. On digestion with boiling acetic anhydride and pyridine for about ½ minute, crystals separated and when cold these were collected and recrystallised from much acetic anhydride. The acetyl compound thus produced became greenish-black at about 280°, melted at 293—295° (A), and was unaltered by further recrystallisation from the same solvent. On the other hand, by repeated crystallisation from tetrachloroethane or a mixture of this with acetic anhydride, the melting point rose to 314—316° (B) [Found: (A) C, 76·7; H, 4·2. (B) C, 76·6; H, 4·0; $CH_3 \cdot CO_2H$, 23·9. $C_{32}H_{20}O_6$ requires C, 76·8; H, 4·0; $CH_3 \cdot CO_2H$, 24·0%].

Owing to its sparing solubility in alcohol, the substance for the acetyl determination was dissolved in cold sulphuric acid overnight; the solution was then diluted with alcohol and treated in the usual manner. 3 : 6′-*Diacetoxydianthraquinone* forms small, pale yellow crystals sparingly soluble in the usual solvents, the solutions when hot possessing a green colour which fades on cooling; this property, also possessed by 3 : 6′-dihydroxydianthraquinone, appears to be characteristic of dianthraquinone derivatives. When diacetoxydianthraquinone (0·5 g.) in benzene (200 c.c.) was exposed to light for 5 weeks, it yielded an orange-brown, crystalline deposit (0·37 g.). This, on recrystallisation from nitrobenzene with the aid of animal charcoal, yielded pale yellow needles, melting above 350° and soluble in sulphuric acid with a red coloration, consisting evidently of diacetoxynaphthadianthrone (Found: C, 77·2; H, 3·4. $C_{32}H_{16}O_6$ requires C, 77·4; H, 3·3%).

As diacetoxydianthraquinone could not be satisfactorily hydrolysed with mineral acids, its suspension (1 g.) in boiling alcohol (25 c.c.) was treated with 10% caustic soda solution until all had dissolved. The solution was diluted with boiling water (25 c.c.) and immediately neutralised with hydrochloric acid; * pale yellow leaflets

* This operation must be carried out rapidly, otherwise discoloration is liable to occur.

then commenced to separate. After dilution with hot water (25 c.c.) and cooling, the crystals (yield 96% of theoretical) were collected and washed with a little acetone, which removed a trace of a red impurity (Found: C, 80·8; H, 4·0. $C_{28}H_{16}O_4$ requires C, 80·8; H, 3·8%).

Dihydroxydianthraquinone crystallises from pyridine and water in pale yellow plates which become black at about 280° and scarcely have a definite melting point. It is sparingly soluble in the usual solvents, but dissolves in alkalis with an orange-yellow colour which is fairly permanent in air. With sulphuric acid it gives a maroon-coloured liquid quickly passing to brownish-black and from this, after keeping, water precipitates a brown-black precipitate soluble in alkali with a similar colour. This is reduced by sodium hyposulphite to an orange-yellow liquid which quickly oxidises in air. The boiling ammoniacal solution is quickly decolorised by zinc dust, and on acidification deposits crystals, which give an acetyl compound, m. p. 158—159°, identical with 3-acetoxyanthranol. A solution of dihydroxyanthraquinone (0·2 g.) in absolute alcohol (160 c.c.) rapidly became orange-coloured in sunlight and after 6 weeks' exposure had deposited 0·1675 g. of crystals. These, after acetylation and fractional crystallisation of the product, gave 0·1 g. of diacetoxynaphthadianthrone, m. p. above 350°, and a little diacetoxyhelianthrone, m. p. 275—279°.

Dihydroxydianthraquinone is best kept in the dark, as the crystals become orange-coloured in a few hours, owing evidently to the action of light. Dihydroxydianthraquinone (1 g.) in water (25 c.c.) was dissolved by addition of 10% sodium hydroxide solution (3 c.c.), and 20% potassium ferricyanide (9 c.c.) slowly added in the cold. After 15 minutes, the mixture was acidified and the red precipitate collected (1·03 g.). This, after acetylation and recrystallisation of the product from benzene, gave 0·97 g. of diacetoxyhelianthrone, m. p. 277—279° (Found: C, 76·75; H, 3·6. Calc., C, 77·1; H, 3·6%).

Dibenzoyldihydroxydianthraquinone was obtained by heating dihydroxydianthraquinone (0·5 g.), benzoic anhydride (5 g.), and a trace of pyridine at 210° for 2 hours. Addition of alcohol to the partly cooled liquid caused the deposition of crystals, which were washed with an alcoholic solution of benzoic anhydride and finally with alcohol. The product was dissolved in much boiling benzene, the solution filtered and evaporated, when small, yellow plates separated, which darkened at 295° and melted at 301—302° to a green liquid (Found: C, 80·4; H, 3·8. $C_{44}H_{24}O_6$ requires C, 80·7; H, 3·8%).

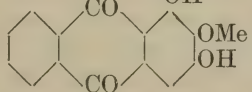
Dimethoxydianthraquinone was prepared by treating the dihydr-

oxy-compound (1 g.) in methyl alcohol (30 c.c.) with equivalent amounts of methyl sulphate and methyl-alcoholic potash, until no colour change occurred on the addition of the latter. After dilution with hot water the crystals (0·85 g.) were collected, washed with cold alcohol, and dissolved in pyridine; the green solution was treated with a little sodium hydroxide, and hot water cautiously added. The crystals were collected and the latter operation, which has for its object the removal of a trace of incompletely methylated substance, was repeated. By recrystallisation from pyridine, the *dimethoxy*-derivative was obtained in small, rectangular, yellow plates which became green at about 270° and melted at 297—299°. On exposure to light it soon develops an orange colour (Found: C, 81·4; H, 4·5; CH_3, 6·7. $C_{30}H_{20}O_4$ requires C, 81·1; H, 4·5; CH_3, 6·75%).

When dimethoxydianthraquinone (1 g.) is dissolved in the necessary amount of boiling acetone in daylight (1300 c.c. approx.), and the solution evaporated to a small bulk, alteration occurs even during this short period and the crystalline deposit can be separated by fractionation from pyridine into (*a*) dimethoxydianthraquinone, m. p. 297—299°, and (*b*) a very sparingly soluble, orange compound (A), which did not melt at 320° dissolves in sulphuric acid with a red coloration and is probably dimethoxynaphthadianthrone. Again, a solution of dimethoxydianthraquinone (0·3 g.) in benzene (100 c.c.) on exposure to light became orange-coloured in about 30 minutes, and commenced to deposit an orange powder. This (0·128 g.), by crystallisation from nitrobenzene, was obtained in microscopic needles, which had not melted at 340° and were soluble in sulphuric acid with a red coloration. An analysis of the small amount of this compound available was unsatisfactory, but there can be little doubt that this and the compound A referred to above, which closely resembled it, consist of *dimethoxynaphthadianthrone*. The benzene filtrate on evaporation to dryness gave a dark-coloured residue which after solution in hot alcohol yielded yellow crystals; these, after purification, were soluble in sulphuric acid with a violet coloration and had the properties of dimethoxyhelianthrone.

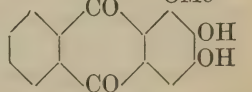
CLOTHWORKERS RESEARCH LABORATORY,
THE UNIVERSITY, LEEDS. [*Received, June 17th,* 1925.]

CCLV.—*A Wandering of the Acetyl Group during Methylation.*



By Onro Kubota and Arthur George Perkin.

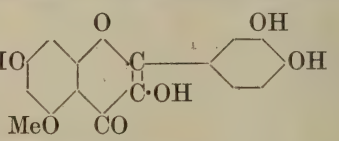
Oesch and Perkin (P., 1914, **30**, 213) submitted monoacetylalizarin (J., 1899, **75**, 433) to the action of diazomethane and after hydrolysis isolated from the product a small amount of alizarin 1-methyl ether (1) identical with that obtained from Chay root (J., 1893, **64**, 1160; 1907, **91**, 2068). Reinvestigation has now shown that, although the 1-methyl ether is always produced in this way, the main product is the 2-methyl ether. Careful examination of the monoacetylalizarin employed in these experiments indicated it to be a single substance, and indeed were this not the case it would be more likely to consist of a mixture of mono- and di-acetylalizarins than of the 1- and 2-acetyl derivatives.* The formation of alizarin 2-methyl ether in these experiments shows that whereas a small portion of the 2-acetylalizarin reacts normally with diazomethane, the acetyl group must wander from the 2- to the 1-position at some stage of the process, and the methyl then enters its place to give 2-methoxy-1-acetoxyanthraquinone; the yield of this is about 80% of the theoretical.



2 : 3-Diacetylanthragallol again, which can be readily obtained by the partial acetylation of anthragallol, on treatment with diazomethane gives as the main product a diacetylanthragallol monomethyl ether which evidently contains the methoxy-group in the 2-position, because the free substance (II), which crystallises in yellow needles, is soluble in dilute alkali with a red coloration similar to that given by purpuroxanthin. The more soluble fraction of the reaction product when hydrolysed gave a mixture from which, by means of the sparing solubility of its ammonium salt, the isomeric ether was isolated. This crystallises in orange-red needles, dissolves in alkali with a deep blue colour, and dyes mordanted calico shades of the alizarin type. It must therefore contain adjacent hydroxyls and is clearly anthragallol 1-methyl ether (III) (1-methoxyhystazarin), for if it were anthragallol

(I.)

(II.)



(III.)

* It is well known that in the anthraquinone series the 2-hydroxyl group is more readily acetylated than the 1-hydroxyl group (compare Dimroth, Friedemann, and Kämmerer, *Ber.*, 1920, **53**, 481).

3-methyl ether (3-methoxyalizarin) its formation would necessitate the respective wandering of the 2- and 3-acetyl groups into the 1- and 2-positions, or of the 3-acetyl group into the 1-position. It is unfortunate that a monoacetylanthragallol has not yet been obtained, for the action of diazomethane thereon should yield one or other of the anthragallol dimethyl ethers referred to above.

In a third series of experiments, tetra-acetylquercetin was employed, a substance which has been prepared by the action of acetic anhydride and sodium acetate on quercetin in the cold. This substance was originally thought (*loc. cit.*) to be the triacetyl derivative, but as a result of the present experiments only 3 : 7 : 3′ : 4′-tetra-acetylquercetin could be obtained. This acetyl derivative required more drastic treatment with diazomethane than was necessary in the case of the hydroxyanthraquinones, and in the product only one tetra-acetylquercetin monomethyl ether could be detected. The almost colourless, sparingly soluble quercetin monomethyl ether obtained by hydrolysis closely resembled, but is not identical with, the quercetin monomethyl ether, rhamnetin, previously studied (J., 1902, **81**, 469). By decomposition with alcoholic potash, it yielded phloroglucinol monomethyl ether, identified as its benzeneazo-compound, and there can be no doubt that this new quercetin methyl ether contains the methoxy-group in the 5-position adjacent to the carbonyl group (IV).

(IV.)

A wandering of the acetyl group does not occur in these circumstances. Interesting is the fact that this 5-methyl ether yields with alcoholic potassium acetate the salt $C_{16}H_{11}O_7K$, for, as quercetin gives a similar compound, it seems clear that the reactive hydroxyl, the position of which has not yet been determined with certainty, cannot be that situated in the 5-position. The wandering of an acetyl group has been observed by Wislicenus and Körner (*Ber.*, 1901, **84**, 218) in the case of the *o*-acetyl derivative of ethyl acetoacetate (compare also Claisen and Haase, *Ber.*, 1900, **33**, 3778), and numerous instances are known of its migration from hydroxyl to the amino-group (Auwers, *Annalen*, 1901, **332**, 159, etc.; Raiford and Couture, *J. Amer. Chem. Soc.*, 1922, **44**, 1792). Very interesting, again, is the work of Fischer, Bergmann, and Lipschitz (*Ber.*, 1918, **51**, 45), who showed that 3 : 4 : 5 : 3′ : 5′-penta-acetyl(para)-digallic acid, when hydrolysed, yields the 3 : 4 : 5 : 3′ : 4′-penta-hydroxy-*m*-digallic acid, a wandering of the galloyl nucleus from

the *p*- to the *m*-position occurring. Again, 3 : 5-diacetyl-4-benzoylgallic acid on hydrolysis in a similar manner yields not the *p*- but the *m*-benzoyl derivative, and a similar change has been observed in the case of 3-acetyl-4-benzoylprotocatechuic acid. Herzig and Tichatschek (*Ber.*, 1908, **39**, 268, 1557) have shown that under the influence of diazomethane the acetyl group in triacetylpyrogallol is partly replaced by methyl, whereas acetylphloroglucinol diethyl ether gives phloroglucinol methyl diethyl ether * in the same circumstances.

p-Acetoxybenzoic and *m*-hydroxybenzoic acids are mainly converted by diazomethane into the corresponding methoxybenzoic acids. The results of this investigation, however, differ † from the cases just mentioned in that the wandering of the acetyl group occurs during methylation itself, and though it was scarcely necessary to do so, this has been proved by an examination of the reaction products of each experiment. It is well known in the case of substances such, for instance, as β-resorcylic acid (J., 1895, **67**, 990), luteolin (J., 1900, **77**, 1316), and quercetin (J., 1913, **103**, 1632), all of which contain meta-hydroxyl, that on methylation with methyl iodide the methyl group in part, rather than substitute the hydrogen of the hydroxyl next to the carbonyl group, actually enters the ring. In the cases of 2-acetylalizarin and of 2 : 3-diacetylanthragallol, this cannot occur, and with 3 : 7 : 5′ : 4′-tetra-acetylquercetin this would appear to be prevented by the presence of the 3-acetyl group.

This curious interchange of methyl and acetyl is without doubt connected with the peculiar property of the hydroxyl adjacent to the carbonyl group,‡ and it has been suggested that this may be due to the existence of the ortho-quinonoid arrangement (V) (*loc. cit.*).

(V.) (VI.)

Dimroth and Faust (*Ber.*, 1921, **54**, 3020) presume that there is an unstable valency between the ketonic oxygen and the

* Experiment has shown that diacetylalizarin is not affected by treatment with diazomethane.

† On the other hand, when 2-acetylalizarin 1-methyl ether is hydrolysed with alcoholic ammonia or with hydrochloric acid the resulting free ether, which when pure is yellow, is always contaminated with a trace of red impurity which may be removed with baryta water. Although a wandering of the methyl group with formation of alizarin 2-methyl ether may be suspected, this is as yet uncertain.

‡ Or, as the result of the work of Fischer (*loc. cit.*), of that in the para-position thereto.

hydrogen of the 1-hydroxyl group, a view also taken by Sidgwick and Callow (J., 1924, **125**, 527), who suppose that a six-membered chelate ring (VI) exists in compounds of this type.

A grouping of this kind evidently does not exist, or is much weakened, when an acyl or an alkyl group is substituted for the hydrogen of the 1-hydroxyl group, since such substances possess the pale yellow colour characteristic of anthraquinone itself, and if this chelate ring is present, the ease or otherwise with which this substitution takes place will depend upon the readiness with which this linking is broken or weakened. It is very difficult to compare the relative facility with which the processes of acetylation and methylation occur, but acetylation of the hydroxyl in the 1-position in the presence of a catalyst takes place so readily that it may be assumed to occur with more facility than the process of methylation. Even if this is so, it is difficult to understand why the acetyl group, which, similarly to the methyl group, favours the 2-position, should wander to the 1-position in the circumstances mentioned above, unless indeed 1-acetylalizarin 2-methyl ether is a more stable substance than 2-acetylalizarin 1-methyl ether.* Experiments to determine whether a conversion of the latter into the former can be effected are in progress, and the behaviour of other acyl groups in similar circumstances is also being studied.

Experimental.

Monoacetylalizarin.—A mixture of commercial alizarin (5 g.), potassium acetate (2·5 g.), and acetic anhydride (25 c.c.) is kept for 24 hours, and then diluted with alcohol. The product, collected after 1 hour and recrystallised repeatedly from alcohol–acetic acid, separates in golden-yellow needles, m. p. 204—206° (Found: $CH_3{\cdot}CO_2H$, 21·0. Calc., 21·3%).

Methylation. Monoacetylalizarin (2 g.) suspended in purified ether (50 c.c.) was mixed with diazomethane from nitrosomethylurethrane (12 c.c.) in ether (200 c.c.). After 5 days, the crystals were collected (1·8 g.) and the mother-liquor was evaporated to dryness; the viscid residue, on digestion with methyl alcohol, deposited a further 0·16 g. of acetylalizarin monomethyl ether (Found: $CH_3{\cdot}CO_2H$, 20·3. $C_{17}H_{12}O_5$ requires $CH_3{\cdot}CO_2H$, 20·2%). After hydrolysis with hydrochloric acid in the presence of acetic acid, the product, which sintered at 170° and melted at 217°, gave, after two or three recrystallisations from alcohol, orange-red needles,

* That the methyl of alizarin 1-methyl ether is loosely held, is evident from the fact that in presence of boiling baryta water, gradual hydrolysis occurs, with formation of barium alizarate.

m. p. 229—230° (Found: C, 70·8; H, 4·05. $C_{15}H_{10}O_4$ requires C, 70·9; H, 3·9%).

The *acetyl* derivative, obtained in yellow needles, melted at 204—206° and there could be no doubt that this, the main product of the reaction, is alizarin 2-monomethyl ether.

The alcoholic filtrate from this substance was evaporated to dryness, the residue dissolved in hot alcohol, and, after the addition of a little ammonia, baryta water was added drop by drop so long as a precipitate, consisting mainly of barium alizarate 2-methyl ether, was formed. This was removed, and on acidifying the bright red filtrate fine, hair-like needles (0·18 g.) separated.* This substance, which became opaque at 100° with loss of water of crystallisation, a characteristic property of alizarin 1-methyl ether, was purified by conversion into the ammonium salt (*loc. cit.*) and recrystallisation from benzene, from which it separated in pale yellow needles, m. p. 179—181° (Found: C, 70·9; H, 4·0. Calc., C, 70·9; H, 3·9%).

Since the acetyl derivative melted at 210—212°, there can be no doubt that this substance was identical with the alizarin 1-methyl ether of Chay root. By fractionally crystallising the diazomethane reaction product of 2-acetylalizarin (2 g.) from a mixture of alcohol and acetic acid, 2-acetylalizarin 1-methyl ether could be isolated in the pure condition (0·3 g. approx.).

Diacetylanthragallol.—A mixture of anthragallol (5 g.), acetic acid (15 c.c.), and acetic anhydride (7 c.c.) was treated in the cold with pyridine (2 c.c.) and kept for about 18 hours. The yellow, crystalline precipitate (5·79 g.) (filtrate A) gave on recrystallisation from acetone 4·3 g. of long, thin plates, m. p. 223—224° (Found: $C_{14}H_8O_5$, 74·4. $C_{18}H_{12}O_7$ requires $C_{14}H_8O_5$, 75·3%).

The filtrate A contained some triacetylanthragallol, which was isolated in a slightly impure condition, m. p. 175—180° (Found: $C_{14}H_8O_5$, 66·9. $C_{20}H_{14}O_8$ requires $C_{14}H_8O_5$, 67·02%).

Methylation. Diacetylanthragallol (2 g.), in ether (50 c.c.) cooled by ice, was treated with diazomethane from nitrosomethylurethrane (8 c.c.) in ether (250 c.c.), and the mixture kept for 2 days. The crystalline suspension (1 g.), after being washed with ether, melted at 145—152°. The filtrate, washed with a little 1% sodium hydroxide solution and partially evaporated, gave 0·75 g. of crystals (filtrate A). By recrystallisation from acetone, large, yellow, prismatic needles were obtained, m. p. 152—154° (Found: C, 64·55; H, 4·15; CH_3, 4·3. $C_{19}H_{14}O_7$ requires C, 64·4; H, 3·95; CH_3, 4·23%).

Hydrolysis with hydrochloric acid in acetic acid solution gave

* In a second experiment 4 g. of monoacetylalizarin gave 0·32 g. of alizarin 1-methyl ether.

78·5% of a yellow, crystalline precipitate which separated from much benzene as a spongy mass of microscopic needles, m. p. 218—220° (Found: C, 66·9; H, 3·7; CH_3, 5·55%).

This substance dissolves in dilute alkali with a scarlet colour and is evidently *anthragallol 2-monomethyl ether*, since the alkali solutions of anthragallol 1- and 3-methyl ethers have a blue or bluish-violet tint. The filtrate A was evaporated to dryness and the residue dissolved in hot alcohol mixed with a few drops of ammonia. On keeping, violet-black crystals of an ammonium salt separated which, on drying at 100°, evolved ammonia, yielding an orange-red mass. By recrystallisation from alcohol, this gave red needles (0·3 g.), m. p. 239—241° (Found: C, 66·6; H, 3·9; CH_3, 5·6. $C_{15}H_{10}O_5$ requires C, 66·7; H, 3·7; CH_3, 5·55%).

It dissolves in dilute alkalis with a deep blue colour and dyes mordanted wool the following alizarin-like shades: *chromium*, violet-maroon; *aluminium*, pale maroon; *tin*, orange-red; *iron*, dead black. The diacetyl derivative, obtained as fine, flat, yellow needles, melted at 203—205° (Found: C, 64·5; H, 4·2. $C_{19}H_{15}O_7$ requires C, 64·4; H, 3·95%).

For reasons given in the introduction, this compound is evidently *anthragallol 1-methyl ether*.

Tetra-acetylquercetin.—A mixture of monopotassium quercetin (10 g.) and acetic anhydride (100 g.) was kept for 2 hours. The semi-solid mass was mixed with alcohol; the crystals were then collected and recrystallised from alcohol–acetic acid until the melting point of the colourless, silky needles was constant at 188—190° (Found: $C_{15}H_{10}O_7$, 64·4. $C_{23}H_{18}O_{11}$ requires $C_{15}H_{10}O_7$, 64·25%).

Methylation. Tetra-acetylquercetin suspended in ether was very little attacked by diazomethane and after keeping for 2 days contained only 1·08% of methyl. Better results were obtained by treating the substance (2 g.), dissolved in tetrachloroethane (10 c.c.), with the diazomethane from nitrosomethylurethane (8 c.c.) in ether (125 c.c.). After 4 days, the crystalline deposit (1·7 g.) was collected, and from the filtrate, by removal of the ether by evaporation and the tetrachloroethane by distilling with steam, a colourless, viscid product was isolated from which, by solution in hot alcohol and keeping, a second crop of crystals was obtained. The product was hydrolysed with hydrochloric acid in the usual manner and the precipitate, which consisted largely of an oxonium salt, was repeatedly washed with water to decompose the latter. The product was then dissolved in much alcohol, the solution concentrated until crystallisation commenced, and the operation repeated. The *quercetin monomethyl ether* separated in prismatic

needles, m. p. 305—308° (Found: C, 60·65; H, 4·2; CH_3, 4·2. $C_{16}H_{12}O_7$ requires C, 60·75; H, 3·8; CH_3, 4·6%).

This methyl ether closely resembles rhamnetin (*loc. cit.*) as regards its sparing solubility in solvents, but, on the other hand, it is almost colourless, whereas rhamnetin is yellow. Dilute alkalis dissolve it with an orange coloration and on hydrolysing its acetyl derivative with mineral acids, orange-red oxonium salts can be obtained which crystallise in needles.

The *tetra-acetyl* derivative crystallises from acetone in minute, colourless needles which sinter at 199° and melt at 202—204° (Found: C, 59·5; H, 4·2. $C_{24}H_{20}O_{11}$ requires C, 59·5; H, 4·1%).

Only by very slow deposition from a mixture of acetic anhydride and alcohol can the acetyl derivative be obtained in fair-sized, prismatic needles, whereas acetylrhamnetin crystallises readily in long needles, m. p. 191—193°. When the acetyl compound was digested with boiling alcoholic potassium acetate, lemon-yellow needles of the *monopotassium* salt were gradually deposited, and these were washed with alcohol (Found: K, 11·1. $C_{16}H_{11}O_7K$ requires K, 11·0%).

This potassium salt dissolves in boiling water to form a pale yellow solution, from which on rapid cooling it separates unchanged. On longer digestion, however, some hydrolysis occurs with deposition of the quercetin methyl ether, though it is more resistant to hydrolysis than monopotassium quercetin itself.

The hydrolysis of the quercetin monomethyl ether was effected by heating with methyl-alcoholic potash at 180° for 3 hours. The product freed from alcohol was dissolved in water, and the solution acidified, filtered, and extracted with ether; the syrupy residue obtained by evaporation was then dissolved in sodium bicarbonate solution, and again extracted with ether. The viscid product thus isolated gave with diazobenzene in presence of sodium carbonate a dull red precipitate, which was dried, extracted with boiling alcohol to remove resin, and then crystallised from alcohol–acetic acid. The glistening, orange-red crystals, m. p. 253—255°,* evidently consisted of benzeneazophloroglucinol monomethyl ether. In a second experiment air was aspirated through a dilute alkaline solution of the quercetin methyl ether and, from the brown liquid, phloroglucinol monomethyl ether could again be isolated in the form of its benzene azo-compound.

For reasons given in the introduction, this quercetin monomethyl ether must contain the methoxy-group in the position 5, adjacent to the carbonyl group (IV). The methylation of this hydroxyl

* The m. p. 250—252° previously given for this compound (*loc. cit.*) is slightly too low.

group has no influence on the tinctorial property of quercetin, as dyeing experiments employing mordanted woollen cloth show: *chromium*, red-brown; *aluminium*, orange-yellow; *tin*, bright orange; *iron*, olive-black.

These shades were identical with those given by a sample of quercetin dyed at the same time (J., 1902, **81**, 473) and as quercetin and rhamnetin dye alike (Perkin and Allison) there can be no doubt that the phloroglucinol hydroxyl groups of quercetin do not affect its tinctorial property.

CCLVI.—*Hydrogen and Oxygen Electrode Titrations of Some Dibasic Acids and of Dextrose.*

By HUBERT THOMAS STANLEY BRITTON.

APART from the recent work of Auerbach and Smolczyk (*Z. physikal. Chem.*, 1924, **110**, 83), the study of the ionisation of dibasic acids has been confined to solutions containing (*a*) the free acids and (*b*) the acid salts only, instead of to solutions which are typical of the whole courses of neutralisation. Hildebrand (*J. Amer. Chem. Soc.*, 1913, **35**, 847) obtained several titration curves with the hydrogen electrode, but as he used fairly concentrated solutions and appears to have aimed at an accuracy in his *E.M.F.* measurements of about a centivolt, his curves are useless for the purpose of calculating dissociation constants.

Auerbach and Smolczyk used the quinhydrone electrode in their titrations and derived formulæ by which the dissociation constants could be calculated from their data. Although their equations are based on the assumption that the salts formed in dilute solutions may be taken as being completely dissociated, they used $N/10$-acid and $N/8$-alkali solutions. The amounts of alkali used in their titrations were very small, being as a rule only 8 c.c. It is remarkable that such fundamental titrations should have been carried out with an electrode other than the hydrogen electrode. Some time before the appearance of Auerbach and Smolczyk's paper, the author had used the hydrogen electrode to titrate solutions of acids which were more dilute and required much larger volumes of alkali. Those titrations had been made for the purpose of comparing them with those given by oxygen electrodes; as the accuracy of the voltages obtained with the hydrogen electrode was of the order of a millivolt, it was considered that the curves would furnish an excellent

method of testing the applicability of the formulæ of Auerbach and Smolczyk.

The titration of dextrose has been included in this communication as it is of importance in connexion with some work to be published later.

Experimental.

Part I. *The Hydrogen Electrode.*

The problem of preparing hydrogen electrodes which are immediately sensitive to changes in hydrogen-ion concentration has been one of some difficulty, and this appears to have been the experience of previous experimenters. Thus Böttger (*Z. physikal. Chem.*, 1897, **24**, 251), who first used the hydrogen electrode for titration work, failed to obtain good results with platinised platinum and resorted to gold electrodes coated with palladium black. Andrews (*J. Biol. Chem.*, 1924, **50**, 479) has, however, found palladium black on platinum to be less trustworthy than platinum black. Treadwell and Weiss (*Helv. Chim. Acta*, 1920, **2**, 433) stated that the ordinary platinum electrode required too much time to come to equilibrium to be of use in titrations, and they also preferred palladinised gold.

For ordinary purposes, there is no doubt that the hydrogen electrode when made of platinised platinum does attain, if given sufficient time, true equilibrium, independent of the depth of the platinum black layer. Platinum foil electrodes having a thick coating of platinum black require, in general, an appreciable time before the true *E.M.F.*'s are attained, and are therefore unserviceable for titrations. The efficient electrodes which have been prepared have invariably been made of highly polished platinum foil covered with thin deposits of platinum black such as may be deposited from the usual platinising solution in 5 minutes, the current being reversed every half-minute and a vigorous evolution of gas maintained. Half a dozen electrodes were prepared at a time from which were chosen two electrodes which gave the same *E.M.F.* within a millivolt throughout the entire titration. These two electrodes were used together and the results were taken as accurate if they showed the same *E.M.F.* immediately the current of hydrogen was stopped. Other efficient electrodes were always kept in readiness in case one suddenly became erratic or sluggish, which was especially apt to occur when the electrode was being subjected to a rapid change in hydrion concentration.

The electrodes were of the Hildebrand pattern (*loc. cit.*) and the titrations were performed in the way described previously (J., 1924, **125**, 1576). The results obtained are given in the first two

columns of Tables I—V, the *P.D.*'s being recorded to the nearest millivolt.

The third column of each table gives the p_H calculated by means of the Nernst formula. The figures in the remaining columns of the first four tables were obtained on the assumption that the alkali (up to the first equivalent) reacted only with the hydrions arising from the first stage of ionisation and that thereafter it reacted (to the second equivalent) with those from the second dissociation. This assumption, of course, is only justifiable when K_1 is much greater than K_2, but the figures so obtained do give some idea of the process of neutralisation in the cases where the ratio of K_1 to K_2 is small. The fourth columns relating to the first halves

of the titrations therefore contain the concentration of acid minus that which was supposed to be converted into the acid salt. The degree of dissociation, α, of the free acid given in the fifth column, was obtained by dividing the hydrogen-ion concentration by the concentration of the acid. Column 6 gives the concentration of undissociated acid. The concentrations of HR′ ions given in the next column represent the sum of the concentrations of NaHR (taken as completely dissociated into $Na^{\cdot}$ and HR′) and the HR′ ions from the free H_2R. In the last column the values of K_1 ($=[H^{\cdot}][HR']/[H_2R]$ are given.

If the first equivalent of alkali be regarded as producing acid

salt only, the addition of further alkali will convert equivalent amounts into Na_2R. Then $K_2 = [H^\cdot][R'']/[HR']$ may be calculated if the NaHR and Na_2R be taken as either completely or equally dissociated into $Na^\cdot$ and HR′, and $2Na^\cdot$ and R″ respectively, in which case $K_2 = [H^\cdot](x - y/2)/(y - x)$, where x is the number of c.c. of NaOH added, and y the number of c.c. required for neutralisation. For the second half of the titrations, the fourth and fifth columns give the number of c.c of alkali, $(y - x)$ and $(x - y/2)$ respectively, which are proportional to the respective concentrations of NaHR and Na_2R. The values of K_2 thus found are given in the last column.

The titration curves together with that of dextrose are given in Fig. 1. The curve of the latter shows that dextrose had the effect of depressing the alkalinity of the added sodium hydroxide. The monobasic acid nature of dextrose, $C_6H_{12}O_6 \rightleftharpoons H^{\cdot} + C_6H_{11}O_6'$, is revealed in the formation of salts with the alkali metals. The dissociation constant, $K = [H^{\cdot}][C_6H_{11}O_6']/[C_6H_{12}O_6]$, has been calculated from the various observations made during the titration.

* Omitted in calculating mean.

As the solution remained appreciably alkaline throughout the titration, it was evident that some of the sodium hydroxide had remained uncombined, the concentrations of which were found from the hydrion data, and were equal to $K_w/[H^\cdot]$, K_w at 18° being $10^{-14\cdot14}$, if the dissociation of the alkali be assumed complete.

These concentrations are given in the fourth column, and as the combined concentrations of the sodium hydroxide and the sodium salt of dextrose were equal to the sodium concentrations produced by the added alkali, given in the fifth column, the actual concentrations of sodium glucoside were known (column 6). Then, as the concentrations of sodium glucoside were very small, it followed that these concentrations were very nearly those of the glucoside ion. Thus by knowing the concentrations of undissociated glucose, which in the circumstances were equal to those of unattacked glucose, the affinity constant was found. It will be seen that, except in the first two values, which can only be regarded as approximate in view of the rapid change in hydrion concentration which was then taking place, the values are in fairly good agreement, the average being 5·77 × 10^{-13}. The acid nature of glucose has been previously studied by Cohen (*Proc. K. Akad. Wetensch. Amsterdam*, 1900, **2**, 628) and by Madsen (*Z. physikal. Chem.*, 1901, **36**, 290), both of whom measured the rate of saponification of ethyl acetate by alkaline solutions of dextrose. From the data obtained by the former worker, Osaka (*Z. physikal. Chem.*, 1900, **35**, 673) showed that,

if dextrose be regarded as a monobasic acid, $K = 5{\cdot}9 \times 10^{-13}$, and Euler (*Ber.*, 1906, **39**, 344), using the latter's observations, obtained a value $K = 3{\cdot}6 \times 10^{-13}$ at 18°. Later, Michaelis and Rona (*Biochem. Z.*, 1913, **49**, 248), measuring the p_H values of some alkali–dextrose solutions with the hydrogen electrode, found $K = 6{\cdot}6 \times 10^{-13}$.

FIG. 1.

Calculation of the Dissociation Constants of Dibasic Acids from Titration Curves.

The following equations are based on the mass law and apply to solutions which are so dilute that the sodium salts may be taken as completely dissociated. The equations, however, differ from those of Auerbach and Smolczyk (*loc. cit.*) in that no approximations have been introduced.

Let c = the total concentration of acid, a = total concentration of added alkali, and h = hydrogen-ion concentration. A dibasic acid, H_2R, dissociates thus :

(i) $H_2R \rightleftharpoons H^{\cdot} + HR'$ (ii) $HR' \rightleftharpoons H^{\cdot} + R''$,

such that $K_1 = h[HR']/[H_2R]$ and $K_2 = h[R'']/[HR']$. Then $[H_2R] + [HR'] + [R''] = c$ and $[HR'] + 2[R''] = a - h$. By eliminating the unknowns from these four equations, it is found that

$$K_1 = h^2(a + h)/\{K_2(2c - a - h) - (ah + h^2 - hc)\} \quad \ldots\ldots\ldots (1)$$

$$K_2 = \{h^2(a + h) + K_1(ah + h^2 - hc)\}/K_1(2c - a - h) \quad \ldots\ldots (2)$$

Putting $a_n h_n + h_n^2 - h_n c_n = A_n$, $2c_n - a_n - h_n = B_n$, and $h_n^2\,(a_n + h_n) = D_n$,

then

$$K_1 = D_n/(K_2B_n - A_n) \text{ and } K_2 = (D_n + K_1A_n)/K_1B_n.$$

Hence, by taking any two points on the titration curve whose parameters are respectively A_1, B_1, D_1, and A_2, B_2, D_2, the values of K_1 and K_2 can be found.

Thus

$$K_1 = (B_1D_2 - B_2D_1)/(A_1B_2 - A_2B_1) \quad \ldots\ldots\ldots (3)$$

$$K_2 = (A_1D_2 - A_2D_1)/(B_1D_2 - B_2D_1) \quad \ldots\ldots\ldots (4)$$

Many of the values of K_2 for dibasic acids have hitherto been obtained from determinations of the hydrogen-ion concentrations of solutions of the acid salts and calculated by means of a formula, worked out by Noyes (*Z. physikal. Chem.*, 1893, **11**, 495), identical with (2), for when $a = c$, as is the case with an acid salt, NaHR, the equation becomes

$$K_2 = h^2(c + K_1 + h)/K_1(c - h) \quad \ldots\ldots\ldots (5)$$

A disadvantage of using the acid salt only is that the dissociation of the acid to the second stage in such a solution is often very small and consequently necessitates an accuracy in the measurements of the hydrion concentration which is rarely obtained. Another drawback is that the formula involves K_1.

Auerbach and Smolczyk used the supposed identity $K_1K_2 = h^2_{x_{a_1/2}}$ as a criterion of the accuracy of the values of K_1 and K_2 calculated from their formulæ. It seems hardly necessary to state that the hydrogen-ion concentrations of dilute solutions of acid salts, or of solutions undergoing titration when half the total amount of alkali has been added, are functions of the concentrations of the salts. The measurements of Drucker (*Z. physikal. Chem.*, 1921, **96**, 419) show that at 20° the p_H of solutions of potassium hydrogen tartrate varies from 3·47 in 0·025M-solution to 3·55 in 0·01M-solution and to 3·93 in 0·001M-solution. Such variations render the above relationship useless, especially when applied to Auerbach and Smolczyk's titrations in which the concentration of acid salt was 0·036M-$NaHC_4H_4O_6$ at the mid-point of the tartaric acid titration. It follows also from equation (5) that K_1K_2 can be equal to h^2 only

when the expression $(c + K_1 + h)/(c - h)$ is equal to unity, *i. e.*, when $K_1 = -2h$. This condition can never be obtained, and, as the data given in this paper show, the expression rarely even approximates to 1, except where K_1 is negligibly small compared with c, as in the case of succinic acid.*

* The author's attention has been directed to the following. If the supposed identity, $K_1K_2 = h^2$, be substituted in Noyes's equation, it follows that K_1 must be equal to $4K_2$. As a rule, K_1 is greater than $4K_2$, but it will be observed from the following tables that in the cases of succinic and tartaric acids, where the ratio $K_1 : K_2$ is not considerable, the product K_1K_2 is only a little greater than h^2.

Table VI gives the values of the dissociation constants of oxalic acid calculated from the data of pairs of typical points on the titration curve from equations (3) and (4). The values recorded in Table I for the appropriate stages of the titration are also given for comparison. Auerbach and Smolczyk did not use their formula for oxalic acid, as they considered it to be too strong an acid. In Tables VII, VIII, and IX, the values of K_1 and K_2 are given for tartaric, succinic, and malonic acids respectively, as calculated from formulæ (3) and (4), also from those of Auerbach and Smolczyk, together with the comparable values already given in Tables II to IV.

Discussion.

It will be seen from Tables I and VI that the first stage of dissociation of oxalic acid is that of a strong acid and consequently does not rigidly obey the mass law. Chandler (*J. Amer. Chem. Soc.*, 1908, **30**, 705), however, found by the conductivity method that K_1 at 25° was equal to $3{\cdot}8 \times 10^{-2}$, and Drucker (*Z. physikal. Chem.*, 1920, **96**, 381) obtained a mean value $5{\cdot}7 \times 10^{-2}$ at 18°, the actual values varying from 5·2 to $8{\cdot}3 \times 10^{-2}$. The values of K_1 given in Table IV are much higher than these and, as Table I shows, correspond to a degree of dissociation of 0·89. For the value of K_1 to have been that obtained by Drucker, the *P.D.* for the free acid should have been 4 millivolts greater. The *E.M.F.* here recorded has, however, been obtained repeatedly. The values of K_1 given in Tables I and VI are fairly concordant over the first part of the titration, but, as Table I shows, α began to increase after 10 c.c of alkali had been added, due to the appearance of hydrions from the second stage of ionisation. The values of K_1, 0·15 and 0·16, calculated by means of equation (3) from the respective pairs of points, 15, 35 and 20, 30, show that a part only of the change in hydrion concentration thereafter was due to dissociation in the first stage.

The values of K_2 for oxalic acid calculated by the two methods at the different stages of the titration are in good agreement, although the value $1{\cdot}05 \times 10^{-4}$ obtained at 30 c.c. (Table I) is somewhat low. The value of K_2 obtained from the points 0 and 25·5 is also low, and it is at this point that equation (4) becomes, in effect, the well-known Noyes equation. The values of K_2 found in the later stages of the titration show a tendency to increase, which is no doubt largely due to the neglected ionisation of the acid and normal salts formed. The first four low values of K_2 given in Table I for the first part of the second half of the titration appear to be due to the fact that all the ions arising from the first stage of dissociation had not been neutralised. The last two values of K_2 in Table I are merely approximate, for, as the curve shows, they refer to a stage in the titration during which an exceedingly rapid change in hydrogen-ion concentration was taking place. From the values of the constants K_1 and K_2 given in Tables I and VI it will be seen that at the beginning of the titration the first dissociation only came into play, in the middle portion, represented in the diagram by the inflexion, both stages of dissociation were affected, and in the last third of the titration the second stage of dissociation alone functioned.

The average value of K_1 for oxalic acid is 0·17 and of K_2, $1{\cdot}34 \times 10^{-4}$, and therefore $K_1 = 1269\ K_2$. Chandler obtained values of K_1 ranging from $840K_2$ to $1087\ K_2$; and Drucker's values of K_2

ranged from 1·5 to 9 × 10^{-5}, the average value being 6·9 × 10^{-5}, and thus $K_1 = 825K_2$, the actual values ranging from $3800K_2$ to $650K_2$. The value now found for K_2 is thus somewhat higher than the value obtained hitherto, but it does account for the changes in hydrion concentration which take place during the process of neutralisation within narrow limits. The great difference in the two dissociation constants explains why they may be calculated in the manner adopted in Table I from the data given in the first and the last stage of the titration.

The data given in Table VII for the dissociation constants of tartaric acid calculated from formulæ (3) and (4), and from those of Auerbach and Smolczyk, show that more consistent values are obtainable from the former equations. Several values have been calculated by means of the equations given in this paper for which no corresponding values from Auerbach and Smolczyk's formulæ have been given, their formulæ having been designed for pairs of points, one on each side of the mid-point. The values of K_1 give a mean of 1·27 × 10^{-3} when calculated from equation (3) and 0·94 × 10^{-3} by Auerbach and Smolczyk's formula, and $K_2 =$ 9·65 × 10^{-5} and 10·35 × 10^{-5} by the respective methods. Taking K_1 and K_2 as 1·27 × 10^{-3} and 9·65 × 10^{-5} respectively, $K_1 = 13K_2$, and thus it becomes clear why the points 0 and 15 could be employed to calculate the value of K_2, as an appreciable quantity of the normal salt must have then been formed. The last two sets of data show that the extent to which the change in p_H between the points 0 and 5 was governed by K_2, and between the points 40 and 45 by K_1, was so small that satisfactory values of the respective constants could not be calculated.

Auerbach and Smolczyk found from their curve, $K_1 = 8{\cdot}96 \times 10^{-4}$ and $K_2 = 7{\cdot}46 \times 10^{-5}$ at 20°, and therefore $K_1 = 12K_2$. Other workers have found for K_1, 9·7 × 10^{-4} at 25° (Ostwald, *Z. physikal. Chem.*, 1889, **3**, 369; Walden, *ibid.*, 1891, **8**, 483) and 1·17 × 10^{-3} (Drucker, *ibid.*, 1920, **96**, 382), and the values of K_2 range from 2·9 to 6·9 × 10^{-5} (Smith, *ibid.*, 1898, **25**, 260; Wegscheider, *Monatsh.*, 1902, **23**, 635; McCoy, *J. Amer. Chem. Soc.*, 1908, **30**, 694; Datta and Dhar, J., 1915, **107**, 824; Paul, *Z. Elektrochem.*, 1915, **21**, 552; 1917, **23**, 70; *Z. physikal. Chem.*, 1924, **110**, 417; Drucker, *loc. cit.*; Larsson, *Z. anorg. Chem.*, 1922, **125**, 281). The values of K_1 given in Table II are approximately true for the first three readings, and the highest values of K_2 are a little lower than the actual value.

There seems to be little difference between the respective values of K_1 and K_2 for succinic acid (Table VIII) as calculated by the two methods. The values based on the assumptions made in Table III

for the first part of the titration, even in the initial stages, appear to be somewhat too high, and those for the main portion of the second stage of the titration to be a little too low. The values obtained for the middle part of the titration are erratic. Excluding the values of K_1 and K_2 given in brackets in Table VII, which were obtained from pairs of points each lying in the extreme halves of the curves, $K_1 = 9{\cdot}21 \times 10^{-5}$ and $K_2 = 5{\cdot}30 \times 10^{-6}$ and therefore $K_1 = 17K_2$; and it happens that the mean values given by Auerbach and Smolczyk's formulæ give the same relationship. Auerbach and Smolczyk obtained from their titration data at 20° $K_1 = 6{\cdot}86 \times 10^{-5}$ and $K_2 = 3{\cdot}97 \times 10^{-6}$, whereas previous workers have found $K_1 = 6{\cdot}55 \times 10^{-5}$ at 25° (Ostwald, *Z. physikal. Chem.*, 1889, **3**, 272; White and Jones, *Amer. Chem. J.*, 1910, **44**, 197) and values for K_2 ranging from 2·2 to 4·3 $\times 10^{-6}$ (Noyes, *Z. physikal. Chem.*, 1893, **11**, 495; Smith, *loc. cit.*; Datta and Dhar, *loc. cit.*; Chandler, *loc. cit.*; Larsson, *loc. cit.*). The data of Chandler show a variation in the ratio of K_1 to K_2 from 15·5 to 26·6.

Contrary to the good agreement between the values for K_1 for succinic acid obtained by the two methods of calculation, Table IX, referring to malonic acid, shows that whereas concordant values are given by equation (3) and Table IV, the values calculated from Auerbach and Smolczyk's formula are low and increase as the points from which they were calculated approach the mid-point of the curve. The values of K_2, however, found by each of the three methods are in good agreement. Taking $K_1 = 2{\cdot}02 \times 10^{-3}$ and $K_2 = 4{\cdot}41 \times 10^{-6}$, it follows that $K_1 = 476K_2$, as compared with Chandler's results at 25°, which show a variation of K_1 from $357K_2$ to 493 K_2 when the latter constant was determined by McCoy's partition method, whereas K_1 is given as $1{\cdot}58 \times 10^{-3}$, which was also obtained by Ostwald (*loc. cit.*), and K_2 as $2{\cdot}1 \times 10^{-6}$, from conductivities, and thus $K_1 = 752K_2$. Other values are: K_1, $1{\cdot}61 \times 10^{-3}$ at 25° (White and Jones, *loc. cit.*) and K_2, $1{\cdot}41 \times 10^{-6}$ at 25° (Datta and Dhar, *loc. cit.*).

It was mentioned on p. 1904 that Auerbach and Smolczyk used the expression $K_1K_2 = h^2$, where h was the hydrogen-ion concentration at the point of half neutralisation, and this could only be true if $(c + K_1 + h)/(c - h)$ in the expression $K_2 = h^2 (c + K_1 + h)/K_1(c - h)$ was equal to unity. Putting $\lambda = (c + K_1 + h)/(c - h)$, then $K_1K_2 = \lambda h_2$.

Table X gives the values of λ as calculated from (*a*) the data obtained at the mid-points of the titrations, the mean values of K_1 obtained from formula (3) being used, (*b*) the products K_1K_2 divided by h^2, the constants having been calculated from equations (3) and (4), λ_B, and (*c*) the products K_1K_2 divided by h^2, the constants used

being those found by Auerbach and Smolczyk's formulæ, λ_A. The numbers given in brackets show the variations in the products and the corresponding changes produced in the values of λ.

TABLE X.

			Form. 3 and 4.		A. & S.'s form.	
Acid.	h^2.	λ.	K_1K_2.	λ_B.	K_1K_2.	λ_A.
Oxalic	$1{\cdot}76\times10^{-6}$	10·1	$2{\cdot}28\times10^{-5}$	13·0	—	—
			(1·83—2·52)	(10·4—14·3)		
Tartaric	$1{\cdot}13\times10^{-7}$	1·10	$1{\cdot}23\times10^{-7}$	1·09	$0{\cdot}97\times10^{-7}$	0·86
			(1·11—1·29)	(0·98—1·14)	(0·64—1·17)	(0·57—1·04)
Succinic	$3{\cdot}44\times10^{-10}$	1·01	$4{\cdot}88\times10^{-10}$	1·42	$4{\cdot}72\times10^{-10}$	1·37
			(3·46—5·50)	(1·01—1·60)	(4·07—5·91)	(1·18—1·72)
Malonic	$6{\cdot}11\times10^{-9}$	1·12	$8{\cdot}90\times10^{-9}$	1·45	$7{\cdot}18\times10^{-9}$	1·17
			(6·89—11·46)	(1·13—1·87)	(4·27—8·51)	(0·70—1·39)

It is evident from the table that only in the case of succinic acid does $\lambda = 1$; the expression $(c + K_1 + h)/(c + h)$ shows that this can be so only when K_1 is exceedingly small and h has become correspondingly small, such as happens to be the case with succinic acid. For the other acids, both K_1 and h are sufficiently large compared with c to render λ appreciably greater than 1, the extreme case being that of oxalic acid, for which $\lambda = 10$. The values of λ_B, whilst being of the same order as λ, show some variations which are due largely to the neglect of the ionisation of the salts formed during the titrations. The values of λ_A show similar, although somewhat greater variations, and these are caused by errors due both to dissociation and to the fact that the Auerbach–Smolczyk formulæ do not yield satisfactory results for K_1 when it happens to be fairly large, *e. g.*, of the order of 10^{-3}.

By an approximate mathematical analysis Auerbach and Smolczyk have shown how the character of the titration curves is determined by the ratio of their dissociation constants. Thus when K_1 is greater than $16K_2$ the curve will have an inflexion in the middle, whereas when $K_1 = 16K_2$ the curve will be a straight line, and when K_1 is less than $16K_2$ the curve will be similar to that of a monobasic acid. The curves of oxalic and malonic acids, the second dissociation constants of which are considerably less than $1/16K_1$, *viz.*, 1/1269 and 1/476 respectively, have each large inflexions (Fig. 1), whereas in that of succinic acid an exceedingly small inflexion is perhaps just discernible, and the curve for tartaric acid ($K_1 = 13K_2$) is straighter.

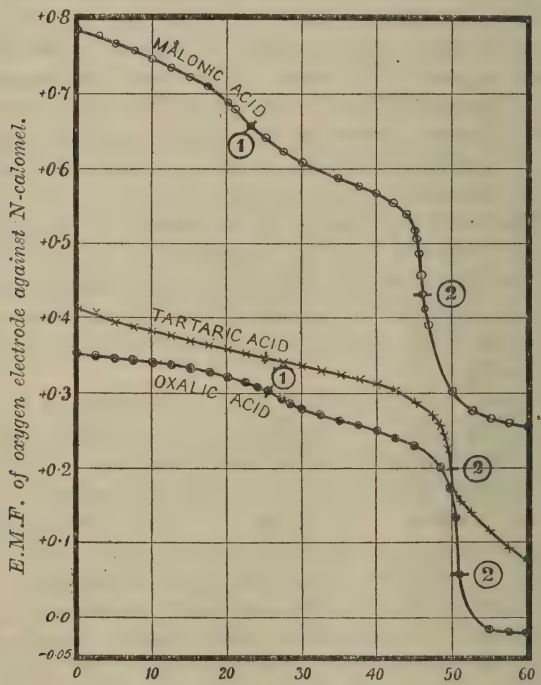
It is striking that the first two members—oxalic acid and malonic acid—of the saturated dibasic acid series,

$$HO_2C{\cdot}[CH_2]_n{\cdot}CO_2H,$$

should exhibit such a great difference in their two dissociation

constants, in each case the first constant being several hundred times the second, as compared with the next member, succinic acid, the first constant of which is only seventeen times the second. The dissociation constants found by Chandler (*J. Amer. Chem. Soc.*, 1908, **30**, 713) for the remaining members of the series up to sebacic acid, $n = 8$, reveal the remarkable fact that the values of K_2 from malonic acid upwards are all approximately equal and of the order 10^{-6}, and that there is only a small diminution in K_1 of the ascending acids of the series, but they are all of the order given by succinic acid, *viz.*, 10^{-5}. Hence the titration curves of these acids will be similar to that of succinic acid and, in fact, almost coincident with it.

The views relating to the acidity of dibasic acids held at the present time appear to be those which were first enunciated by Ostwald (*Z. physikal. Chem.*, 1892, **9**, 553) and are based on the electrostatic charges carried by the various ions and the influence that may be exerted by virtue of the proximity of the carboxyl groups. He considered that in the ionisation of a dicarboxylic acid the negative charge carried by the anion, arising from the first dissociation, exerted a force of repulsion on the negative charge carried by the other carboxyl group and that the nearer one carboxyl group was to the other the greater would be this repulsive force, which would therefore tend to prevent the ionisation proceeding to the second stage.



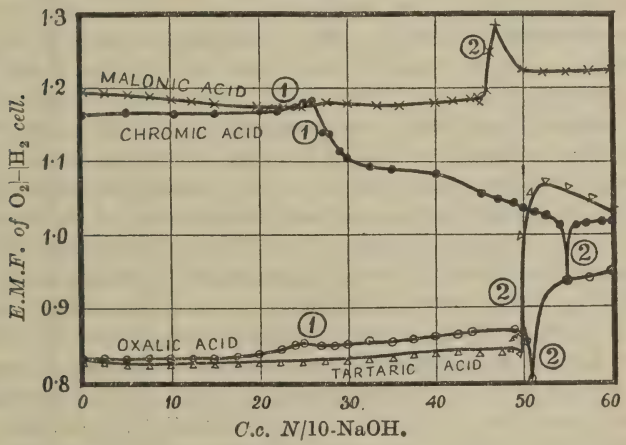
The examples which Ostwald gave were those of fumaric and maleic acids and thus the hypothesis gave excellent support to the van 't Hoff theory accounting for their structure. The hypothesis does not, however, obtain such a marked success when applied to the series in question. It does seem to hold when applied to the first two acids—oxalic and malonic—but it is difficult to see why the interposition of a further methylene group in the case of succinic acid should have such a considerable effect in making K_1 approach K_2 in magnitude. It would have been expected, moreover, that as the chain of methylene groups became longer and longer and the repulsive force between the negative charges held by the carboxyl groups grew less and less, the second stage of dissociation would have become greater and greater, gradually becoming equal to the very slowly decreasing K_1, instead of remaining unchanged.

Part II. *Oxygen Electrode Titrations.*

For the purpose of examining more closely the behaviour of the oxygen electrodes during titrations, three of the acid solutions titrated with the hydrogen electrode were chosen, for their titrations involved changes in hydrogen-ion concentrations which extended over the whole acid zone. 100 C.c. each of 0·0230*M*-malonic acid,

0·0250*M*-tartaric acid, and 0·0255*M*-oxalic acid were titrated at 18° with *N*/10-sodium hydroxide, the oxygen electrode being used in the way outlined in an earlier paper (Britton, J., 1924, **125**, 1572). Observations were made similar to those in the titrations of chromic acid (*loc. cit.*) regarding the initial *E.M.F.*'s, which were again independent of the nature of the acid, and to some extent independent of the initial hydrogen-ion concentration of the solution. As a rule, no two oxygen electrodes ever gave the same *E.M.F.*'s

FIG. 2.



when immersed in the same solution. Typical titration curves are given in Fig. 2, the ordinates being the observed *P.D.*'s between the oxygen electrode and the normal calomel electrode, and the abscissæ the amount of alkali added. The three titrations were made on successive days with the same electrode, of the Hildebrand type but having a platinised platinum wire instead of foil, and were carried out in the order malonic, tartaric, and finally oxalic acid. As the electrode became more and more aged, the *E.M.F.* readings became less positive. The electrodes also tended to become more

and more erratic after having been subjected to rapid changes in hydrion concentration.

Comparison of Oxygen and Hydrogen Electrode Curves.

In the previous paper it was pointed out that, if the oxygen electrode behaved ideally, the algebraic differences between the *E.M.F.*'s given by the oxygen electrode and by the hydrogen electrode at comparable stages of a titration should remain constant, these differences being the *P.D.*'s of the oxygen–hydrogen cell in the various solutions. These differences have been ascertained for each of the three titrations and are plotted in Fig. 3.

Fig. 3.

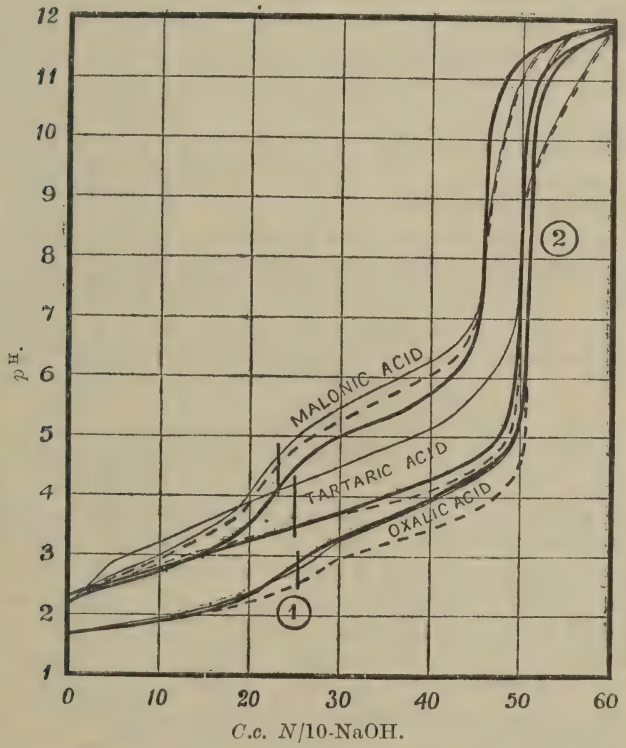
The *E.M.F.*'s of the oxygen–hydrogen cell extrapolated from the titration curves of the three organic acids show that in the case of malonic acid there was a gradual but small diminution until the first equivalent had been neutralised, after which the *P.D.* remained constant until the end-point had been reached; it then suddenly increased, but afterwards fell to a value somewhat higher than the initial *E.M.F.* The oxalic and tartaric acid titrations, which were performed with electrodes which had become a little aged, produced small and gradual increases in *P.D.* apart from the slight inflexion which occurred at the mid-point of the oxalic acid curve due to a lag in the *E.M.F.* of the oxygen electrode, until the neutralisation was complete; the *E.M.F.* of the oxygen–hydrogen cell then suddenly increased and thereafter remained constant in the case of the oxalic acid curve but fell somewhat for the tartaric curve. Thus in these three titrations the extrapolated *E.M.F.*'s of the oxygen–

hydrogen cell were greater at the end of the titration than at the beginning; the actual values are given in Table XI.

TABLE XI.

Acid.	*E.M.F.* of oxygen–hydrogen cell at Beginning.	End.	Difference.
Malonic	1·195	1·228	+0·033
Tartaric	0·828	1·034	+0·206
Oxalic	0·830	0·950	+0·120
Chromic	1·162	1·027	−0·135

The curves in Fig. 3 show that the differences were not proportionally incorporated in the oxygen electrode voltages, but were included mainly in the end-point readings. It was thought that these differences were due simply to a lag in the *E.M.F.*'s of the oxygen electrodes caused by the considerable change in hydrion concentration, which could be overcome by allowing time before taking further readings. When the change was considerable, it was sometimes found that time produced some little effect, but in general, the extrapolated *E.M.F.*'s never fell to the initial values. This change which takes place as the titrated solution attains alkalinity seems to be connected both with the age of the electrodes and with the oxidising nature of the acids. The curve showing the change which took place in the titration of chromic acid is also given in Fig. 3, the actual titration curve being No. 1, Fig. 2, in the previous paper. Although there was no change in the *P.D.* during the first half of the neutralisation, there was a somewhat irregular falling off during the second stage and when the solution had become alkaline it was found that the extrapolated *E.M.F.* was less than the initial value. This occurred in every one of the many titrations undertaken. The hydrogen-ion concentration prevailing during the second half of the titration lay between 10^{-6} and 10^{-7} and it seems that it was here and later in the alkaline solution that the oxidising nature of the chromic acid came into play. No irregularities occurred with the non-oxidising acids dealt with in this paper and especially with malonic acid, the second part of the neutralisation of which was not far removed from the neutral point.



Calibration of the Oxygen Electrode in Titrations.

The erratic behaviour of the oxygen electrode whilst being subjected to rapid changes in hydrion concentration, such as shown in Fig. 3 to take place at the end-points of titrations, renders it almost impossible to affix a satisfactory hydrogen-ion concentration scale to the measured voltages. It is possible, however, to get an approximate idea of the changes in p_H over the greater range of the

itration, for which purpose the following two schemes of calibration ıave been examined.

First, knowing the p_H's of solutions at two remote stages of a itration and the corresponding voltages given by the oxygen elec- rode, one assumes that the intermediate p_H's are proportional to he observed *E.M.F.*'s. In Fig. 4, the p_H curves of the three organic ɛids obtained with the hydrogen electrode are given as heavy lines

Fig. 4.

nd the thin line lying near to each one of them is the curve calcu- ıted from the oxygen electrode titration voltages. It will be seen hat the p_H's given by the malonic acid curve are higher by about ·5 unit, due to a lag of 0·033 volt being divided proportionally over he p_H range of the titration, whereas the lag of 0·206 volt shown by he tartaric acid curve causes the oxygen curve to lie higher on the iagram, in some places nearly a whole p_H unit, and yet in the ase of oxalic acid, with its lag of 0·120 volt, the oxygen curve is lmost coincident with the hydrogen curve, save for a small deviation ı the middle section. This is due to the gradual increase in the

extrapolated *E.M.F.* which took place throughout the acid zon of the oxalic acid titration.

The second method of calibration was based on the fact, illus trated by Fig. 3, that the oxygen electrode voltages are mor positive than the corresponding hydrogen electrode voltages b approximately a fixed amount, when working over a range of hydrio concentration which does not involve sudden changes, and tha the appreciable variations occur only when a very sharp change i hydrion is encountered. Thus in any one of the present titrations if the p_H's at the beginning and at the end are known, the *E.M.F.*' given by the hydrogen electrode as compared with the norma calomel can be calculated, and thus the *P.D.* of the correspondin oxygen–hydrogen cells can be extrapolated. The difference betwee the initial and the final values may then be assumed to have bee introduced at that stage of the titration where the addition of a fe drops of alkali caused a considerable change in the observed *E.M.F* This difference is then added to or subtracted from, as the case ma be, those readings which were taken after the marked change ha taken place. To the titration readings which have thus been adjusted the hydrogen-ion concentration scale may be found by proportion or by what amounts to the same thing, from the formula: Observe *E.M.F.* = Initial extrapolated *P.D.* of the oxygen–hydrogen ce

$$+ 0{\cdot}283 + 0{\cdot}0577 \log 1/[H^{\cdot}].$$

For example, suppose that all that was known of the tartaric aci titration was the initial p_H, 2·29, and the p_H when 60 c.c. of alka had been added, *viz.*, 11·75. The oxygen electrode compared wit the normal calomel gave + 0·413 and + 0·073 volt respectively and from the known p_H's it is calculated that the *E.M.F.* of th hydrogen electrode against the normal calomel would have bee − 0·415 volt at the beginning and − 0·961 volt at the end. Henc the extrapolated *P.D.* of the oxygen–hydrogen cell increased fro + 0·413 −(−0·415) = 0·828 volt to + 0·073 − (− 0·961) = 1·03 volt in the course of the titration, a difference of 0·206 volt. Thi is a considerable quantity to be divided proportionally over th whole titration as was done in the first method of calibration, an consequently would produce a very unsatisfactory hydrion scal But, as Fig. 3 shows, the greater part of this difference was intro duced at the end-point. Therefore, if the difference 0·206 volt b added to each of the voltages observed after the end-point had bee passed and then either a proportional scale be affixed or calculate from $E = 0{\cdot}828 + 0{\cdot}283 + 0{\cdot}0577 \log 1/[H^{\cdot}]$, a more satisfactor calibration is obtained, save for that part of the curve correspondin to the initial alkaline solutions. The curves obtained by thi procedure are given by dotted lines in Fig. 4. The tartaric aci

curve is nearly coincident with the one obtained by the hydrogen electrode, and the malonic acid curve lies closer to the true curve. The oxalic curve, however, is less satisfactory.

In conclusion, it seems that, provided the substances being titrated are not oxidising agents, the second method of calibration leads to the more satisfactory results; when oxidising agents are involved, as, for example, chromic acid, the first method is probably more satisfactory.

Summary.

(1) Oxalic, malonic, succinic, and tartaric acids and dextrose have been titrated electrometrically at 18°. The four acids produce in the course of their neutralisation hydrogen-ion concentrations which extend over the whole acid zone, and therefore partly neutralised solutions may be used for reference purposes in colorimetric determinations of p_{H}.

(2) The dissociation constant of dextrose as a monobasic acid has been found.

(3) Formulæ have been derived for the calculation of the dissociation constants of dibasic acids from the hydrogen electrode titration curves.

(4) The formulæ derived by Auerbach and Smolczyk have been shown to give less accurate results.

(5) Auerbach and Smolczyk's identity, $K_1K_2 = h^2$, where h is the hydrion concentration at the mid-point of the titration curve of a dibasic acid, has been shown to be erroneous.

(6) Attempts have been made to use the oxygen electrode for the purpose of indicating hydrion concentrations in titrations.

The author desires to take this opportunity to thank the Department of Scientific and Industrial Research for a personal grant, and also Prof. J. C. Philip, F.R.S., for facilities for carrying out this work.

IMPERIAL COLLEGE OF SCIENCE AND TECHNOLOGY,
SOUTH KENSINGTON. [*Received, May 26th*, 1925.]

CCLVII.—*Researches on Residual Affinity and Co-ordination. Part XXIV. Heats of Chelation of Dithiolated Metallic Halides.*

By GILBERT T. MORGAN, SYDNEY RAYMOND CARTER, and WILLIAM FINNEMORE HARRISON.

WHEN present in organic thioethers, bivalent sulphur exhibits residual affinity to a remarkable extent so that dialkyl sulphides

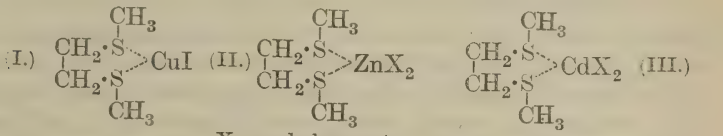
combine additively with many metallic halides, giving rise to thiolated co-ordination compounds such as $2Me_2S,SnCl_4$ (Werner and Pfeiffer, *Z. anorg. Chem.*, 1898, **17**, 101), Me_2S,CdI_2 (Werner, *ibid.*, 1897, **15**, 14), $[2Me_2S,PtCl_2]$ and $[Pt,4Me_2S]PtCl_4$ (Tschugaev and Subbotin, *Ber.*, 1910, **43**, 1200). Increased stability is acquired by these thiolated metallic halides when the sulphur is present in a chelate group as in dimethyldithiolethylene, $CH_3{\cdot}S{\cdot}CH_2{\cdot}CH_2{\cdot}S{\cdot}CH_3$, a substance which functions as two associating units giving rise by implication of the metallic atom to co-ordination complexes containing one or more five-membered rings (formulæ I, II, and III).

In a previous communication (J., 1922, **121**, 2882) attention was directed to the coincidence that metallic radicals yielding the characteristic insoluble sulphides of analytical practice also give rise to well-defined co-ordination compounds with thioethers. The selective affinity between metal and sulphur is manifested in a similar manner whether in sulphide formation or in the production of thiolated metallic salts.

Moreover, in the case of metals of variable valency, both these modes of combination between metallic radical and sulphur afford an insight into the relative stabilities of the electronic structures of the metallic atoms corresponding with these valency changes.

Copper and gold, which fall into a natural family of univalent metals, have the fundamental electronic structures of Cu^{I} = 2,224,22446,**1** and Au^{I} = 2,8,18,32,18,**1** with single valency electrons. But in their cupric and auric salts the two metals exhibit alternative electronic structures, Cu^{II} = 2,224,22445,**2** and Au^{III} = 2,8,18,32,16,**3** with two and three valency electrons respectively as displayed in cupric and auric salts. In their combinations with sulphur, there is a marked tendency to revert to the lower state of valency, that is, to change from the alternative to the fundamental electronic structure. When cupric halides combine with dimethyldithiolethylene or with other thioethers the resulting thiolated cupric halides change readily to cuprous derivatives. Similarly, the thiolated auric compounds are unstable and especially sensitive to moisture, which promotes a spontaneous change to thiolated aurous derivatives (*ibid.*, p. 2883).

In the case of mercury, thiolation promotes an exaltation of valency (*ibid.*, p. 2884) corresponding with a change from the less stable electronic structure of univalent mercury, Hg^{I} = 2,8,18,32,18,1,**1** to the more stable electronic structure of the bivalent metal, Hg^{II} = 2,8,18,32,18,**2**, which is characteristic of its natural position among the chemical elements.



During these earlier investigations it was noticed that the formation of certain dithiolated metallic halides was accompanied by

a very appreciable rise of temperature and we have now determined the heats of chelation of fifteen of these co-ordination compounds.

With the same metallic radical it was found that the heat of combination of dithiol and metallic halides varied with the nature of the halogen, and missing members of the series were prepared in order to obtain comparative measurements.

Dimethyldithiolethylene cuprous iodide * (I), is a pale yellow substance stable in air and only slowly attacked by boiling water.

The zinc series was completed by the production of *dimethyldithiolethylene zinc chloride* and *iodide* (II), the bromide having been already described, and *dimethyldithiolethylene cadmium chloride* and *bromide* (III) were also prepared.

X = a halogen atom.

The thermal measurements described in this paper show how very vague is the former division of chemical substances into atomic and molecular compounds.

Heats of reaction do not represent exactly the free energy of change involved in building up a substance from its simpler components, and cannot, therefore, in the case of these thiolated derivatives, represent the work actually done by residual affinity, but since in many cases the free energy changes are not very different from total energy changes, a certain degree of approximation may be expected. Thus not only the free energy but also the bound energy may be assumed to have some relation to chemical structure.

The heat of chelation of cupric chloride by dimethyldithiolethylene is +14·85 Cals., whereas the heat of formation of cupric sulphide is +9·93 Cals. On the other hand, the more stable cuprous sulphide is formed with the generation of 18·26 Cals., whereas the dithiolated cuprous iodide has a heat of chelation of +5·9 Cals.

The influence of the halogen on the heat of chelation of the dithiolated metallic halides is demonstrated by a study of the complete series of mercury compounds; the data for the chloride, bromide, and iodide are in the descending order of +13·23, +11·33, and +4·83 Cals. In the case of the most exothermic of these three

* *Erratum.*—In the copper compounds each copper atom becomes associated with one molecular proportion of dithiol. The name of the cupric derivative (J., 1922, **121**, 2887) should be *dimethyldithiolethylene cupric chloride*; the prefix *bis* refers to a double molecule as in the preceding dithiolated cuprous bromide.

changes, the value exceeds appreciably that of the heat of formation of mercuric sulphide (10·75 Cals.). The three dithiolated cadmium halides give the series: chloride +12·16 Cals., bromide +11·27 Cals., and iodide +9·96 Cals., these values being all lower than the heat of formation of cadmium sulphide (34·36 Cals). It is of interest to compare the heats of chelation of this dithiolated series with the heats of co-ordination of the cadmium halides with ammonia; the latter values are as follow: $CdCl_2,2NH_3$, 37·24 Cals.; $CdBr_2,2NH_3$, 35·2 Cals.; $CdI_2,2NH_3$, 29·6 Cals. (Tassily, *Ann. Chim. Phys.*, 1899, **17**, 38).

A discrepancy was observed in the case of the dimethyldithiolethylene zinc halides, where the values were chloride, 13·21 Cals. (87°); bromide, 15·35 Cals. (79°); and iodide, 14·23 Cals. (71°), the value obtained for the bromide derivative being the highest of the three (heat of formation of zinc sulphide+41·3 Cals.).

The zinc halides also combine with methylamine to give co-ordination compounds having the general formula $ZnX_2,5NH_2{\cdot}CH_3$ (Ephraim and Linn, *Ber.*, 1913, **46**, 3742), and for these the heats of co-ordination are chloride, 12·79, bromide, 12·48, and iodide, 12·17 Cals., a diminishing series resembling the values obtained with the dithiolated cadmium and mercuric halides. However, in their combinations with ammonia (Isambert, *Compt. rend.*, 1878, **86**, 968; André, *Ann. Chim. Phys.*, 1884, **3**, 66; Tassily, *loc. cit.*) the zinc halides give the following heats of co-ordination: $ZnCl_2,4NH_3$, 68·0 Cals.; $ZnI_2,4NH_3$, 73·95 Cals.; $ZnBr_2,5NH_3$, 82·2 Cals. The ammoniated zinc bromide is anomalous both in composition and in its heat of co-ordination.

The maximum heat of chelation was observed in the case of dithiolated stannic chloride and the next highest value was noted with the corresponding bromide, the values for these two co-ordination compounds, $CH_3{\cdot}S{\cdot}C_2H_4{\cdot}S{\cdot}CH_3,SnX_2$, being 28·06 and 19·40 Cals., respectively. Stannic iodide does not yield a chelated compound, for in this combination two molecular proportions of the iodide combine with one of the dithiol, $CH_3{\cdot}S{\cdot}C_2H_4{\cdot}S{\cdot}CH_3,2SnI_4$. Nevertheless even in this case the heat of co-ordination is very considerable, being 16·58 Cals.

A heat of co-ordination of +12·0 Cals. was observed in the combination of 3 mols. of dimethyldithiolethylene with 2 mols. of bismuth iodide to form the bright scarlet complex,

$$3CH_3{\cdot}S{\cdot}C_2H_4{\cdot}S{\cdot}CH_3,2BiI_3.$$

The following table summarises the calorimetric results obtained for the heats of chelation or co-ordination, in large calories, of the fifteen dithiolated metallic halides; the heats of formation of the corresponding metallic sulphides recorded in Landolt-Börnstein

" Physikalisch-Chemische Tabellen," 1912, based on the work of Berthelot (B) and Thomsen (T), are also included.

Metal.	Dithiolated. Chloride.	Bromide.	Iodide.	Sulphide.
Copper (ic)	+14·85	—	—	+9·93 (Mean B and T)
Copper (ous)	—	—	+5·88	18·26 (T)
Zinc	13·21	+15·35	14·23	41·28 (Mean B and T)
Cadmium	12·16	11·27	9·96	34·35 (T)
Mercury	13·23	11·33	4·83	10·6 (B)
Tin	28·06	19·40	16·58	—
Bismuth	—	—	12·0	—

Experimental.

I. *Preparation and Purification of Dimethyldithiolethylene.*

Dimethyldithiolethylene, prepared by the action of sodium mercaptide on ethylene dibromide (Morgan and Ledbury, J., 1922, **121**, 2882), was purified through the characteristic dithiolated nickel thiocyanate, $Ni(CNS)_2,2CH_3{\cdot}S{\cdot}C_2H_4{\cdot}S{\cdot}CH_3$ (Tschugaev and Kobljamski, *Ber.*, 1908, **41**, 2222). This compound crystallised from 85% alcohol in blue needles which were dried and distilled in steam. The colourless disulphide which separated from the distillate then boiled at 182·5°/750 mm.

II. *Preparation of Dithiolated Metallic Halides.*

Dimethyldithiolethylene Zinc Chloride.—Dry chlorine was passed into a suspension of zinc dust in anhydrous ether and the disulphide was added to the filtered ethereal solution; the white dithiolated compound then separated in crystalline form, melting at 131—132° to a clear liquid. It was very unstable in a moist atmosphere and was immediately decomposed by cold water with liberation of the disulphide (Found: Zn, 25·1; Cl, 27·3; S, 24·4. $C_4H_{10}Cl_2S_2Zn$ requires Zn, 25·3; Cl, 27·45; S, 24·8%. This zinc compound was only slightly soluble in ether but very soluble in acetone; it dissolved in alcohol with decomposition.

Dimethyldithiolethylene zinc iodide was distinctly less affected by moisture than the corresponding chloride or bromide (*ibid.*, p. 2888). Zinc dust (2 g.) and iodine (6 g.) were combined in dry ether and 1 g. of the disulphide was added to the filtered solution; small, white crystals then separated, melting at 169—170° to a clear liquid (Found: Zn, 14·6; I, 57·3; S, 14·4. $C_4H_{10}I_2S_2Zn$ requires Zn, 14·8; I, 57·5; S, 14·5%). The compound was very soluble in acetone and slightly soluble in ether; it dissolved readily in methyl and ethyl alcohols with slight decomposition on boiling, but was only sparingly soluble in other solvents.

Dimethyldithiolethylene Cadmium Chloride.—On addition of the

disulphide to a solution of anhydrous cadmium chloride in dry alcohol, a white, crystalline compound separated, which was very soluble in warm alcohol and crystallised from this solvent in colourless needles; it did not melt below 285° (Found: Cd, 36·95; Cl, 23·2; S, 20·85. $C_4H_{10}Cl_2S_2Cd$ requires Cd, 36·8; Cl, 23·2; S, 21·0%). The thiolated compound was readily soluble in methyl alcohol but almost insoluble in acetone; it was slowly decomposed by cold water.

Dimethyldithiolethylene cadmium bromide, prepared in a similar manner to the preceding compound, had similar properties but did not melt below 285° (Found: Cd, 28·3; Br, 40·7; S, 16·4. $C_4H_{10}Br_2S_2Cd$ requires Cd, 28·5; Br, 40·5; S, 16·2%). The dithiolated cadmium bromide was readily soluble in acetone, ether, or methyl alcohol.

Dimethyldithiolethylene Cuprous Iodide.—A solution of copper sulphate in water was saturated with sulphur dioxide and on the addition of the organic disulphide and potassium iodide, a pale yellow substance was precipitated which was extracted with a strong solution of potassium iodide to remove any unchanged cuprous iodide. The additive compound was then washed with alcohol and dried in a vacuum desiccator. Insoluble in the ordinary organic media, it was unchanged by cold water but slowly decomposed on boiling, leaving cuprous iodide. It was very stable in air, melting and decomposing at 156°, leaving a black residue (Found: Cu, 20·1; I, 40·3; S, 20·8. $C_8H_{20}I_2S_4Cu_2$ requires Cu, 20·3; I, 40·6; S, 20·5%).

III. *Thermal Measurements.*

Description of Apparatus.—In the following calorimetric measurements the two reacting liquids were placed in separate vessels and their temperatures recorded at intervals of a minute; the one reagent was then added to the other, the temperature change being observed. A silver calorimeter of half a litre capacity was used in those cases where the metal was unattacked by the reagents. In the experiments with mercury salts a thin-walled glass calorimeter was employed. The stirrer, which consisted of two rings of sheet nickel, each perforated with eight holes and connected by nickel rods, was raised and lowered about sixty times a minute. The second liquid, contained in a tap funnel, was stirred with a small glass propeller stirrer.

The experimental methods based on the former work (Morgan and Ledbury, *loc. cit.*) were frequently modified in order to obtain reactions of a speed suitable for thermal measurements. In the case of the more stable additive compounds, the thermal data were obtained in the formation of the co-ordination compounds. For

the less stable dithiolated derivatives it was more convenient to prepare the compounds first and subsequently to determine their heats of dissociation.

Dimethyldithiolethylene cupric chloride. This compound is immediately decomposed by a large excess of water. About 2 g. of the substance were decomposed in a calorimeter and the fall in temperature was measured. The heat of dissociation was −3·77 Cals. The heat of solution of cupric chloride in water (1 : 600 water, which was the concentration employed) is given as +11·08 Cals. (Thomsen, *J. pr. Chem.*, 1875, **12**, 276). The heat of reaction of cupric chloride and the disulphide is +14·85 Cals.

Dimethyldithiolethylene cuprous iodide. Potassium iodide solution was added to a solution of copper sulphate (2·2%) and the disulphide and the resulting temperature change compared with a blank experiment in which the disulphide was absent. The difference, which gives the heat of reaction of cuprous iodide and the disulphide, was +5·88 Cals.

Dimethyldithiolethylene zinc chloride. This dithiolated chloride was decomposed with water and the heat of dissociation found to be +2·44 Cals. The heat of solution of zinc chloride (1 : 300) is given by Thomsen as +15·63 Cals. (*J. pr. Chem.*, 1875, **11**, 410). This gives the heat of reaction of zinc chloride and disulphide as +13·19 Cals.

Dimethyldithiolethylene zinc bromide (*loc. cit.*, p. 2888) was treated as in the preceding case. The heat of dissociation was −0·324 Cal. The heat of solution of zinc bromide in water is given by Thomsen as +15·03 Cals. (*J. pr. Chem.*, 1877, **16**, 328); hence the heat of reaction is +15·35 Cals.

Dimethyldithiolethylene zinc iodide. The heat of dissociation with water was −2·87 Cals., the heat of solution of zinc iodide in water (1 : 400) is +11·31 Cals. (Thomsen, *ibid.*, 1877) and hence the heat of reaction of zinc iodide and the disulphide is +14·18 Cals.

Dimethyldithiolethylene cadmium chloride. The cadmium compounds were all decomposed with 2% hydrochloric acid. The specific heat of such a solution is 0·9650 (Marignac, *Ann. Chim. Phys.*, 1876, **8**, 410). The heat of dissociation was −9·15 Cals. The heat of solution of cadmium chloride in water (1 : 400) is +3·01 Cals. (Thomsen, *ibid.*, 1875). Hence the heat of reaction of the dithiol with cadmium chloride is +12·16 Cals.

Dimethyldithiolethylene cadmium bromide. The heat of dissociation was −10·83 Cals.; the heat of solution of cadmium bromide in water (1 : 400) (Thomsen, *ibid.*, 1877) is +0·44 Cal., and hence the heat of reaction is +11·27 Cals.

Dimethyldithiolethylene cadmium iodide. The heat of dissociation was −10·92 Cals. The heat of solution of cadmium iodide in water (1 : 400) is −0·96 Cal. (Thomsen, *ibid.*, 1877). Accordingly, the heat of reaction of cadmium iodide and the disulphide is +9·96 Cals.

Dimethyldithiolethylene mercuric chloride. The heat of reaction was directly measured by the addition of the disulphide to a 3% solution of mercuric chloride in water. The specific heat of such a solution is given by Blümcke as 0·96 (*Ber.*, 1884, **17**, 555). The heat of reaction was +13·23 Cals.

Dimethyldithiolethylene mercuric bromide. A weighed amount of the disulphide was added to an alcoholic solution of mercuric bromide. The heat of solution of mercuric bromide in alcohol was ascertained to be negligible. The heat of reaction was thus found to be +11·33 Cals.

Dimethyldithiolethylene mercuric iodide. Excess of the disulphide was added to a solution of mercuric iodide in alcohol. The heat of reaction was +6·93 Cals. The heat of solution of mercuric iodide in alcohol, which was difficult to determine owing to very sparing solubility, was found to be about −2·1 Cals. Thus the heat of reaction of mercuric iodide and the disulphide is +4·83 Cals.

Trisdimethyldithiolethylene dibismuthotri-iodide. Into a solution of bismuth oxychloride in dilute hydrochloric acid about 1 g. of the disulphide was introduced. Then a solution of about one-third of the theoretical quantity of potassium iodide was added, when the characteristic red compound was formed. The heat of reaction was +35·6 Cals. and correcting for the side reactions this gives a result of +12·0 Cals. for the heat of reaction of bismuth iodide and the disulphide.

Dimethyldithiolethylene stannichloride. For the thermal measurements of the dithiolated tin compounds the copper calorimeter employed was tinned internally. A solution of the disulphide in carbon tetrachloride was run into a solution of stannic chloride in the same solvent, the co-ordination compound being insoluble in this medium. The heat of reaction was +26·98 Cals. The heat of solution of stannic chloride in the solvent was difficult to determine owing to the very hygroscopic nature of the chloride and the resulting rise in temperature. The hydration effects were minimised by leading dry carbon dioxide above the calorimeter liquid and placing fused calcium chloride between the ebonite lids; readings were taken every 15 seconds. The heat of solution (1 g. of stannic chloride to 300 g. of carbon tetrachloride) was +0·870 Cal. The heat of solution of the disulphide in the solvent was +0·232 Cal. The specific heat of carbon tetrachloride was taken as 0·2014

(Mills and MacRae, *J. physical Chem.*, 1895, **9**, 360). Correcting for the heats of solution of the reacting substances, a value of +28·06 Cals. is obtained for the heat of reaction of stannic chloride and the disulphide.

Dimethyldithiolethylene stannibromide. The heat of reaction of the bromide and disulphide, both in carbon tetrachloride solution, was +22·32 Cals. The heat of solution of stannic bromide in carbon tetrachloride was found to be —3·15 Cals. (1 g. of stannic bromide to 100 g. of carbon tetrachloride). The heat of solution of disulphide in carbon tetrachloride is +0·232 Cal.

$$C_4H_{10}S_2 + SnBr_4 \longrightarrow C_4H_{10}S_2,SnBr_4 + 19{\cdot}40 \text{ Cals.}$$

Dimethyldithiolethylene stanni-iodide. By adopting the foregoing method the reaction was not complete using the common organic solvents. Finally a solution of stannic chloride in carbon tetrachloride was added to a solution of dimethyldithiolethylene stanni-iodide in carbon tetrachloride; dimethyldithiolethylene stanni-chloride and free stannic iodide were then produced. Nearly twice the theoretical quantity of stannic chloride was necessary to complete the chemical change.

$$\underset{\text{soln.}}{C_4H_{10}S_2,2SnI_4} + \underset{\text{soln.}}{SnCl_4} \longrightarrow C_4H_{10}S_2,SnCl_4 + \underset{\text{soln.}}{2SnI_4} + 30{\cdot}30 \text{ Cals.}$$

$$\underset{\text{soln.}}{C_4H_{10}S_2} + \underset{\text{soln.}}{SnCl_4} \longrightarrow C_4H_{10}S_2,SnCl_4 + 26{\cdot}98 \text{ Cals.}$$

$$\text{Hence, } \underset{\text{soln.}}{2SnI_4} + \underset{\text{soln.}}{C_4H_{10}S_2} \rightarrow \underset{\text{soln.}}{C_4H_{10}S_2,2SnI_4} - 3{\cdot}3 \text{ Cals.}$$

The heat of solution of stannic iodide in carbon tetrachloride (1 : 200) was found to be —3·81 Cals. The heat of solution of dimethyldithiolethylene stanni-iodide in carbon tetrachloride (1 : 200) was —27·27 Cals. The heat of solution of the disulphide in carbon tetrachloride (1 : 200) was +0·232 Cal. Hence the heat of reaction of the disulphide and stannic iodide is +16·58 Cals.

The authors desire to express their thanks to the Advisory Council of the Department of Scientific and Industrial Research and to Messrs. Brunner Mond and Company, Limited, for grants which have helped to defray the expense of this investigation.

UNIVERSITY OF BIRMINGHAM,
EDGBASTON.

CCLVIII.—*The Rotatory Dispersion of Derivatives of Tartaric Acid. Part II. Acetyl Derivatives.*

By Percy Corlett Austin and James Ritchie Park.

The effect produced on the character of the rotatory dispersion of tartaric acid by bridging across various hydroxyl groups with methylene (Austin and Carpenter, J., 1924, **125**, 1939) was so remarkable that an investigation of other types of bridging became desirable. Condensation of the carboxyl groups with production of an anhydride ring is readily effected if the alcoholic groups are acetylated at the same time (Chattaway and Parkes, J., 1923, **123**, 663). Diacetyltartaric anhydride is dextrorotatory in solution in acetone or benzene and lævorotatory in alcohol or water (Anschütz and Pictet, *Ber.*, 1880, **13**, 1178; Pictet, *Arch. Sci. phys. nat.*, 1882, **7**, 82; Freundler, *Ann. Chim. Phys.*, 1895, **4**, 242), but the data recorded show considerable variations. Freundler states that whereas the rotations of dibenzoyltartaric anhydride in solution in acetone are practically independent of concentration, this is not the case with the diacetyl compound. He points out, however, that some of the solutions examined show mutarotation.* It seemed desirable, therefore, to study the compound in detail.

The Cause of the Mutarotation of Diacetyltartaric Anhydride.

We have found that if special care is taken to eliminate moisture, solutions of diacetyltartaric anhydride in acetone or ethyl acetate do not exhibit mutarotation and the strong dextrorotations are permanent. The rotations conform to the requirements of the law of "simple" rotatory dispersion (compare Austin and Carpenter, *loc. cit.*; Lowry and Cutter, this vol., p. 604). This led us to surmise that the variations in the values of the specific rotation with changes of concentration which were recorded by Freundler might also be due to the presence of moisture in the solvent. *This we have verified experimentally.* It is therefore clear that when a dry solvent is used the two principal anomalies which are characteristic of tartaric acid and of many of its derivatives, *viz.*, anomalous rotatory dispersion and sensitiveness of rotatory power to changes of concentration, disappear simultaneously.

On adding water to the dry solutions, a change of rotation soon became apparent, the rate of change increasing with the amount of water present; with one and with four molecular proportions of water, final steady values were reached after about $1\frac{1}{2}$ days

* The values given by Freundler for specific rotations are obviously intended to represent molecular rotations.

and 16 days, respectively. The fact that this mutarotation is due to the hydrolysis of the anhydride ring and not to an isomeric change catalysed by the water (compare Lowry, this vol., p. 1376) was proved by isolating pure *diacetyltartaric acid* from solutions in which mutarotation was complete. The final readings were strongly lævorotatory, but the values depended on the amount of water used, as is shown in Table I.

TABLE I.

Influence of Water upon the Rotatory Power of Diacetyltartaric Acid in Acetone at 20°.

Ten g. of $C_8H_8O_7$ (anhydride) in 100 c.c. $l = 4$.

Mols. of H_2O.	α_{5780}.	α_{5461}.	α_{4359}.	Mols. of H_2O.	α_{5780}.	α_{5461}.	α_{4359}.
1	−11·23°	−13·12°	−26·43°	4	−13·10°	−15·26°	−30·31°
2	−12·18	−14·10	−28·27	5	−13·56	−15·68	−31·13
3	−12·91	−14·93	−29·29	12	−14·61	−17·00	−33·20

The cause of this increase of lævorotation with increasing amounts of water has not yet been determined. It may be due (i) to association with water molecules or (ii) to ionic dissociation of the diacetyltartaric acid. That some such influence is involved can be inferred from a study of the velocity coefficients (Table V).

The Formation of Diacetyltartaric Acid.

The results shown in Table I left us in doubt as to the true value of the rotatory power of diacetyltartaric acid until the latter substance had been isolated and identified. The purification of the acid was a somewhat troublesome process, since we were long unable to obtain any definite crystals from the solutions. Moreover, the data in reference to the properties of this acid were very meagre. Rochleder, who appears to have been the first to obtain crystals of the acid (*Sitz. Ber. Akad. Wiss. Wien*, 1859, **29**, 26), merely states that it is deliquescent; he gives neither analysis nor melting-point. W. H. Perkin, sen. (J., 1867, **20**, 138), describes the acid as a transparent, gum-like substance, whilst Colson (*Compt. rend.*, 1892, **114**, 177) obtained deliquescent crystals of a lævorotatory compound, melting at 58° and corresponding with the formula $C_8H_{10}O_8,3H_2O$. This substance we have been unable to obtain; but we have separated from solutions in benzene large, soft crystals, containing benzene of crystallisation (1½ mols.). The benzene was easily driven off by heat; the residual white powder melted at 118° and was the anhydrous acid, $C_8H_{10}O_8$. A solution of this in dry acetone was strongly lævorotatory and its rotatory dispersion was also simple. Moreover, its molecular

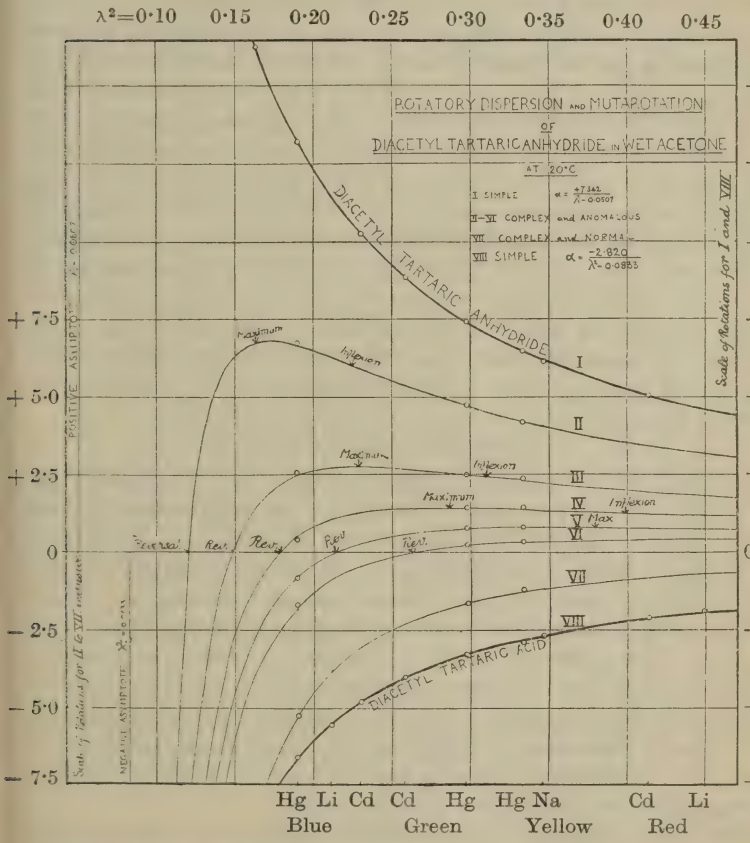
rotatory power was identical with that calculated from the final readings after mutarotation, when one molecular proportion of water was used. Thus, when the anhydride and water are mixed in equimolecular proportion in the presence of acetone, hydrolysis of the anhydride is complete in about 16 days and the exaltation of the lævorotation in the presence of more water must be due to some other cause.

Since the simple salts of tartaric acid have been proved to exhibit complex rotatory dispersion (Lowry and Austin, Bakerian Lecture, *Phil. Trans.*, 1922, *A*, **222**, 249), this is the first instance of simple rotatory dispersion in the tartaric acid series, which is independent of any ring formation. Even more important, however, is the fact that the anomalies have been eliminated by replacing the hydroxylic hydrogen atoms by acyl groups without bridging, whereas the substitution of alkyl groups for the carboxylic hydrogen atoms is known to be without effect.

We may therefore conclude that *the alcoholic hydroxyl groups are important, though possibly not essential factors, in the development of anomalous rotatory dispersion in tartaric acid* (compare Lowry and Austin, *Nature*, 1924, **114**, 431).

Anomalous Rotatory Dispersion caused by the Superposition of Opposite Partial Rotations.

(*a*) An interesting feature of the mutarotation of diacetyltartaric anhydride is the development of anomalous rotatory dispersion during the transition from the simple dispersion of the dextrorotatory anhydride to the simple dispersion of the lævorotatory acid. This is clearly shown in Fig. 1 and is a striking vindication of Arndtsen's hypothesis in reference to the origin of the anomalous rotatory dispersion of tartaric acid (*Ann. Chim. Phys.*, 1858, **54**, 421; Lowry and Austin, *Phil. Trans.*, *loc. cit.*; Lowry and Cutter, this vol., p. 607).



It is an essential feature of this hypothesis that the two compounds the partial rotations of which are superposed, in order to produce an anomalous dispersion, must not only be opposite in sign but of unequal dispersion. This condition is fulfilled in the present instance, since, whilst the anhydride has a dispersion-constant $\lambda^2 = 0{\cdot}0507$, the acid has a dispersion-constant $\lambda^2 = 0{\cdot}0833$, the lævo-component being the more dispersive (see Table V) just as in the case of tartaric acid and its esters (Lowry and Austin, *loc. cit.*) and of the two methylene derivatives (Austin and Carpenter, *loc. cit.*).

The figure shows the curves of simple dispersion representing the anhydride (I) and the acid (VIII) respectively together with six

intermediate curves, which are plotted on a larger vertical scale in order to show the anomalies.*

During the course of the mutarotation only the three mercury lines were read, but the form of the dispersion curves can be accurately determined by extrapolation beyond these points, since we know that we are dealing with mixtures of two known components.

FIG. 1.

It will be seen that five of the curves (II—VI) are not only *complex* but also *anomalous*, the positions of the characteristic anomalies being indicated in Table V. No. VII, although still obviously complex (since mutarotation is incomplete), is *normal*, as are also all

* The characteristic anomalies are (i) reversal of sign, λ_ρ; (ii) maximum point at λ_μ; and (iii) point of inflexion at λ_σ (Table V). In several instances the actual reversals were observed experimentally for the mercury violet, green and yellow lines in succession.

the curves (not shown in the diagram) which lie between Nos. VII and VIII. This follows necessarily from the fact that k_2 has become greater than k_1, whilst λ_2^2 is also greater than λ_1^2. Similarly, all curves which lie between I and II must be complex and anomalous.

(*b*) A change of a very similar character was observed when a solution of the anhydride in warm water was cooled to 20°. Hydrolysis of the anhydride was so rapid that the first readings which could be obtained were lævorotatory, but instead of remaining constant they soon began to diminish and a very *slow mutarotation in the opposite direction* to that shown in Fig. 1 took place until eventually only dextrorotations were observed. Thus the simple lævorotatory dispersion gave place to complex and later to anomalous dispersion, the rotation for the yellow mercury line showing reversal of sign after 19 days. This was followed by a reversal in the green after 20 days and in the violet after 32 days (Table VI). This change is obviously due to slow hydrolysis of the acetyl groups with the liberation of dextrorotatory tartaric acid. A similar hydrolysis, which was slower still, was also noticed in the case of the mutarotation of the anhydride in acetone, with twelve molecular proportions of water (p. 1927), after the attainment of the maximum lævorotations.

Experimental.

Diacetyltartaric anhydride was prepared by Chattaway and Parkes's method (*loc. cit.*). Owing to its deliquescent nature, recrystallisation from benzene did not suffice to purify it; eventually very pure specimens were obtained by allowing hot solutions of the compound in acetic anhydride to cool in a desiccator. Traces of the solvent were eliminated by washing with dry ether. The rotations were measured at 20° in solutions in acetone and in ethyl acetate. Both solvents were carefully dried shortly before use by the addition of phosphorus pentoxide, followed by refractionation. The specific rotations in ethyl acetate were considerably lower than those in acetone. Results are set forth in Tables II and III, photographic readings being given in italics.

The Mutarotation of Diacetyltartaric Anhydride in Wet Acetone.—A solution of diacetyltartaric anhydride (10 g.) in dry acetone (nearly 100 c.c.) at 20° was, after the addition of water (0·85 c.c. = 1 mol.), made up to 100 c.c. with dry solvent. The solution was transferred as rapidly as possible into a 4-dcm. tube and readings were taken at intervals measured from the moment when the water was added. Comparison of the final constant readings with those obtained from a solution of an equivalent quantity of the pure acid in dry acetone showed that the reaction was complete

in about 16 days. Thus, since the proportion of acid to anhydride could be readily calculated at any moment, attempts were made to measure the reaction velocity coefficient. The results (Table IV) show that after a short period of induction (about 10—12 minutes) the reaction approximates more closely to the unimolecular than to the bimolecular type, but the agreement is not wholly satisfactory, since after 2 or 3 days the values of k' fall off rapidly. This fact, taken in conjunction with the gradual increase of lævorotation with increasing amounts of water (Table I), leads us to conjecture that there are probably two reactions taking place simultaneously or consecutively, *viz.* (1) opening of the anhydride ring and (2) association of anhydride or of acid with water. Previous attempts to measure the reaction velocity (Deakin and Rivett, J., 1912, **101**, 127) of this compound by conductivity measurements in aqueous solutions failed on account of the rapidity of hydration of the anhydride. We also made observations of mutarotation with larger amounts of water, but these are reserved for further investigation.

lysed almost immediately to diacetyltartaric acid, the first reading (after an interval of 45 minutes) giving a value — 13·36° for Hg_{5461} in a 4-dcm. tube. On standing, slow mutarotation took place, the readings for the mercury yellow, green, and violet lines becoming positive after 19, 20, and 33 days respectively. Thus the rotatory dispersion became anomalous owing to the slow liberation of tartaric acid. Results are set forth in Table VI.

The Preparation of Diacetyltartaric Acid, $\begin{matrix} CH_3{\cdot}CO{\cdot}O{\cdot}CH{\cdot}CO_2H \\ | \\ CH_3{\cdot}CO{\cdot}O{\cdot}CH{\cdot}CO_2H \end{matrix}$—

A solution in which mutarotation of the anhydride was complete was allowed to evaporate in a vacuum desiccator. The colourless syrup obtained (in one case only this crystallised on long standing) was dissolved in hot benzene, in which it was only slightly soluble, and the solution was allowed to remain in the desiccator. The soft, large, transparent crystals that formed slowly smelled of benzene and soon became opaque when the solvent was decanted

(Found by titration with KOH : equiv., 174·3. $C_8H_{10}O_8 + 1\frac{1}{2}C_6H_6$ requires equiv., 175·5). When the crystals were heated at 85° for 15—20 minutes and crushed, the smell of benzene was removed (Found : equiv., 116·8. $C_8H_{10}O_8$ requires equiv., 117·0). The substance, m. p. 118°, was therefore pure. A solution in dry acetone containing 10·8336 g. (equivalent to 10 g. of anhydride) in 100 c.c. was lævorotatory and the dispersion simple. The readings corresponded exactly with the final readings obtained in the mutarotation of an equivalent quantity of the anhydride in acetone containing water (1 mol.). The results are set forth in Table VII.

TABLE VII.

Rotatory Dispersion of Diacetyltartaric Acid in Acetone at 20°.

CCLIX.—*The Chemistry of Petroleum. Part II. The Action of Sodium Hypochlorite on Sulphur Compounds of the Types found in Petroleum Distillates.*

By STANLEY FRANCIS BIRCH and WOODFORD STANLEY GOWAN PLUCKNETT NORRIS.

THE refining of petroleum distillates by the "hypochlorite process" as advocated by Dunstan and Brooks (*Ind. Eng. Chem.*, 1922, **14**, 1112), which involves the oxidation of the offensive sulphur com-

pounds by means of an alkali hypochlorite, has not only been adopted as a standard method of treating the light distillates from Persian petroleum, but is rapidly becoming more generally used throughout the petroleum industry. For this reason, and more particularly because misleading statements reflecting unfavourably upon the efficiency of this process have appeared in the technical literature, it was of obvious importance to investigate the mechanism of the oxidation. In the present paper we describe the action of sodium hypochlorite solution on petroleum solutions of representative members of the types of sulphur compounds which occur in the soda-washed distillate (see Part I, this vol., p. 898).

Observations relevant to this subject have been made by Waterman and Heimal (*J. Inst. Pet. Tech.*, 1924, **46**, 812). Under the conditions they employed, diphenyl sulphide, ethyl mercaptan, carbon disulphide, diphenylsulphone, diethylsulphone, and ethyl thiocyanate were " completely removed " from petroleum solution, whilst phenyl mercaptan, diethyl sulphide, phenylthiocarbimide, phenylthiocyanate, and diphenyl sulphoxide were " substantially removed." Organic disulphides were not examined, nor were any of the oxidation products investigated. Wood, Lowy, and Faragher (*Ind. Eng. Chem.*, 1924, **16**, 1116) state quite definitely that alkyl sulphides, alkyl disulphides, and thiophen are not attacked by sodium hypochlorite solution. They also state that mercaptans are simply converted into the disulphides, which remain dissolved in the solvent employed; that they obtained no evidence of chemical action between the aqueous reagent and free sulphur, sulphoxides, or sulphones; and that hydrogen sulphide is oxidised to free sulphur and water, whilst carbon disulphide is converted into sodium carbonate and sodium sulphate.

The discrepancies between the two sets of results have made it necessary to investigate the subject anew.

It may be stated at once that all the mercaptans, organic sulphides, and organic disulphides which we have examined are quantitatively oxidised by sodium hypochlorite, the reaction proceeding quite readily provided a suitably active solution is employed, whilst thiophen and elementary sulphur remain unattacked.

The greater the tendency of a solution of sodium hypochlorite to decompose spontaneously the greater, naturally, will be its reactivity towards oxidisable compounds. Kaufmann (*Z. angew. Chem.*, 1924, **37**, 364), who considers the active agent in hypochlorite solutions to be free hypochlorous acid, $OCl' + H_2O \rightleftharpoons HOCl + OH'$, has shown that the velocity of spontaneous decomposition of aqueous sodium hypochlorite is inversely proportional to the concentration of hydroxyl ions, and that the fraction of the

total hypochlorite ions destroyed in unit time is independent of the actual concentration of hypochlorite. Thus the reactivity of a solution of sodium hypochlorite should be increased by dilution and decreased by the addition of free alkali, conclusions which have been independently reached in studying the interaction of this reagent and various compounds of sulphur. It is for this reason that, in stating certain derivatives of sulphur to be readily oxidised by hypochlorite, we have also stated that the latter must be " suitably active."

The organic solvent used was a special fraction of petroleum, b. p. 100—175°, which had been freed from aromatic compounds by shaking with a large excess of concentrated sulphuric acid, and afterwards thoroughly washed with a solution of sodium hypochlorite ; the sulphur content was thereby reduced below 0·005%.* To the petroleum thus purified, the various sulphur compounds were added in amounts sufficient to give solutions containing from 0·6% to 0·9% S. The solutions of sodium hypochlorite were prepared by leading chlorine into an aqueous solution of pure sodium hydroxide until the free alkali had been reduced to a predetermined amount ; greater alkali content could then be obtained by adding solid sodium hydroxide, without appreciably altering the amount of available chlorine. The latter was determined by adding acetic acid and potassium iodide and titrating the liberated iodine. For the estimation of free alkali, the hypochlorite was first decomposed by boiling with hydrogen peroxide ; the cooled liquid was then titrated with hydrochloric acid, with methyl-orange as indicator, and, the quantity of sodium carbonate being quite small, the result calculated as sodium hydroxide (*vide infra*, p. 1942).

It was usual to shake 25 c.c. of the analysed reagent with 25 c.c. of the standard solution of sulphur compound in a bottle closed by means of a cork covered with tin-foil. A mechanical shaker was used, the speed being maintained constant throughout this research. After a period of shaking previously decided upon, the petroleum layer and the aqueous liquid were separated, and analysed.

Organic Sulphides.

Since no complication arises from the formation of acidic oxidation products, it is convenient to consider first the interaction of aqueous

* All estimations of sulphur in petroleum were carried out by means of the lamp method.

We wish here to thank Miss G. E. Hickes and Mr. D. Carter, of the Analytical Department, for carrying out the numerous estimations which this research has entailed.

sodium hypochlorite and a petroleum solution of an organic sulphide. The latter is converted quantitatively into the corresponding sulphone. Not even traces of any intermediate compound (*i.e.*, a sulphoxide) could be isolated, nor does hypochlorite appear to exert any further action on sulphones; in fact, the available chlorine used up generally corresponds very closely with four atoms per atom of sulphur oxidised. The reagent does not become appreciably less alkaline during this reaction.

Kahlbaum's diethyl, di-*n*-propyl, di*iso*butyl, and di*iso*amyl sulphides were employed without further purification. In the case of diethyl sulphide, at the conclusion of the reaction, the aqueous liquid was evaporated and the residue extracted with chloroform; the diethylsulphone, m. p. 70°, obtained from the extract in 75% yield, was identified by comparison with a genuine specimen. The higher sulphones, which are more soluble in petroleum than in water, were prepared in yields of over 70% by shaking the corresponding sulphides with aqueous sodium hypochlorite alone; the resulting oils were taken up in chloroform, and after drying over calcium chloride, the solvent was removed, and the residue distilled. Di*iso*butylsulphone and di*iso*amylsulphone have b. p. 263° and 296° respectively (both with slight decomposition) (Beckmann, *J. pr. Chem.*, 1878, **17**, 448, gives b. p. 265° and 295° respectively.)

The effect of alkalinity upon the rate of oxidation of the sulphides was tested by means of eight solutions of sodium hypochlorite which contained 8·42% of available chlorine, but in which the alkalinity (calculated as sodium hydroxide) varied from 0·22% to 6·64%. Solutions of diethyl, di-*n*-propyl, di*iso*butyl, and di*iso*amyl sulphides were employed, having sulphur contents of, respectively, 0·736, 0·864, 0·912 and 0·875%. Preliminary experiments led us to adopt, for the times of shaking, 15, 30, 120, and 240 minutes, respectively. The results are summarised in Table I.

TABLE I.

Available chlorine in reagent = 8·42%.

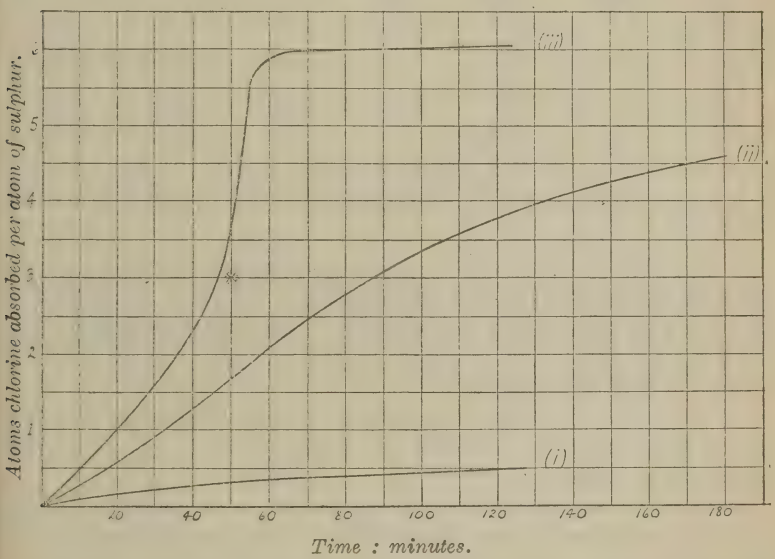
n = atoms of available chlorine absorbed, per atom of sulphur present.
x = % sulphur in residual petroleum.

Diethyl sulphide was always completely oxidised after 15 minutes; since diethylsulphone is much more soluble in water than in petroleum, the latter was invariably free from sulphur. It was, however, possible to demonstrate the retarding effect of sodium hydroxide on the oxidation of diethyl sulphide by using a solution of hypochlorite which contained 20·4% of sodium hydroxide and 7·89% of available chlorine; after 15 minutes, only 21·1% of the sulphide had been oxidised, and even after 60 minutes' shaking still only 53·4% had been removed. The inhibiting influence of the free alkali is more noticeable in the oxidation of the higher sulphides. Thus, with di-*n*-propyl sulphide there is a gradual diminution in the extent of oxidation, a correspondingly increasing quantity of sulphur remaining in the petroleum. In the case of di*iso*butyl and di*iso*amyl sulphides, the figures for the residual sulphur in the petroleum are irregular; this has been traced to the existence of a partition of the resulting sulphones between the aqueous reagent and the organic solvent. It was usual, before proceeding to the analysis of the petroleum layer, to wash it once or twice with a small quantity of sodium hydroxide solution to remove any free hypochlorous acid; in consequence, varying quantities of the higher sulphones were dissolved from the petroleum. This has been confirmed, for by washing petroleum solutions of di*iso*butyl- and di*iso*amyl-sulphones several times with water the sulphur content of the petroleum was reduced. Any of the sulphides dealt with was rapidly oxidised by a dilute, faintly alkaline, solution of sodium hypochlorite. It is evident that even using so strongly alkaline a solution as one containing 6·64% of free alkali, the reaction between aqueous sodium hypochlorite and a dialkyl sulphide may be said to proceed quite readily by comparison with the prolonged reactions which are so common in synthetic organic chemistry; and even with a reagent containing 20% of free alkali the reaction with diethyl sulphide is still obvious and could scarcely fail to be detected. In fact (*vide supra*), this reaction offers a very convenient method for the preparation of sulphones.

Organic Disulphides.



Diethyl and di*iso*propyl disulphides were quite readily freed from traces of the mercaptan or sulphide by fractional distillation. Their behaviour towards aqueous sodium hypochlorite is evidently typical of the disulphides, since parallel results were obtained in the two cases.

The primary oxidation products from diethyl disulphide, unlike the product from a sulphide, are acidic, *i.e.*, ethanesulphonic acid together with a smaller quantity of sulphuric acid; these appear as

sodium salts, and therefore the alkalinity of the aqueous phase is gradually reduced. Since the sulphonic acid (as its sodium salt) is not attacked by hypochlorite, the sulphuric acid is formed directly from the disulphide :

$$Na_2SO_4 \leftarrow H_2SO_4 \leftarrow R_2S_2 \rightarrow R{\cdot}SO_3H \rightarrow R{\cdot}SO_3Na.$$

The gradual removal of the alkali hydroxide makes it necessary, in describing the effect of alkalinity on the reaction, to distinguish two somewhat different cases. (1) The free alkali present is more than equivalent to the total possible acid products; the reagent will always remain alkaline. (2) The free alkali is less than equivalent

to the total possible acid products; if the reaction is continued long enough, the reagent will become acidic. The reaction in the first case may be described as the normal one; plotting the atoms of available chlorine absorbed, per atom of sulphur, against time, curves are obtained, of which (i), for a strongly alkaline, and (ii), for a weakly alkaline reagent, are typical. The influence of the added alkali hydroxide is very marked. If, however, the alkalinity of the reagent is so chosen that it falls into the second class, the additional complication causes the curve to assume quite a different form (iii). The initial part of the reaction takes the normal course until the acidic primary products have completely neutralised the free alkali present; at that point (*) there occurs a very rapid absorption of available chlorine until the sulphur compound is entirely removed

from the petroleum solution; the reaction then tails off and only a slow spontaneous decomposition of the residual dilute acid hypochlorite continues to take place.

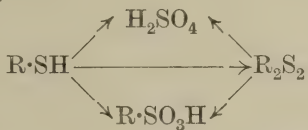
d = % "free alkali" in residual aqueous reagent. *n* = atoms of available chlorine absorbed per atom of sulphur present. *x* = % sulphur in residual petroleum.

A considerable evolution of heat occurred at and immediately after the point in the reaction marked with an asterisk; the oxidation at this stage was so rapid that a sample of the reagent corresponding with the points intermediate between this and the completion of the reaction could not be isolated.

It must be noted that even 20% of sodium hydroxide does not completely inhibit the oxidation of a disulphide by means of aqueous sodium hypochlorite.

Sodium ethanesulphonate was identified as a product of the oxidation of diethyl disulphide as follows. The disulphide, dissolved in petroleum, was shaken with a faintly alkaline solution of sodium hypochlorite in slight excess, until the mixture had become warm and had commenced to cool again. The aqueous liquid was warmed and treated with sulphur dioxide to decompose any residual hypochlorite and any sodium chlorate present. After adding an excess of hydrochloric acid, the excess of sulphur dioxide was expelled by boiling, and the solution neutralised, and evaporated to dryness. Sodium ethanesulphonate, mixed with sodium chloride, was extracted by means of absolute alcohol from the residue, dried at 110°. The pure salt was obtained after repeated crystallisation from absolute alcohol until it no longer contained chlorine (Found: Na, 17·4. Calc. Na, 17·5%).

A portion of the aqueous layer from the oxidation was boiled with ammonia, and hydrochloric acid and barium chloride were



added; on boiling, a white precipitate of barium sulphate was obtained.

Mercaptans.

Ethyl mercaptan was used for these experiments; results obtained with *iso*propyl and *iso*butyl mercaptans indicated that the reactions followed the same course.

The mercaptans, before being fractionally redistilled, were washed with a small quantity of sodium hydroxide solution to remove any hydrogen sulphide.

The apparent course of the reaction between sodium hypochlorite and ethyl mercaptan depends greatly upon the alkalinity of the reagent. The first action leads simultaneously to the formation of ethanesulphonic acid, sulphuric acid, and diethyl disulphide; the last, if the reagent is sufficiently reactive, is destroyed as it is formed, the acids (as their sodium salts) being the only products. But with a more stable solution of hypochlorite a much slower decomposition of the disulphide occurs, and this substance then appears as the chief product, accompanied by smaller quantities of the acids, which have been formed, for the most part, by direct oxidation of the mercaptan. The first part of the reaction, in which the mercaptan itself takes part, does not appear to be affected by the alkalinity of the reagent, whilst the factors which influence the destruction of the resulting disulphide are those which govern the normal interaction of this type of compound with sodium hypochlorite (*vide supra*).

The proof that ethanesulphonic and sulphuric acids are formed concurrently with the disulphide is as follows: A solution of ethyl mercaptan containing 0·715% of sulphur and a solution of sodium hypochlorite containing 5·3% of available chlorine and 27·7% of sodium hydroxide being used, after 15 minutes 4·8 atoms of chlorine per atom of sulphur had been taken up, simple conversion to the disulphide requiring only one, and this figure did not appreciably increase after a further 45 minutes' agitation. This shows quite clearly that diethyl disulphide, once it is formed, is not appreciably attacked by hypochlorite having the alkalinity mentioned; this was confirmed by treating a solution of diethyl disulphide with the same reagent, when, even after 2 hours, only 0·4 atom of chlorine per atom of sulphur had been absorbed.

The influence of alkali hydroxide upon the extent of oxidation of

ethyl mercaptan during a fixed time of shaking is exhibited in Table III.

TABLE III.

Ethanesulphonic acid was identified in the manner described above; the sodium salt was analysed (Found : Na, 17·4%). Sulphuric acid was identified as before. Diethyl disulphide was isolated from the petroleum at the conclusion of the reaction; the yield, however, never exceeded approximately 50%.

The Influence of Sodium Carbonate and the Effect of Dilution.

Solutions of sodium hypochlorite invariably contain sodium carbonate in addition to sodium hydroxide, sodium chloride, and sodium chlorate.

During the earlier experiments, estimations were made of the actual sodium hydroxide, as well as of sodium carbonate, in the aqueous reagent. The experimental procedure thereby involved made it, however, very inconvenient to carry out a sufficient number of experiments during many of the more rapid oxidations. In seeking a more simple method for determining the alkalinity of the hypochlorite, it was therefore necessary to ascertain whether sodium carbonate has any appreciable effect upon the reactivity of the reagent. For this purpose, the reaction with diethyl disulphide was chosen, as being the most sensitive towards the influence of added alkali. The results are summarised in Table IV, in which a comparison is drawn between the course of the reaction between a standard solution of diethyl disulphide and (i) a weakly alkaline solution of sodium hypochlorite, (ii) the same solution after the addition of solid sodium carbonate.

These figures do not show any detectable increase in stability brought about by the addition of sodium carbonate. This is scarcely surprising, since no appreciable alteration is produced in the concentration of hydroxyl ions by adding sodium carbonate to a solution already containing a comparatively large quantity of sodium hydroxide.

It was, in consequence, possible to adopt quite a simple method for determining the alkalinities of a series of reagents. The object of these analyses was twofold; the decrease in the alkali present before and after a reaction gave a measure of the acid products,

* Calculated as sodium hydroxide.

whilst the alkalinities of a series of reagents formed an indication of their reactivities. The solutions all contained approximately the same concentration of sodium carbonate, present as impurity in the weakly alkaline solution of sodium hypochlorite to which varying quantities of solid sodium hydroxide had been added. Since differences in alkalinity were to be compared, as distinct from the actual hydroxyl-ion concentrations, the alkalinity was estimated, after destroying the hypochlorite by means of hydrogen peroxide, by titration against hydrochloric acid with methyl-orange as indicator. Hence curves in which alkalinity is plotted as one of the co-ordinates are slightly displaced in a direction parallel to the axis of alkalinity; for the present purpose this is immaterial.

The increase in reactivity brought about by diluting a solution of sodium hypochlorite (compare p. 1936) was demonstrated by means of the reaction with diethyl disulphide. The reagent used was the same solution which had been employed for the experiments with sodium carbonate; in one series the solution was diluted to one-half, in the second to one-fifth of its original concentration. The results, which clearly indicate an increase in the velocity of reaction with

decrease in concentration of the sodium hypochlorite, are included in Table IV.

Elementary Sulphur and Hydrogen Sulphides; Thiophen.

The observation of Wood, Lowy, and Faragher (*loc. cit.*) that free sulphur is precipitated when hydrogen sulphide reacts with sodium hypochlorite, has been confirmed, but evidence of the simultaneous production of sulphuric acid has been obtained. This is not formed by further oxidation of the elementary sulphur, since the latter has been shown to be quite inert towards sodium hypochlorite.

Thiophen does not react with sodium hypochlorite.

Our thanks are due to Professor J. F. Thorpe, C.B.E., F.R.S., for his kind help and encouragement and to Dr. A. E. Dunstan and Dr. F. B. Thole for their interest in the present work.

CCLX.—*The Action of Formic Acid on certain Sesquiterpenes.*

By JOHN MONTEATH ROBERTSON, CARL ALOYSIUS KERR, and GEORGE GERALD HENDERSON.

THE experiments described below were undertaken last year as part of a larger investigation which is not yet complete, but it appears desirable to communicate the results now, in view of the interesting work carried out recently by Ruzicka and Capato (*Helv. Chim. Acta*, 1925, **8**, 259).

The action of anhydrous formic acid as a means of effecting ring closure in the sesquiterpenes is now well established. Semmler and Spornitz (*Ber.*, 1913, **46**, 4025) ascertained the transition of the aliphatic sesquiterpene from Java-citronella oil into a monocyclic isomeride by the action of concentrated formic acid. Ruzicka and Capato (*loc. cit.*) in their synthesis of bisabolene from nerolidol have now shown that the action of formic acid in the cold closes one ring in the nerolidol structure, whereas, by more prolonged action with the same reagent at a higher temperature, the closure of two rings is effected, a hexahydrocadalene being thus produced. They also observed the production of alcohols as intermediate compounds.

This reagent may also act in another way, as was shown by Wallach (*Annalen*, 1896, **289**, 337), who found that on refluxing

pulegone with anhydrous formic acid for several days, acetone and 1-methyl-3-*cyclo*hexanone resulted.

We have investigated the action of anhydrous formic acid on the dicyclic sesquiterpenes β-caryophyllene and cadinene and on the tricyclic sesquiterpene cedrene, and our results support the above conclusions with regard to the efficacy of this reagent in producing isomeric hydrocarbons and in effecting ring closure.

From β-caryophyllene we obtained the *formic* ester, $C_{16}H_{26}O_2$, of caryophyllene alcohol, together with a mixture of hydrocarbons, probably consisting of clovene and unattacked caryophyllene. Since caryophyllene alcohol is a saturated substance and on dehydration yields clovene, it is presumably tricyclic. Hence in this case the action of formic acid has effected ring closure, the sesquiterpene passing from the dicyclic caryophyllene structure to the tricyclic clovene structure.

The chief product from cadinene consisted of a hydrocarbon, or a mixture of hydrocarbons, $C_{15}H_{24}$, b. p. 118—124°/9 mm., which did not form a stable hydrochloride, together with some unchanged cadinene. On heating cadinene in an autoclave, Semmler and Jakubowicz (*Ber.*, 1914, **47**, 2252) obtained a substance, b. p. 120—130°, d 0·9025, n_D 1·50829, which they considered to be a monocyclic sesquiterpene mixed with cadinene. The product we obtained agrees closely with the above in its physical properties.

Cedrene yielded as chief product an isomeric unsaturated hydrocarbon, b. p. 114—118°/9 mm., some unchanged cedrene, and a small fraction of higher boiling point in which the presence of alcoholic compounds is suspected.

Experimental

Action of Formic Acid on β-Caryophyllene.—β-Caryophyllene was prepared by fractional distillation under diminished pressure of the commercial hydrocarbon which had stood for some time in contact with solid potassium hydroxide. The main product had b. p. 118—119°/9·7 mm., $n_D^{17°}$ 1·5009, $d_4^{17°}$ 0·9052, and gave a practically quantitative yield of the crystalline dihydrochloride of β-caryophyllene, m. p. 69°; $[\alpha]_D^{15°}$ + 67·2° in 2·5% ethyl-alcoholic solution. Caryophyllene (25 c.c.) was heated under reflux with an equal amount of formic acid for several days. A reaction set in at once, and when completed the excess of acid was neutralised with sodium carbonate, and by extraction of the mixture with ether an oil was obtained which after several fractionations yielded a colourless liquid, b. p. 141—145°/10 mm., $d_4^{17°}$ 1·22, $n_D^{20°}$ 1·4967, $[\alpha]_{5461}^{17°}$ − 10·46°. Analysis indicated that this liquid was the formic ester of caryophyllene alcohol, $C_{15}H_{25}O(CHO)$ (Found: C, 76·9; H, 10·5.

$C_{16}H_{26}O_2$ requires C, 76·8; H, 10·4%), and this was confirmed by hydrolysis of the ester, when the alcohol was obtained in crystals, which, after recrystallisation from ether–light petroleum, melted at 96°. The yield of the ester was about 35% of the caryophyllene taken. The other fractions of the distillation, b. p. 115—130°/10 mm., consisted of hydrocarbons. Heating caryophyllene in a sealed tube at 200° with anhydrous formic acid for 5 hours did not lead to an increased yield of the formic ester.

Action of Formic Acid on Cadinene.—Cadinene was prepared from the dihydrochloride, m. p. 118°, by regeneration with anhydrous sodium acetate in glacial acetic acid solution. Equal quantities of cadinene, b. p. 134—136°/11 mm., $d_4^{20°}$ 0·9189, $n_D^{20°}$ 1·5079, $[\alpha]_{5461}^{18°}$ − 125°, and 99% formic acid were heated together under reflux at 100° for 40 hours. The liquid slowly became red. After neutralisation, the products were extracted with ether and hydrolysed. The final products were distilled under diminished pressure. After several distillations two main fractions were obtained: (*a*) b. p. 118—124°/9 mm. and (*b*) b. p. 126—134°/9 mm., together with some brown resinous substances. The fraction (*a*) consisted of an unsaturated hydrocarbon, $d_4^{17°}$ 0·9086, $n_D^{14°}$ 1·5010 (Found: C, 87·3; H, 12·1. $C_{15}H_{24}$ requires C, 88·2; H, 11·85%). The fraction (*b*) consisted chiefly of unchanged cadinene.

Action of Formic Acid on Cedrene.—Cedrene, purified by distillation over sodium, b. p. 122—124°/9 mm., $d_4^{20°}$ 0·9361, $n_D^{21°}$ 1·5005, was treated with formic acid in the same way as cadinene, and the products were worked up as before. After a large number of distillations under reduced pressure, the following fractions were obtained: (*a*) b. p. 114—118°/9 mm., comprising about 50% of the product; (*b*) 118—130°/9 mm.; (*c*) 130—135°/9 mm., a small fraction. The fraction (*a*) consisted of an unsaturated hydrocarbon, $d_4^{20°}$ 0·9333, $n_D^{21°}$ 1·4988 (Found: C, 87·9; H, 11·9. $C_{15}H_{24}$ requires C, 88·2; H, 11·8%), from which no derivative could be obtained. It appears to be tricylic from its physical constants. The fraction (*b*) consisted chiefly of unattacked cedrene The fraction (*c*) appears from its analysis to contain alcoholic substances as well as hydrocarbons (Found: C, 84·8; H, 11·25%), but only a small quantity was available.

We are indebted to the Carnegie Trust for grants which enabled us to carry out this work.

UNIVERSITY OF GLASGOW. [*Received, June 13th,* 1925.]

CCLXI.—*Cryoscopic Measurements with Benzene.*

By Edward Richard Jones and Charles R. Bury.

The object of the work described in this paper was to see how far certain conclusions, reached in the study of nitrobenzene as a solvent for cryoscopy, could be applied to benzene, a far more important solvent from the point of view of ordinary laboratory practice.

First, the most important source of error is the change in water content of the solvent: this is usually overlooked with benzene, but is by no means negligible in accurate work (Sidgwick, J., 1920, **117**, 1340). The difference between the freezing point of dry and of wet benzene is 0·097° (Sidgwick, *loc. cit.*; Richards, Carver, and Schumb, *J. Amer. Chem. Soc.*, 1919, **41**, 2024). This error can be easily avoided by keeping the solvent in contact with a substance the aqueous vapour pressure of which is constant (Roberts and Bury, J., 1923, **123**, 2037).

Secondly, the usual van 't Hoff formula is strictly true only at infinite dilution; with depressions up to about 0·5° the error due to the use of this formula is less than the experimental error. At greater concentrations, however, far more accurate results may be obtained from the formula discussed by Brown and Bury (J., 1924, **125**, 2219):

$$\Delta t_u + \Delta t_w = k[n_u + Cn_v]/[n_u + (1 + C)n_v],$$

where Δt_u is the observed depression, n_u and n_v are the number of mols. of solute and solvent respectively, Δt_w and C are constants depending on the degree of moisture of the solvent, *i.e.*, on the vapour pressure of the substance with which it is in contact. These have been calculated by the method described by Brown and Bury, assuming that the freezing point of benzene is a linear function of the aqueous vapour pressure (Crowther and Puri, *Proc. Roy. Soc.*, 1924, *A.*, **106**, 232). For the substances used in this research the values are:

	Aq. vap. pressure.	Δt_w.	C.
Phosphorus pentoxide, alumina ...	0·0 mm.	0	0
$Na_2SO_4,0—10H_2O$	4·40	0·063°	0·00094
Water	6·76	0·097	0·00145

With this formula it should be possible to detect combination between solute and solvent, or solvation (Washburn, " Principles of Physical Chemistry," 1915, p. 174). If every molecule of solute combines with N of solvent, the number of mols. of solute is unaltered, but the number of mols. of solvent is reduced by Nn_u: when N is 1, and the solvent is dry, the formula given reduces to that of van 't Hoff. Azobenzene, triphenylmethane, picric acid,

and trinitrotoluene, all of which separate from benzene with 1 mol. of benzene of crystallisation, have been studied to see if solvation can be detected. The existence of solid compounds is, of course, no proof that these substances form compounds with benzene in solution. It is, however, probable that the compounds of picric acid and trinitrotoluene with benzene exist in solution, since similar compounds, such as naphthalene picrate, are not entirely dissociated in inert solvents (Brown, this vol., p. 345).

Experimental.

The benzene used was a pure thiophen-free sample supplied by Robinson, Nelson and Co., and was further purified by the method described by Roberts and Bury (*loc. cit.*). The substances used as solutes were chosen with the idea of covering as wide a range of types of compounds as possible, and were all purified by repeated crystallisation.

The usual Beckmann method was employed. All depressions recorded are the mean of at least three closely agreeing determinations. After a number of preliminary experiments, it was decided that the loss of solvent by evaporation could not be avoided without seriously complicating the apparatus, but was negligible provided the experiment did not last more than $2\frac{1}{2}$ hours.

The degree of supercooling attainable varies rather remarkably with conditions : with very pure and dry benzene it is difficult to get that small amount of supercooling which is essential to the Beckmann method; with the wet solvent, however, it is difficult to avoid a supercooling of 2°.

The freezing point of benzene has been found to be much more susceptible than that of nitrobenzene to errors due to friction and radiation, depending on the rates of stirring and the temperature of the bath. These were minimised as far as possible by maintaining a standard rate of stirring and by keeping the bath temperature 1—1·5° below the freezing point. In working with the dry solvent in the presence of phosphorus pentoxide, the usual precaution of passing dry air through the apparatus could not be used on account of the volatility of the solvent; consequently the phosphorus pentoxide soon became sticky, and the frictional effects generated by stirring made the determination of the freezing points difficult. Alumina was found to be nearly as efficient as a drying agent, and free from this disadvantage.

Conclusions.

A typical selection of the results obtained with normal solutes is given in Table I; the first column gives the weight of solute per

100 g. of solvent (W), the second the observed depression, and the third the molecular weights (M) calculated from the above formula. The solute, its molecular weight, and the degree of moisture of the solvent are given at the head. (Na_2SO_4 signifies that the solvent was partially saturated, in contact with the salt hydrate pair Na_2SO_4,0—10H_2O.) It is obvious that the calculated molecular weights are more consistent and accurate than are obtained by the usual Beckmann method, *i.e.*, by using the van 't Hoff formula, and neglecting the changing water content of the solvent.

The results obtained with the dry solvent, and quoted in this table, were used to calculate k. Assuming the theoretical molecular weights, the mean value found was 66·95, and this has been used in calculating the figures in the third column. This value corresponds to a value of 52·27 for the van 't Hoff constant, and 29·53 cals. for the latent heat of fusion of benzene. The published values for the latent heat are somewhat conflicting, and vary from 29·1 to 30·7 cals. : most direct determinations of the van 't Hoff constant are rather lower than 52·27, but it must be remembered that low values for this constant must always be obtained when working with solutions that are not infinitely dilute (Brown and Bury, *loc. cit.*).

With benzene, in which water is only very slightly soluble, little error is introduced by neglecting the water content of the solvent in calculating molecular weights, provided, of course, that it is kept constant during the experiments. If C and Δt_w are put equal to 0, as when working with the dry solvents, the calculation is considerably simplified, and the error introduced is only about 0·2%.

We have obtained no definite evidence of solvation. Azobenzene (Table I) is a perfectly normal solute. With picric acid and trinitrotoluene, the deviation that might be expected if solvation occurs is masked by a deviation in the opposite direction, possibly due to association. Triphenylmethane appears to be solvated but is, unfortunately, too insoluble for the evidence to be conclusive. The maximum depression obtainable is rather less than 0·8°, and such small depressions are liable to an experimental error of 0·5%, which is comparable with the theoretical deviation (1%) to be expected if solvation occurs. Values of k and of the van 't Hoff constant K, calculated from the experimental results with triphenylmethane, are shown in Table II. The van 't Hoff law appears to fit the

17·304	5·147	162·2	69·11

results better, which indicates solvation, for the mean value of K is nearer than that of k to the values of these constants obtained with normal substances; k shows a distinct tendency to increase with the concentration whilst the variation of K is haphazard.

Substances tend to be more abnormal in benzene than in nitrobenzene. No solute which has been found normal in benzene, and which has also been studied in nitrobenzene, has proved to be abnormal in the latter solvent, but many solutes, normal in nitrobenzene, are abnormal in benzene, *e.g.*, picric acid, trinitrotoluene, methyl oxalate, α-nitronaphthalene, tetrachloroethane, and benzil. In the majority of cases these substances appear to be associated and we hope to discuss this phenomenon fully in a later paper. Tetrachloroethane behaves in a somewhat unusual manner: it is normal in dilute solution, but the law for normal substances

breaks down at higher concentrations: as shown in Table III, the calculated molecular weights are too small at the higher concentrations.

One of us (E. R. J.) desires to acknowledge his indebtedness for a Garrod Thomas research scholarship of this College.

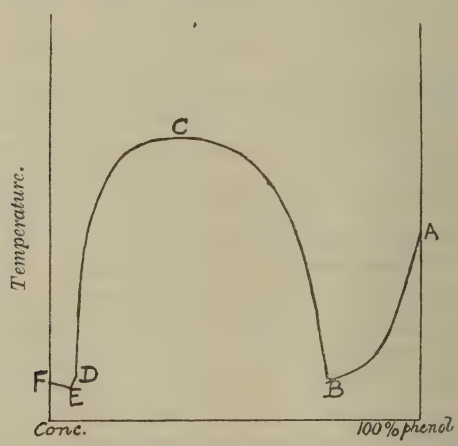
CCLXII.—*The Condensed Ternary System Phenol–Water–Salicylic Acid.*

By CHARLES REYNOLDS BAILEY.

TERNARY systems containing water and two organic substances have attracted workers on phase rule questions because of the varied phenomena which are to be met with. In one or more of the binary systems concerned, an upper or lower critical solution temperature frequently occurs and two liquid layers are to be found; references to many systems will be seen in Vols. II, ii, and III, ii, of Roozeboom's "Die Heterogenen Gleichgewichte" and in Tammann's work on the same subject. Difficulties in the quantitative analysis of such systems where mixtures of organic substances are involved have generally led to the restriction of their examination to the "synthetic" method; this method neglects the possible formation of mixed crystals; in the present research both analytic and synthetic methods have been applied.



The system phenol–water–salicylic acid was chosen as it presents certain features of considerable interest and it was anticipated that by the interplay of these characteristics important solubility relations would arise. Some of the chief points are: (i) the binary system water–salicylic acid gives two liquid layers in the metastable region; (ii) the system phenol–water has two liquid layers in the stable region and the phenomenon of "melting under the liquid" occurs at an easily accessible temperature; (iii) salicylic acid has very slight solubility in water but a much higher solubility in phenol.

By use of the synthetic method it has been possible to extend the research well into the metastable region. In applying the analytic method the mixtures were stirred in a thermostat, the one or two liquid layers sucked off and, together with the moist residue, analysed as indicated below.

The Binary Systems.

(1) *Phenol–Water.*—Temperature–concentration diagrams have been given by Smits and Maarse (*Proc. K. Akad. Wetensch. Amsterdam*, 1911, **14**, 192) and by Rhodes and Markley (*J. Physical Chem.*, 1921, **25**, 527). The former workers do not give the concentrations which correspond to many of the phase changes, although the temperatures are in general agreement with those obtained by the latter workers. No trace of the stable phenol hydrate was observed in the present research and the values for certain binary and ternary mixtures are strictly metastable. The two-liquid-layer area has been explored by a large number of workers and no two determinations seem to agree, the departure from the mean being

FIG. 1.

greatest at high temperatures. In many cases this is due to the use of impure materials and in others to inaccurate use of the synthetic method. Most workers have taken as the critical saturation temperature the mean between the temperatures of clouding and clearing. If, however, the very definite temperature of sudden thickening is taken, it is possible to get readings concordant to 0·1° and agreeing with those of Timmermans (*Z. physikal. Chem.*, 1907, **58**, 129) and with the values obtained by analysis of the two liquid layers after the mixture has completely cleared in a thermostat. The difficulty does not occur to the same marked extent at lower temperatures, and it is possible to correct the concentration given by Rhodes and Markley (*loc. cit.*) for the point D (Fig. 1) where solid phenol is in equilibrium with a water-rich solution. The concentration given is 10·0% phenol at 1·7°, which is well inside the two-liquid layer area: the true concentration at this

point is 7·6% and agrees with a redetermination made by the present author by thermal analysis.

The important temperatures in the system are as follows, the letters referring to Fig. 1 :—

TABLE I.

Point.	% Phenol.	Temp.	
A	100·0	40·8°	M. p. of pure phenol
B	75·0	1·7	
C	36·5	65·3	Crit. soln. temp.
D	7·6	1·7	
E	6·5	−1·2	Eutectic
F	0·0	0·0	M. p. of ice

(2) *Salicylic Acid–Water.*—Here again many incomplete determinations are to be found in the literature; the values for the solubility of salicylic acid in water are extremely divergent: the most recent data, due to Savorro (*Atti R. Accad. Sci. Torino*, 1914, **48**, 948) are not only above the mean of the best data available, but exhibit several breaks in the curve which do not correspond to any accompanying phase change. The values obtained in the present research (Table II) coincide with those of Walker and Wood (J., 1898, **73**, 620) up to 30°, but are slightly and uniformly larger at higher temperatures. A fresh determination of the metastable region has been made and the results differ slightly from those of Flaschner and Rankin (*Monatsh.*, 1910, **31**, 23). A careful determination of the eutectic ice–salicylic acid places this at − 0·07° and 0·103% salicylic acid.

TABLE II.

(The values are given in grams per 100 g. of solution.)

Stable.		Metastable.		
		Water layer.	Salicylic layer.	
% Sal.	Temp.			Temp.
0·131	10·0°	4·4	69·6	60·0°

0·592	50·0	30·0	30·0	87·0
0·864	60·0			

(3) *Phenol–Salicylic Acid.*—This system does not appear to have been previously investigated. Walden (*Z. physikal. Chem.*, 1920, **94**, 331) found that the depression of freezing point of phenol by salicylic acid was normal. In the present case thermal analysis was resorted to; at the higher temperatures near the melting point of the acid, mixtures were sealed in glass tubes, and the temperatures of appearance and disappearance of the solid phase noted. At the lower temperatures the eutectic halts were measured

and it was found that their prolongation met the composition axis at 100% salicylic acid. Hence the system offers a simple eutectic at 5·0% salicylic acid and 38·16°. The results are given in Table III. For the mixture containing 1·5% acid the lowering of the phenol freezing point is 0·8°; if the cryoscopic constant for phenol is taken as 72·7, the molecular weight of the acid is 138·7 (calc. 138·1).

TABLE III.

EXPERIMENTAL.

Materials.—(i) *Phenol.* The detached crystals marketed by the British Drug Houses seem to be a very satisfactory product, and preserve their whiteness unchanged even on long exposure to light. They were twice distilled and the end portions rejected in each case; the product obtained melted at 40·8°.

(ii) *Salicylic acid.* Both the commercial variety and the physiologically pure acid were used. The samples were recrystallised by dissolving in boiling water and pouring into cold: the process was carried out four times. This removes completely the sweet smell characterising the commercial acid, which is nevertheless of a high degree of purity nowadays. The brown colour found in specimens of the physiologically pure acid is not removed in this way. The older methods for effecting this involved distillation in steam or solution in glycerol, whereas it was found best to dissolve the acid in a hot mixture of phenol and water; on cooling, the colourless acid was precipitated and a further supply was obtained by adding water to the mixture. If the solution of the acid in hot water is allowed to cool slowly, the peculiar formation of crystalline threads may be observed (*Nature*, 1923, **112**, 10). After the last two crystallisations the m. p. was constant at 158·7°; when allowance is made for stem exposure, this figure is increased to 160·4°, a result much higher than is usually found in the literature but

agreeing with that of W. J. Bush and Co., Ltd. (*Perfumery and Essent. Oil Rec.*, 1920, **11**, 207). The value was checked by observations both on a single crystal in a melting point tube and also by cooling curves on a large bulk of the acid.

Analysis of Solutions.—Phenol was estimated by the bromide–bromate method (for details, see Redman, Weith, and Brock, *Ind. Eng. Chem.*, 1913, **5**, 389).

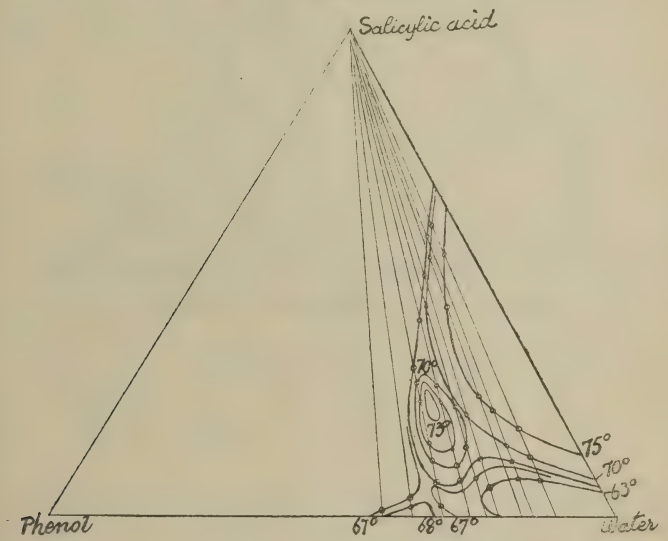
Salicylic acid can be directly estimated with baryta; the indicator chosen was *p*-nitrophenol with titration to a colour match. Kolthoff (*Pharm. Weekblad*, 1921, **58**, 699) has examined the bromometric method in use for phenol as applied to salicylic acid; by careful standardisation of conditions he obtained concordant results. The present author finds that with reasonable care reproducible results are obtained for one and the same concentration of acid, but if that concentration is varied the titre value does not change proportionally. Curves correlating concentration and bromide–bromate titre were constructed but found too complicated to be of use.

Phenol and salicylic acid in mixture in aqueous solution were analysed by various methods, of which the most successful were the following:

(i) By separation and subsequent determination: the phenol was extracted several times with small quantities of ether or chloroform from a solution containing a slight excess of sodium bicarbonate and the extracts were added to caustic soda solution. It was found necessary to drive off all traces of the organic solvent before bromination, as, peculiarly enough, much less bromine was taken up in its presence.

(ii) The method finally adopted was to determine first the salicylic acid alone; this can be effected by titration with baryta and *p*-nitrophenol indicator, since by keeping the phenol in low concentration it has no effect on the indicator. It was then ascertained by careful varying of the concentrations that the presence of the one substance does not affect the bromination of the other in mixtures of phenol and salicylic acid. The total bromide–bromate titre was accordingly determined for a given volume of the solution and the *same* volume of the solution was then evaporated to dryness with excess of sodium bicarbonate solution; this treatment was shown to be sufficient to drive off the phenol and leave the acid as the sodium salt, which was then brominated. The difference between the two titres gives the phenol in the mixture, since it has been shown above that with the same concentration of salicylic acid reproducible results can be obtained on bromination.

Water was determined by difference.



The mixtures were stirred in a thermostat for temperatures

between 20° and 70°. When equilibrium (which was approached from both sides) had been attained, the solution was sucked off through a side tube with filter into a stoppered flask and weighed, transferred to a measuring flask, and made up to a known volume. The conjugate solutions in the case of two liquid layers were allowed to settle out from the emulsion formed and sucked off; fortunately at the higher temperatures the clearing was only the matter of an hour or so; at the lower temperatures a longer period of standing was necessary. The moist residues were analysed similarly to give the solid phase.

The ternary system was also explored by the synthetic method for control purposes and to investigate the metastable region. Varying amounts of salicylic acid were added to known mixtures of phenol and water and the temperature of sudden thickening was determined; separate determinations agreed to within 0·1°. The work was carried out in sealed tubes. At the same time the temperature of the beginning of critical opalescence was determined; it was found possible to obtain reproducible readings within 0·5°. Curves were then constructed showing the relation between the above temperatures and the concentrations of salicylic acid in the particular mixture; from a given series of curves the percentages of salicylic acid present at constant temperature can be laid off: then on the usual triangular diagram the points on the phenol–water axis representing the different initial mixtures taken can be joined to the salicylic acid vertex; the percentages of acid obtained from the previous curves can be marked directly on to the triangular diagram and hence the isotherms are obtained (Figs. 2 and 3). It was found possible to complete the larger number of isotherms having metastable prolongations and so to explain the rather peculiar shape of the binodal curves. In this way two distinct series of isotherms are got and it is interesting to contrast one with the other (Figs. 2 and 3). Both temperatures from their reproducibility seem to be characteristic of the particular mixture under consideration, but it is difficult to trace any relationship between them; there are cases in which the addition of further quantities of the third component lowers the temperature of sudden thickening but actually raises the temperature of beginning of opalescence. There is apparently a " knoll " on the contour system for the critical opalescence which finds no corresponding feature on the system as determined by analysis or by the sudden thickening (the last two methods giving concordant results). Andant (*J. Phys. Radium*, 1924, **5**, 193), in an examination of the opalescence of a liquid and its vapour at the critical temperature, was able to show that the intensity and duration of the opalescence

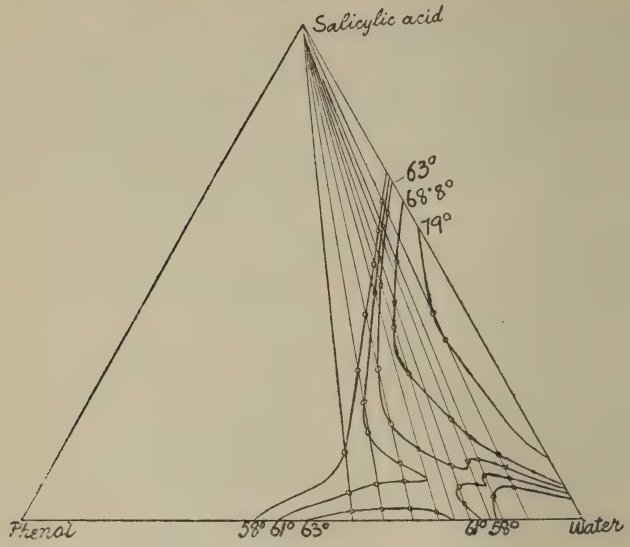
varied with the ratio of the volume of liquid to that of vapour, passing through a maximum when the ratio was unity. In the case of binary and ternary mixtures where the upper liquid layer bears some rough analogy to the vapour phase in the unary equilibria, the correspondence would predict a condition of maximum opalescence for mixtures which are in the neighbourhood of the critical point on the particular binodal curve under consideration. This is roughly borne out by the experimental results, as will be seen on reference to Table V; in mixtures containing a large proportion of any one constituent, and hence generally resolving into

FIG. 2.

Critical opalescence isotherms.

two liquid layers with a large volume ratio, the temperatures of critical opalescence and critical thickening coincide almost exactly.

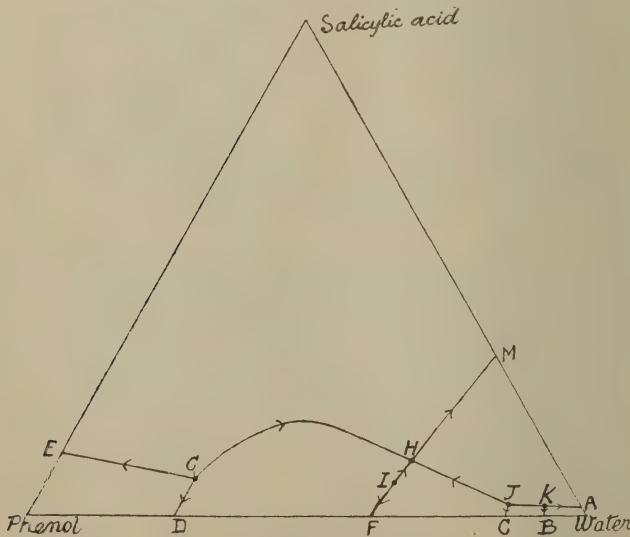
At temperatures below 20°, the system was examined by thermal analysis in a vacuum vessel; the curve which gives the displacement of the temperature at which solid phenol can exist in contact with two liquid layers on addition of the third component was obtained in that way.



No compounds or mixed crystals were observed during the investigation.

The Isotherms.

A selection of the tabulated results will be found at the end of the paper. The two series of isotherms illustrated in Figs. 2 and 3



contain only the binodal curves; the inclusion of the saturation curves for solid salicylic acid would have complicated them unduly.

FIG. 3.

Binodal curves as determined by analysis.

FIG. 4.

It is expedient to consider, first, the polytherm for the system, and, secondly, the individual isotherms in order to obtain a grasp

of the many phase changes which may take place within narrow temperature limits.

The Polytherm (Fig. 4).—The actual conditions in the bottom right hand corner of the diagram have been exaggerated somewhat in order to render them apparent; the necessity for this will be readily seen on consideration of the values given below (Table IV). The arrows indicate the direction of rising temperature. To indicate the phases present the following symbols will be adopted: Solid salicylic acid S; solid phenol P; ice W; and where two coexistent liquid phases are possible: (low acid content) layer rich in phenol L_1, layer rich in water L_2; (low phenol content) layer rich in acid L_3, layer rich in water L_4. Metastable results throughout are enclosed in square brackets.

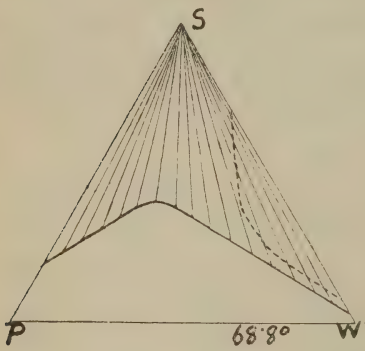
J.	S + P + L_1 layers, S and P.	−0·6	69·9	4·2	25·9

According to Schreinemakers's generalisation (*Z. physikal. Chem.*, 1898, **25**, 320) the temperature of melting under the liquid is depressed by the addition of a third substance when that substance is more soluble in the liquid layer which is rich in the "melting constituent." This is again confirmed: solid phenol is in equilibrium with two liquid layers at D and C; on addition of the acid the temperature and concentration of the ternary univariant phenomenon shift from B → G and C → J (from 1·7° to − 0·6°). The points K (the ternary eutectic) and J are so near to each other that the equilibria J → K are practically unrealisable. K, G, and J are system invariant points, since four phases and vapour are in equilibrium at constant pressure. F → I shows the progress of the phenol–water critical point on the addition of salicylic acid; the latter is soluble to some extent in both liquids and consequently produces a slight lowering of temperature from 65·3° to 61·2°. At I (61·2°), this binodal surface touches another binodal surface

at a second critical point; the two critical points then disappear and with lowering of temperature two binodal curves are obtained for any one temperature which have their end points not on the same base of the triangle but on S—W and P—W. The appearance of the second binodal area is due to the fact that the metastable binodal surface cuts the saturation surface of salicylic acid and has thus a stable portion. G → H and J → H give the com-

Fig. 5.



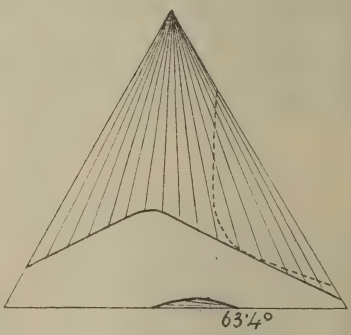


Fig. 6.

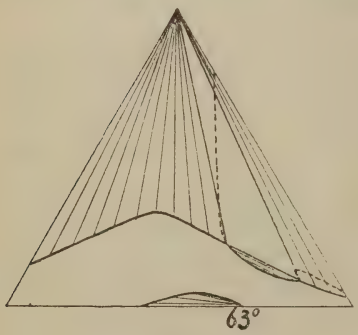

Fig. 7.

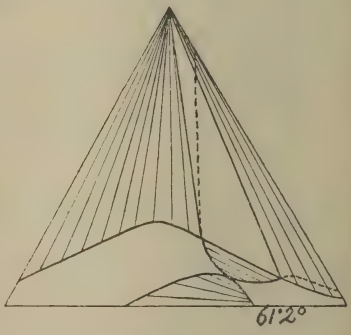

Fig. 8.

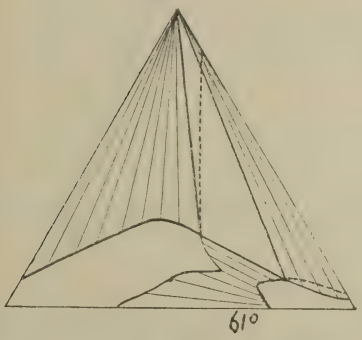
position and temperature of the univariant points where solid salicylic acid is in equilibrium with two liquid layers; again we have a curve showing the transition of the melting point under the liquid, but in this case the solid phase which melts is the third component. At H, the metastable binodal surface touches the saturation surface of salicylic acid internally at a critical point.

The Isotherms.—Certain representative isotherms have been chosen and require little elaboration. The diagrams are to some extent schematic, for it has been necessary to enlarge the con-

ditions in the water corner in order to render them visible; they represent accurately the nature of the phase changes which occur.

It will be seen that the solubility of salicylic acid is much greater in the mixed solvents than in either alone: at 68·8° the solubility of the acid in water is 1·3 g. per 100 g. of solution, in phenol 15·4 g., and at the maximum on the ternary solubility curve, 30·1 g. Below 40·8° solid phenol makes its appearance (see Fig. 11); and below 38·2° (Fig. 12) we have a three-phase area where S and P

Fig. 9.



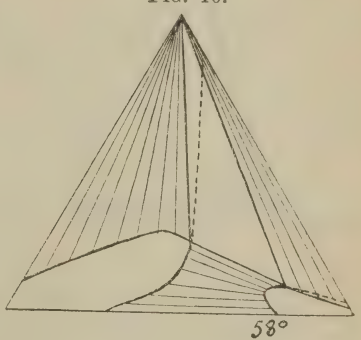


Fig. 10.

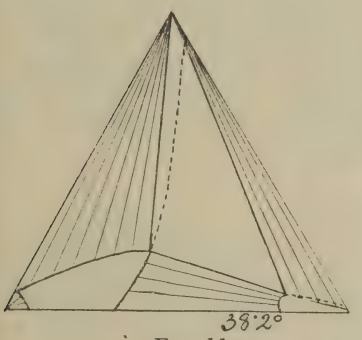

Fig. 11.

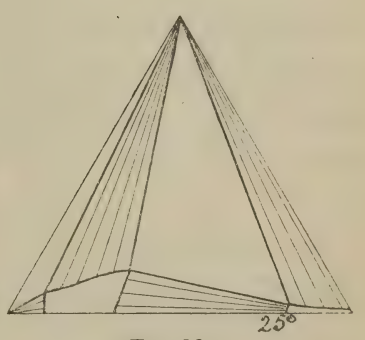

Fig. 12.

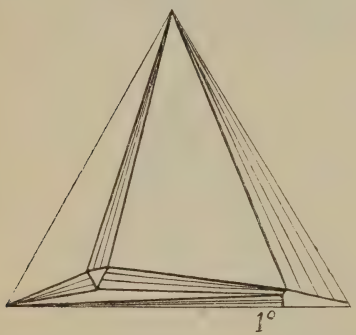
are in equilibrium with solution. From 1·7° to — 0·6° P can be in equilibrium with two liquid layers; between these two temperatures at, say, 1·0°, there are three three-phase areas (Fig. 13), the area of two coexistent liquid phases being very small. Below — 0·6° no two liquid layers are observed (Fig. 14) and finally below — 1·3° the system "dries up."

The binodal curve is a distribution curve and the distribution ratio has been determined at 25°. It has been possible to trace only one case where phenol and water have been used as the two immiscible liquids: in this case potassium iodide was found to have

more or less the same molecular weight in both solvents (Riesenfeld, *Z. physikal. Chem.*, 1902, **41**, 347). Table VIII shows that, after correction for the ionisation of the acid in the water layer (a very small effect, since $K = 0{\cdot}001$), the ratio C_w/C_p approaches constancy as the concentration of acid increases.

FIG. 13.



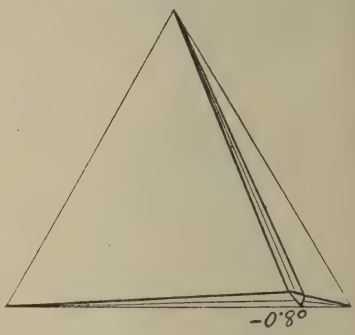


FIG. 14.

Numerical Results.

In the following tables a selection of the more important data for some of the isotherms examined has been made; metastable results throughout are enclosed in square brackets. In order not to complicate the isotherms unduly and to help in the comparison of the temperatures of critical opalescence and solution, the results obtained by the synthetic method are recorded separately. The values given throughout are in weights %.

TABLE V.

The Binodal Curves as obtained by the Synthetic Method.

Under each mixture is given : first, the percentage of phenol in the original mixture, then the percentage additions of salicylic acid, and in the last two rows, the critical solution temperature (C. S. T.) and the temperature of the beginning of critical opalescence (C. Op.).

Mixture B : 9·2% phenol.

CCLXIII.—*Carboxycamphoranilic Acids.*

By Mahan Singh and Ram Singh.

Tingle and his co-workers (*Amer. Chem. J.*, 1907, **37**, 596; **38**, 642; 1908, **39**, 1892), as a result of their researches on the intramolecular rearrangement of phthalamic acids, conclude that the change of these acids into phthalimides

$$C_6H_4<\begin{matrix}CO\cdot NH\cdot C_6H_4R\\CO_2H\end{matrix} \rightarrow C_6H_4<\begin{matrix}CO\\CO\end{matrix}>N\cdot C_6H_4R+H_2O$$

is dependent on the following factors : (1) the nature of the group R, the stability of the acid increasing as R becomes more negative (stability : $CO_2H > NO_2 > OH >$ halogens); (2) the nature of the amine, the amine being more active, the more strongly positive it is; (3) the temperature; (4) the presence of a solvent such as ethyl alcohol.

The reactions of camphoric anhydride with *o*-, *m*-, and *p*-aminobenzoic acids have now been investigated. They proceed thus :

$$C_8H_{14}<\begin{matrix}CO\\CO\end{matrix}>O+H_2N\cdot C_6H_4\cdot CO_2H = C_8H_{14}<\begin{matrix}CO\cdot NH\cdot C_6H_4\cdot CO_2H.\\CO_2H\end{matrix}$$

The carboxycamphoranilic acids produced are very stable and have not been converted into camphorimides at various temperatures, in various solvents, or by treatment with mild dehydrating agents such as fused sodium acetate and anhydrous sodium sulphate. Hence it appears that if the imide is formed at all, it is so unstable that it is immediately hydrolysed. This may be due to the extreme negativity of the carboxyl group.

The condensation product consists of only one acid in each case; whether it is the α- or the β-camphoranilic acid (compare Singh and Biswas, J., 1924, **125**, 1895) has not been determined.

With regard to the optical rotations of the three carboxycamphoranilic acids, (1) the *o*-carboxy-compound gives negative values; (2) a regularity can be observed between the molecular rotation and the position of the carboxyl group. In all solvents, the order is $p > m > o$; (3) for a given acid in different solvents, the rotatory power diminishes in the order : methyl alcohol, ethyl alcohol, acetone, methyl ethyl ketone. The dielectric constants of these solvents are 35·4, 20·8, 21·5, and 17·8, respectively. The rotatory power, therefore, is lowest in the solvent which has the lowest dielectric constant.

Experimental.

Condensation of Camphoric Anhydride with Aminobenzoic Acids. General Method.—Camphoric anhydride and the aminobenzoic acid (equal mols.) are heated together with fused sodium acetate. The product is dissolved in 80% alcohol (alcohol in the case of the

m-carboxy-compound) and precipitated by the addition of water and scratching, being decolorised by charcoal and by repetition of the process if necessary.

2′-*Carboxycamphoranilic acid*, $CO_2H{\cdot}C_8H_{14}{\cdot}CO{\cdot}NH{\cdot}C_6H_4{\cdot}CO_2H$ (temperature of condensation, 125—130°; time, 3 hours. The yield is seriously affected by variation in temperature, being almost nil above 160°) separates in crystals containing $3H_2O$. It melts at 75—80°, then shrinks, solidifies, and finally melts at 199—200°. It is soluble in ethyl alcohol, methyl alcohol, or acetone, and sparingly soluble in benzene or chloroform (Found : C, 55·0; H, 7·1; N, 3·65; equiv., by titration with NaOH, 187·5. Found, in material heated at 75—80° for 1 hour : C, 64·4; H, 6·8. $C_{17}H_{21}O_5N,3H_2O$ requires C, 54·7; H, 7·2; N, 3·75%; equiv., dibasic, 186·5. $C_{17}H_{21}O_5N$ requires C, 63·95; H, 6·6%).

3′-*Carboxycamphoranilic acid* (temperature of condensation, 160°; time, 3 hours; yield nearly quantitative) is a white, amorphous powder, m. p. 249°, which is soluble in ethyl alcohol, methyl alcohol, or acetone, but insoluble in benzene, chloroform, or ether (Found : C, 63·7; H, 6·9; N, 4·5; equiv., 161. $C_{17}H_{21}O_5N$ requires C, 63·95; H, 6·6; N, 4·4%; equiv., 159·5).

4′-*Carboxycamphoranilic acid* (temperature of condensation, 140—145°; time, 4 hours; yield 95%) separates as a white, amorphous mass which melts at 149—150°, shrinks, re-solidifies, and finally melts at 212°. It is slightly soluble in water, readily soluble in ethyl alcohol, methyl alcohol, or acetone, but only very sparingly so in benzene, ether, or chloroform (Found : C, 60·05; H, 7·4; N, 4·2; equiv., 169·5. Found, in material heated for 1 hour at 135—145° : equiv., 160. $C_{17}H_{21}O_5N,H_2O$ requires C, 60·5; H, 6·8; N, 4·15%; equiv. 168·5. $C_{17}H_{21}O_5N$ requires equiv., 159·5).

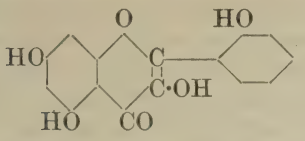
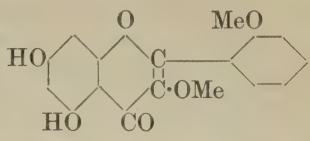
The readings were taken in a 2-dcm. tube within 30 minutes of making up the solution. There was no mutarotation.

The authors desire to thank Dr. H. B. Dunnicliff for guidance and practical help during this investigation.

GOVERNMENT COLLEGE,
LAHORE, INDIA. [*Received, April 15th*, 1925.]

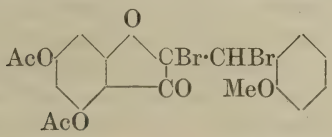


CCLXIV.—*A Synthesis of Datiscetin.*

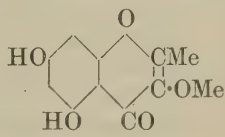


By JAN KALFF and ROBERT ROBINSON.

DATISCIN was isolated by Braconnot in 1816 (*Ann. Chim. Phys.*, **3**, 277) from the leaves of the Bastard Hemp, *Datisca cannabina*, but his largely correct description was ignored and datiscin regarded as identical with inulin until the accurate work of Stenhouse (*Ann. Ch. Pharm.*, 1855, **98**, 166; *Chem. Gaz.*, 1856, No. 318) re-established the individuality of the compound, which he isolated from the roots of the plant. Stenhouse showed that on hydrolysis with acids datiscin yields glucose and datiscetin, $C_{30}H_{10}O_{12}$ (C = 6; O = 8), which by fusion with potassium hydroxide gives salicylic acid or by boiling with dilute nitric acid is changed into nitrosalicylic acid. Roots of *Datisca* from Kew Gardens were examined by Schunck and Marchlewski (*Annalen*, 1893, **277**, 266), who concluded that datiscin is a rhamnoside. The datiscetin isolated in the course of that work had m. p. 237° and differed in some of its properties from the datiscetin of Stenhouse. Fortunately, a small specimen of the material has been preserved in the Schunck Collection housed in the Chemistry Department of this University, and we are of the opinion that it consists essentially of datiscetin mixed with galangin (see p. 1972). It seems possible that the datiscin from the Kew roots was a mixture of galangin rhamnoside and datiscetin glucoside.



Korczyński and Marchlewski (*Bull. Acad. Sci. Cracovie*, 1906, A, 95; 1907, A, 124) again isolated datiscin, from *Datisca* roots from the Punjab, and showed that it gives glucose on hydrolysis. Moreover, after removal of a methoxyl-containing substance, datiscetin, $C_{15}H_{10}O_6$, m. p. 268—269°, was obtained and characterised and this was clearly the true datiscetin of Stenhouse. From the reactions of datiscetin and the fact that it yields phloroglucinol as well as salicylic acid on fusion with potassium hydroxide, Leškiewicz and Marchlewski (*ibid.*, 1914, A, 218; *Ber.*, 1914, **47**, 1599) drew the conclusion that the substance is 3 : 5 : 7 : 2′-tetrahydroxyflavone (I). The 3 : 5 : 7-trimethyl ether of this flavonol

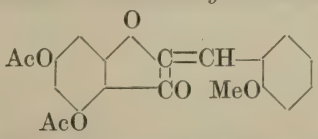


has been synthesised by Bargellini and Peratoner (*Gazzetta*, 1919, **49**, ii, 64), who employed the methods of von Kostanecki, but the derivative has not yet been related to natural datiscetin.

(I.) 

 (II.)

The synthesis now described is an application of the method of Allan and Robinson (J., 1924, **125**, 2192) already used by the present authors (this vol., p. 181) for the syntheses of galangin monomethyl ether and myricetin. ω-Methoxyphloracetophenone (Slater and Stephen, J., 1920, **117**, 316) reacts at 180° with *o*-methoxybenzoic anhydride and sodium *o*-methoxybenzoate to give a product which yields *datiscetin* 3 : 2′-*dimethyl ether* (II) on hydrolysis. On demethylation with hydriodic acid, datiscetin (I) was obtained and we are greatly indebted to Professor Marchlewski for specimens of natural datiscetin and some of its derivatives which have enabled us to make the necessary direct comparisons.



(III.) 

 (IV.)

In some earlier experiments an attempt was made to apply the von Auwers flavonol synthesis (compare *Ber.*, 1915, **48**, 85) to the case of datiscetin. The *compound* III was obtained without difficulty, but no trace of a flavonol could be isolated from the products of its decomposition with alkaline solutions. An attempt was also made to synthesise datiscetin 3-monomethyl ether and accordingly ω-methoxyphloracetophenone was brought into reaction with *o*-acetoxybenzoic anhydride and sodium *o*-acetoxybenzoate. Curiously enough, the acetoxy-groups alone function and we found that the product was 3-*methoxy*-5 : 7-*dihydroxy*-2-*methylchromone* (IV).

Experimental

2-o-*Methoxybenzylidene*-4 : 6-*diacetoxycoumaranone*,

—A satisfactory yield of the methyl ether was obtained by treating salicylaldehyde with methyl sulphate (5 mols.) and aqueous sodium

hydroxide at about 40°. A mixture of *o*-methoxybenzaldehyde (4·1 g.), 4 : 6-dihydroxycoumaranone (5 g.) (Sonn, *Ber.*, 1917, **50**, 1265), and acetic anhydride (90 c.c.) was boiled for 2¼ hours. The product was added to hot water (500 c.c.) and on stirring the oil solidified. The substance crystallised from acetic acid in yellow prisms, m. p. 174° (yield 55%) (Found : C, 65·3; H, 4·5. $C_{20}H_{16}O_7$ requires C, 65·2; H, 4·4%). This substance is insoluble in dilute aqueous sodium hydroxide and gives no coloration with alcoholic ferric chloride. It is sparingly soluble in alcohol or benzene and readily soluble in chloroform. The *dibromide* (formula III) was obtained by the addition with cooling and stirring of bromine (2·4 g.) in chloroform (15 c.c.) to a solution of the methoxybenzylidenediacetoxycoumaranone (5·5 g.) in chloroform (25 c.c.). Evolution of hydrogen bromide did not occur and, after 45 minutes, the substance was precipitated by light petroleum (80 c.c.) and rapidly crystallised from much hot alcohol, separating in small, colourless prisms, m. p. 163° (decomp.) (Found : Br, 31·2, 31·1. $C_{20}H_{16}O_7Br_2$ requires Br, 30·3%). As frequently observed in similar cases, some nuclear bromination has clearly occurred.*

3 : 2′-*Dimethoxy*-5 : 7-*dihydroxyflavone* (II).—*o*-Methoxybenzoic acid of satisfactory purity being somewhat difficult to obtain, an aqueous alkaline solution of salicylic acid was shaken with methyl sulphate (2—3 mols.), the acids isolated, the mixture esterified, and washed with aqueous sodium hydroxide to remove ethyl salicylate. The neutral ester was then hydrolysed.

Comparison of the different processes available for the preparation of *o*-methoxybenzoic anhydride (Rule and Paterson, J., 1924, **125**, 2161) showed that the following is the most convenient (compare D.R.-P. 201325). A 20% solution of carbonyl chloride (1 mol.) in benzene was gradually added with careful cooling to one of the acid (2 mols.) and pyridine (1 mol.) in the same solvent. After 2 hours, the mixture was treated with crushed ice and very dilute sulphuric acid, when the precipitate dissolved. The benzene solution was then further agitated with ice and dilute aqueous sodium carbonate for ½ hour, dried, and the solvent removed by distillation in a vacuum. The residue solidified and was sufficiently pure for most purposes (yield 85%). The product obtained by heating a mixture of ω-methoxyphloracetophenone (5 g.), sodium *o*-methoxybenzoate (7·5 g.), and *o*-methoxybenzoic anhydride (19 g.)

* On prolonged contact with dry methyl alcohol the colourless dibromide changed to yellow prisms which fall to a yellow powder, m. p. 192–193°, at 50–60° [Found: OMe, 7·3. $C_{19}H_{12}O_6Br(OMe)$ requires OMe, 6·95%]. It appears, therefore, that the elements of hydrogen bromide are eliminated and that this process is not accompanied by the introduction of further methoxyl groups.

for 3 hours at 180° was hydrolysed with potassium hydroxide (8·5 g.) in aqueous or alcoholic solution. The phenol, precipitated as a viscous, brown mass by saturating the diluted solution with carbon dioxide, was again treated with aqueous potassium hydroxide on the steam-bath and after isolation as before could be crystallised from aqueous acetic acid (yield 6 g. or 75%). This product was acetylated by treatment with boiling acetic anhydride in presence of sodium acetate. The *diacetyl* derivative crystallised from methyl alcohol in colourless, flat, pointed needles, m. p. 141·5—142·5° (corr.) (Found : C, 63·1; H, 4·5. $C_{21}H_{18}O_8$ requires C, 63·3; H, 4·5%) and was hydrolysed by gently heating with aqueous potassium hydroxide. The datiscetin dimethyl ether, obtained by saturation of the solution with carbon dioxide, crystallised from alcohol in almost colourless, glistening needles, m. p. 218—219° (corr.) [Found : MeO by micro-Zeisel, 19·7. $C_{15}H_8O_4(OMe)_2$ requires MeO, 19·7%]. The yellow solution in sulphuric acid gradually acquires a weak green fluorescence and a yellow solution results when a few drops of a mineral acid are added to a suspension of the dimethyldatiscetin in acetic acid. An alcoholic solution gives a blackish-green coloration with ferric chloride. Mordant dyeing properties were not observed.

Datiscetin (I).—A mixture of 5 : 7-diacetoxy-3 : 2′-dimethoxyflavone (1 g.) and hydriodic acid (15 c.c.; *d* 1·7) was boiled for 30 minutes, and the hot solution filtered (Jena sintered glass) and allowed to cool. The dark yellow crystals of the hydriodide were collected, decomposed by very dilute sulphurous acid, and crystallised from alcohol. The m. p. was at first 260°, but by continued recrystallisation a product, m. p. 276° (corr.), was ultimately obtained in long, pale yellow needles. The specimen of natural datiscetin which was available had m. p. 270·5—271·5° (corr.) and an intimate mixture of the two specimens melted at 273—274° (corr.). The reactions and dyeing properties of the two products were identical. The tetra-acetyl derivative, prepared in the usual manner, crystallised from alcohol in large, colourless, glistening prisms, m. p. 141° (corr.) (Found : C, 60·8; H, 4·0. Calc. for $C_{23}H_{18}O_{10}$, C, 60·8; H, 4·0%). Korczyński and Marchlewski (*loc. cit.*) give 138° (uncorr.) as the m. p. of datiscetin tetra-acetate. The synthetical specimen was also benzoylated by following the method of Korczyński and Marchlewski (*loc. cit.*); the product crystallised from 90% acetic acid in star-shaped aggregates of small needles, m. p. 191—192° (corr.), and at the same temperature when mixed with a specimen prepared from natural datiscetin.

3 : 7 : 2′-*Trimethoxy*-5-*hydroxyflavone*.—Datiscetin dimethyl ether (1 mol.) was methylated by means of methyl iodide (4 mols.) and

potassium hydroxide (4 mols.) in boiling methyl-alcoholic solution for 12 hours. The product crystallised from methyl alcohol in long, colourless needles, m. p. 111—112·5° [Found : MeO, 28·1. $C_{15}H_7O_3(OMe)_3$ requires MeO, 28·3%]. This substance is sparingly soluble in cold methyl alcohol and gives a dull brownish-green coloration with ferric chloride. It is insoluble in cold aqueous sodium hydroxide and on boiling the material becomes yellow but does not dissolve.

3-*Methoxy*-5 : 7-*dihydroxy*-2-*methylchromone* (IV).—A mixture of ω-methoxyphloracetophenone (5 g.), *o*-acetoxybenzoic anhydride (D.R.-P. 201325) (23 g.) and sodium *o*-acetoxybenzoate (9 g.) was heated at 160° for 4·5 hours and then worked up as described in the case of datiscetin dimethyl ether. The phenolic product crystallised from aqueous alcohol in long, pale yellow, glistening needles, m. p. 223—224° (corr.) [Found : MeO, 12·8; loss at 90°, 7·3; in material dried at 90°; MeO, 13·8; *M* by micro-Rast, 208, 228. $C_{10}H_7O_4(OMe),H_2O$ requires MeO, 12·9; H_2O, 7·3%. $C_{10}H_7O_4(OMe)$ requires MeO, 14·0%; *M*, 222]. The substance exhibited the properties of a hydroxylated chromone and we confirmed our view of its nature by the following more rational synthesis. A mixture of ω-methoxyphloracetophenone (3 g.), fused sodium acetate (6 g.), and acetic anhydride (12 c.c.) was heated (oil-bath at 170°) for 4·5 hours, and the chromone isolated in good yield in the usual manner. After crystallisation from alcohol, the substance had m. p. 223—224° (corr.), alone or mixed with the specimen obtained from *o*-acetoxybenzoic acid.

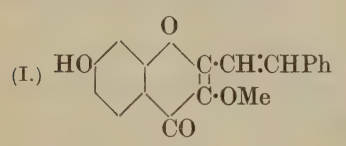
The Occurrence of Galangin in the Root of Datisca cannabina.

The specimen labelled *datiscetin* in the Schunck Collection crystallised from aqueous alcohol in pale yellow needles, m. p. 235—240° with softening from 220°. Its behaviour with solvents, alkaline solutions, mineral acids, potassium acetate and ferric chloride in alcoholic solution closely resembled that of datiscetin and the dyeing properties of the two substances were also identical. There was, however, one striking difference in that the yellow solution in sulphuric acid, at first non-fluorescent, quickly acquired a striking violet fluorescence which was different in tone from the bluer fluorescence due to kaempferol and was entirely distinct from that due to datiscetin. The micro-analyses which we carried out led to no definite conclusion except that methoxyl groups are not present. The substance is hydrated and contains relatively less oxygen than datiscetin. It was then shown by qualitative tests that fusion with potassium hydroxide yields phloroglucinol and that picric acid is produced when the substance is boiled with nitric acid. The clue to

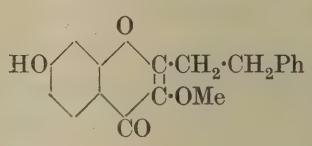
the nature of the material was found in the observation that galangin gives a yellow solution in sulphuric acid which soon develops a brilliant violet fluorescence that is but slightly dulled by the addition of a relatively large amount of datiscetin. The appearance of the sulphuric acid solution of a mixture of synthetical galangin and datiscetin was identical with that of the Schunck specimen dissolved in the same solvent. The following observations were then made under similar conditions: Schunck-datiscetin, m. p. 220—240°; mixed with datiscetin, m. p. 225—245°; mixed with more datiscetin, m. p. 250—260°; mixture of galangin and datiscetin, m. p. 240—255°; the last with more galangin, m. p. 223—240°; the last mixed with Schunck-datiscetin, m. p. 220—238°. A mixture of equal parts of galangin and datiscetin was crystallised from aqueous alcohol and prisms and needles were obtained. The solution was then gently heated to dissolve the needles, filtered, and allowed to cool. The apparently homogeneous needles, m. p. about 240° with previous softening, contained both galangin and datiscetin and closely resembled Schunck-datiscetin in appearance and in the fluorescence of a solution in sulphuric acid.

The authors wish to thank the Royal Society for a grant which has defrayed a part of the expense of the investigation and they also express their gratitude to the Ramsay Memorial Fellowship Trust for a Fellowship (Netherlands) which has enabled one of them to take part in the research.

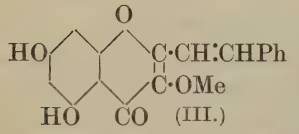
THE UNIVERSITY, MANCHESTER. [*Received, June 18th*, 1925.]



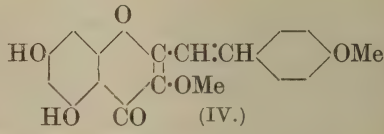
CCLXV.—*The Synthesis of certain 2-Styrylchromonol Derivatives.*



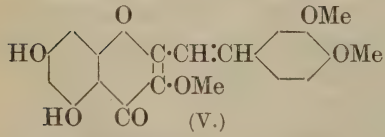
By ROBERT ROBINSON and JUNZO SHINODA.



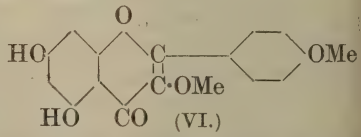
JUST as the difference in composition between successive members of the series of naturally occurring fatty acids is C_2H_4, so it would seem that the increment most common among plant products of the aromatic groups is C_2H_2. Thus benzoic acid and cinnamic acid are associated in many cases and piperic acid represents the next member of the series. Moreover, whilst methyl and propenyl or allylbenzene derivatives are of frequent occurrence, it is less usual to encounter derivatives of ethylbenzene among the constituents of plants.* For this reason we consider it probable that repre-



* There are, of course, exceptions to this rule, but many of the natural products with a side-chain comprising two carbon atoms have an obvious relation to more complex substances. Thus hordenine, adrenaline and mezcaline are probably derived by decarboxylation of derivatives of phenylalanine.



sentatives of the styrylchromones occur in nature and it may be pointed out that fukugetin, $C_{17}H_{12}O_6$ (Perkin and Phipps, J., 1904, **85**, 58), may be a tetrahydroxystyrylchromone related to luteolin, whilst pratensol, $C_{17}H_9O_2(OH)_3$ (Power and Salway, J., 1910, **97**, 231), may be similarly related to apigenin. It is significant that pratensol was found among the constituents of *Trifolium pratense* in company with undoubted flavone derivatives such as quercetin and *iso*rhamnetin, with pratol, probably a hydroxymethoxyflavone, and with a compound, $C_{15}H_7O_3(OH)_3$, isomeric with kaempferol. In the hope of making a contribution to this subject we have synthesised some styrylchromone derivatives which are, however, related to flavonols rather than to flavones. The method adopted was that indicated by Allan and Robinson (J., 1924, **125**, 2192) and utilised by Kalff and Robinson (preceding paper) in the synthesis of methylgalangin, datiscetin, and myricetin. In the simplest example a mixture of ω-methoxyresacetophenone, cinnamic anhydride, and sodium cinnamate is heated at about 180° and after hydrolysis of the product, 7-*hydroxy*-3-*methoxy*-2-*styrylchromone* (I) can be isolated. On reduction with hydrogen in presence of palladium a *dihydro*-derivative (II) is obtained, and the constitution of this substance is confirmed by its synthesis from ω-methoxyresacetophenone, β-phenylpropionic anhydride, and sodium β-phenylpropionate. In a similar manner the compounds III and IV were obtained from ω-methoxyphloracetophenone and the appropriate cinnamic acid derivatives.



The compounds I, II, and III could be demethylated in the usual way by means of hydriodic acid and we have thus, in the last-mentioned case, obtained the styryl analogue of galangin. Unfortunately no crystalline material could be isolated from the products of demethylation of IV and V, so that we have not been

able to examine the styryl analogues of kaempferol and quercetin. Should these substances be encountered in the examination of material of natural origin, they could be recognised by means of their products of methylation under specified conditions. Both IV and V yield monomethyl ethers when shaken in aqueous alkaline solution with methyl sulphate. There can be little doubt that, as in the case of quercetin, it is the hydroxyl in position 5 which is resistant to the methylating agent. Direct comparison shows that the styryl compounds are more intensely coloured than the corresponding flavones and as mordant dyestuffs they are characterised by much greater tinctorial power. Before we were acquainted with the difficulty of demethylating the compound IV, it seemed desirable to acquire a specimen of kaempferol for purposes of comparison. The simplest plan was to adopt the new method of synthesis, and a kaempferol dimethyl ether (VI) was prepared from ω-methoxyphloracetophenone, anisic anhydride, and sodium anisate. On demethylation, kaempferol, identical with the natural product, was readily obtained. This flavonol has been previously synthesised by von Kostanecki and Tambor (*Ber.*, 1904, **37**, 792) and von Kostanecki, Lampe, and Tambor (*ibid.*, p. 2096).

Experimental.

7-*Hydroxy*-3-*methoxy*-2-*styrylchromone* (I).—A mixture of ω-methoxyresacetophenone (4 g.) (Slater and Stephen, J., 1920, **117**, 313), sodium cinnamate (7·5 g.), and cinnamic anhydride (16 g.) was heated (oil-bath at 180—185°) for 3 hours. The product was hydrolysed by boiling with a mixture of potassium hydroxide (8·5 g.), alcohol (100 c.c.), and a little water for 30 minutes. The alcohol was removed by distillation from the steam-bath and sufficient water added to dissolve the residue, the solution being then saturated with carbon dioxide. The yellow precipitate was crystallised several times from acetic acid and dried (4·5 g.) (Found : C, 73·4; H, 4·9. $C_{18}H_{14}O_4$ requires C, 73·5; H, 4·7%). This compound is sparingly soluble in alcohol and acetic acid and crystallises in long, pale yellow needles, m. p. 250°. It develops no coloration with alcoholic ferric chloride and its bright yellow solution in aqueous sodium hydroxide is not fluorescent. The intense yellow solution in sulphuric acid exhibits a vivid green fluorescence.

3 : 7-*Dihydroxy*-2-*styrylchromone* (corresponding with I).—The methyl ether just described was treated with an excess of boiling hydriodic acid (*d* 1·7) for 30 minutes in a stream of carbon dioxide, the mixture added to dilute sulphurous acid, and the bright yellow substance crystallised from methyl alcohol and acetic acid (Found :

C, 72·8; H, 4·5. $C_{17}H_{12}O_4$ requires C, 72·8; H, 4·2%). The woolly needles separating from methyl alcohol have m. p. 257° and the yellow solutions in aqueous sodium hydroxide and in sulphuric acid exhibit green fluorescence. The coloration with alcoholic ferric chloride is dark brownish-green. On an aluminium mordant * a bright and full lemon-yellow colour was produced, whereas 3 : 7-dihydroxyflavone exhibits very poor affinity and the silk is just coloured a pale yellow. On a chromium mordant the styryl compound gives an intense golden-yellow colour, whilst the related flavonol gives a much paler greenish-yellow. On an iron mordant both substances give a deep cinnamon-brown shade. The differences observed are not merely of intensity but also of tone. In order to obtain 3 : 7-dihydroxyflavone for this comparison we demethylated 7-hydroxy-3-methoxyflavone (Allan and Robinson, *loc. cit.*) in the usual manner by means of hydriodic acid; the product, after crystallisation from methyl alcohol, acetic acid, and finally from ethyl acetate, formed pale yellow, glistening, flat needles, m. p. 258° (Found : C, 66·4; H, 4·7; loss at 100° in a high vacuum, 6·9. $C_{15}H_{10}O_4,H_2O$ requires C, 66·2; H, 4·4; H_2O, 6·6%). von Kostanecki and Stoppani (*Ber.*, 1904, **37**, 1180) have previously obtained this substance from its 7-methyl ether, but they do not state that it crystallises with $1H_2O$.

β-*Phenylpropionic Anhydride.*—We have found the method adopted by Liebermann (*Ber.*, 1883, **21**, 3372) for the preparation of cinnamic anhydride to be expeditious and have employed it in other cases. A solution of β-phenylpropionic acid (15 g.) in acetic anhydride (30 g.) was boiled for 4 hours and then distilled; 10 g. of a viscous liquid, b. p. 216—217°/14 mm., were obtained (Found : C, 76·3; H, 6·7. $C_{18}H_{18}O_3$ requires C, 76·6; H, 6·4%).

7-*Hydroxy*-3-*methoxy*-2-β-*phenylethylchromone* (II).—(A) 7-Hydroxy-3-methoxy-2-styrylchromone (1 g.) dissolved in acetic acid (200 c.c.) was reduced by shaking with hydrogen, aqueous palladous chloride (10 c.c. of 1%) having been added to the mixture. Absorption ceased after about 2 hours. The product crystallised from aqueous acetic acid in colourless prisms, m. p. 186—187° (Found : C, 72·6; H, 5·5. $C_{18}H_{16}O_4$ requires C, 72·9; H, 5·4%). The yellow solution in sulphuric acid exhibits a blue fluorescence.

(B) ω-Methoxyresacetophenone (2 g.), sodium β-phenylpropionate, and β-phenylpropionic anhydride (8 g.) were mixed and heated

* All the dye-trials were made on silk. The aluminium mordant was prepared from alum and sodium carbonate and fixed with sodium silicate and it was found to be essential to exclude even traces of iron. The chromium mordant was prepared from basic chrome alum, fixed with sodium silicate, and the fabric was iron-mordanted by successive treatment with a solution of ferric nitrate and a solution containing soap and sodium carbonate.

at about 180° for 3 hours. The product, isolated as in the case of the styryl analogue, crystallised from aqueous acetic acid in colourless prisms, m. p. 186—187°, which was not depressed by admixture with the specimen prepared by the method (A).

3 : 7-*Dihydroxy*-2-β-*phenylethylchromone*, obtained by demethylation of the 3-methyl ether by means of boiling hydriodic acid, crystallises from aqueous alcohol in almost colourless, prismatic needles, m. p. 169° (Found in material dried at 100° with change of appearance: C, 68·0; H, 5·4. $C_{17}H_{14}O_4$ requires C, 68·0; H, 5·3%). The substance is readily soluble in most organic solvents and its solution in aqueous sodium hydroxide is colourless. It is devoid of any trace of mordant dyeing properties. The yellow solution in sulphuric acid exhibits a blue fluorescence and the ferric chloride coloration in alcoholic solution is dark violet.

3-*Methoxy*-5 : 7-*dihydroxy*-2-*styrylchromone* (III).—A good yield of this compound was obtained by following in every detail the method described for the preparation of 3-methoxy-7-hydroxy-2-styrylchromone. The yellow substance crystallises from acetic acid in microscopic needles, m. p. 241° (Found: C, 69·8; H, 4·6. $C_{18}H_{14}O_5$ requires C, 69·9; H, 4·5%). The orange-yellow alcoholic solution is coloured brown by the addition of a trace of ferric chloride, and the yellow solution in sulphuric acid shows a green fluorescence which becomes more intense on standing.

3 : 5 : 7-*Trihydroxy*-2-*styrylchromone* (corresponding with III).—The product of demethylation of the foregoing ether crystallised from alcohol in stellar clusters of yellow needles, m. p. 249° (Found in material dried at 100° in a high vacuum: C, 68·7; H, 4·1. $C_{17}H_{12}O_5$ requires C, 68·9; H, 4·0%). The golden-yellow solution in aqueous sodium hydroxide does not fluoresce, but the sulphuric acid solution exhibits strong fluorescence. The shades yielded by galangin on mordanted silk are almost identical with those given by 3 : 7-dihydroxyflavone, and the styryl analogue of galangin now described yields, on an aluminium mordant and on an iron mordant, shades similar to those given by 3 : 7-dihydroxy-2-styrylchromone. On a chromium mordant, however, it yields a bright orange dyeing. The *triacetyl* derivative was obtained by the action of boiling acetic anhydride in presence of fused sodium acetate on the trihydroxystyrylchromone. It crystallises from alcohol in nearly colourless, prismatic needles, m. p. 215—216°.

4-*Methoxycinnamic Anhydride*.—4-Methoxycinnamic acid was obtained in almost quantitative yield by acidification of a diluted mixture of anisaldehyde (1 mol.), malonic acid (2·5 mols.), pyridine (3 mols.), and a few drops of piperidine which had been heated on the steam-bath during 1·5 hours and then boiled. The acid crystal-

lised from boiling water in colourless, prismatic needles, m. p. 173° (recorded in the literature, 171°), and was dehydrated by vigorously boiling with three times its weight of acetic anhydride for 15 hours. After the excess of acetic anhydride and the acetic acid formed had been removed by distillation, the cooled residue solidified and could be directly employed in the chromonol synthesis. The substance crystallises from ethyl acetate in large prisms, m. p. 119—120° (Found : C, 71·3; H, 5·5. $C_{20}H_{18}O_5$ requires C, 71·0; H, 5·3%). The substitution of methoxyl for hydrogen in the *p*-position in benzoic and also in cinnamic acid has the effect of making anhydride formation by this method very noticeably more difficult. It is possible that methoxyl in the *m*-position has an influence in the other direction, since it is more easy to dehydrate veratric acid and 3 : 4-dimethoxycinnamic acid than anisic acid and 4-methoxycinnamic acid.

The following method has also been successfully employed for preparing the anhydride (compare Fischer and Freudenberg, *Ber.*, 1913, **46**, 1124). 4-Methoxycinnamic acid (5 g.) was converted into the *chloride* by gentle heating during about 25 minutes with purified thionyl chloride (25 g.) and removal of excess of the reagent by distillation in a vacuum. The crystalline chloride together with 4-methoxycinnamic acid (4 g.) was dissolved in chloroform, and pyridine (9 c.c.) gradually introduced. The anhydride crystallised and could be isolated after 3 hours by the addition of alcohol and washing with very dilute aqueous ammonia. Recrystallised from ethyl acetate, it had m. p. 119—120° (yield 8 g.).

3 : 4′-*Dimethoxy*-5 : 7-*dihydroxy*-2-*styrylchromone* (IV).—An intimate mixture of ω-methoxyphloracetophenone (4·5 g.), 4-methoxycinnamic anhydride (18 g.), and sodium 4-methoxycinnamate (9 g.) was heated at 180° in a vacuum for 3 hours, and the product hydrolysed by treatment with potassium hydroxide (10 g.) and alcohol (100 c.c.) at the boiling point for ½ hour. The yellow precipitate obtained by saturating the diluted mixture with carbon dioxide, after being washed and dried (yield 90%), crystallised from acetic acid in aggregates of intensely yellow needles, m. p. 228° (Found : C, 66·7; H, 4·2. $C_{19}H_{16}O_6$ requires C, 67·0; H, 4·2%). The orange solution in sulphuric acid exhibits greenish-yellow fluorescence and the yellow solution in alcohol develops a brown coloration with ferric chloride.

3 : 7 : 4′-*Trimethoxy*-5-*hydroxy*-2-*styrylchromone*, the methyl ether of the substance described in the last section, was obtained by shaking the red solution of the phenol in aqueous sodium hydroxide with methyl sulphate until the yellow precipitate no longer dissolved on the addition of more sodium hydroxide. The product was

collected, washed with water, and crystallised from aqueous acetic acid, separating in bright yellow prisms, m. p. 156° (Found: C, 67·6; H, 5·0. $C_{20}H_{18}O_6$ requires C, 67·8; H, 5·1%). This substance is quite insoluble in aqueous sodium hydroxide, even when boiled, but the intensification of the colour from yellow to orange in alcoholic solution on the addition of solid potassium hydroxide indicates the weak phenolic function. It is curious that on diluting such an alcoholic solution with water a clear yellow liquid is obtained and the phenol actually separates completely on boiling, leaving a colourless solution. The alcoholic solution gives a yellowish-brown coloration on the addition of ferric chloride.

3 : 4-*Dimethoxycinnamic Anhydride*.—3 : 4-Dimethoxycinnamic acid is obtained in almost quantitative yield from veratraldehyde by condensation with malonic acid in pyridine–piperidine solution at 100° and it may also be conveniently prepared by the methylation of ferulic acid which is effected by shaking an aqueous alkaline solution with methyl sulphate. Ferulic acid was produced in 80% yield when a mixture of vanillin (50 g.), malonic acid (104 g.), pyridine (140 c.c.), and piperidine (4 c.c.) was heated for 1·5 hours on the steam-bath. The acid, crystallised from hot water, had m. p. 171° (recorded in the literature, 168—169°). A mixture of 3 : 4-dimethoxycinnamic acid (5 g.) and acetic anhydride (10 g.) was vigorously boiled for 5 hours and the acetic acid and excess of acetic anhydride removed by distillation in a vacuum. The residue was dissolved in a little hot benzene and, on cooling, the new anhydride separated. It crystallised from ethyl acetate in colourless needles, m. p. 174—175° (Found: C, 66·4; H, 5·8. $C_{22}H_{22}O_7$ requires C, 66·3; H, 5·5%).

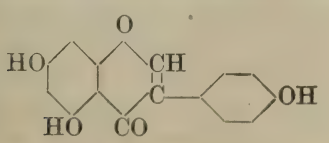
3 : 3′ : 4′-*Trimethoxy*-5 : 7-*dihydroxy*-2-*styrylchromone* (V).—The method of preparation of this substance from ω-methoxyphloracetophenone, 3 : 4-dimethoxycinnamic anhydride, and sodium 3 : 4-dimethoxycinnamate followed exactly the lines of the similar cases described above. The bright yellow substance is readily soluble in alcohol and acetic acid, but may be crystallised from methyl alcohol in fine orange needles (Found: C, 61·7; H, 5·2; loss at 100° in a high vacuum, 5·3. $C_{20}H_{18}O_7,H_2O$ requires C, 61·8; H, 5·3; H_2O, 4·9%). The dried material is yellow and has m. p. 233—234°. The orange solution in sulphuric acid exhibits a weak green fluorescence; the ferric chloride reaction in alcoholic solution is brown; and the alkaline solutions are orange-yellow.

3 : 7 : 3′ : 4′-*Tetramethoxy*-5-*hydroxy*-2-*styrylchromone*.—The phenol last described was mixed with a little water and treated alternately with concentrated potassium hydroxide and methyl sulphate until the solution was no longer red when alkaline. The yellow precipitate

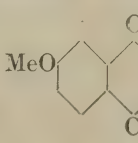
crystallised from alcohol and from ethyl acetate in glistening, yellow leaflets, m. p. 203—204° (Found: C, 65·3; H, 5·2. $C_{21}H_{20}O_7$ requires C, 65·6; H, 5·2%). The behaviour of this compound with aqueous and alcoholic solutions of alkali metal hydroxides and with ferric chloride closely resembled that of 3 : 7 : 4′-trimethoxy-5-hydroxy-2-styrylchromone.

3 : 4′-*Dimethoxy*-5 : 7-*dihydroxyflavone* (VI).—Anisic acid is not completely dehydrated by boiling acetic anhydride in 6 hours, but in 20 hours a good yield of the anhydride is obtained and the process is convenient. The substance isolated as in the example previously described, crystallised from ethyl acetate in needles, m. p. 98—99° (compare Pisani, *Annalen*, 1857, **102**, 284). The preparation of a flavonol derivative from ω-methoxyphloracetophenone (2·5 g.), anisic anhydride (10 g.), and sodium anisate (5 g.) was carried out as in previous cases. The crude product crystallised from aqueous acetic acid in pale yellow platelets with rounded corners, m. p. 234°. The substance exhibits a bronze-like appearance (Found: C, 65·1; H, 4·6. $C_{17}H_{14}O_6$ requires C, 65·0; H, 4·4%). This kaempferol dimethyl ether is sparingly soluble in hot methyl alcohol and gives a violet ferric chloride reaction in alcoholic solution. Its yellow solution in concentrated sulphuric acid exhibits a bright bluish-green fluorescence the intensity of which increases on standing. On demethylation with hydriodic acid (*d* 1·7) in the usual manner, kaempferol was readily obtained. The pale yellow needles deposited from alcoholic solution had m. p. 276—277° and this is the m. p. given by A. G. Perkin (J., 1902, **81**, 585), whereas von Kostanecki and Gordin quote the value 271° (*Ber.*, 1901, **34**, 3723) and von Kostanecki, Lampe, and Tambor (*loc. cit.*) give the m. p. 275° for the synthetical material. The strong greenish-blue fluorescence of the yellow solution in sulphuric acid was observed and the dyeing and other properties were those of kaempferol. The *tetra-acetyl* derivative was prepared and after crystallisation from ethyl alcohol had m. p. 181—182°, but, as stated by A. G. Perkin, when crystallised from methyl alcohol the substance sinters at 116—120° without completely melting, then hardens on further heating and melts at 181—182°. These observations render it certain that the synthetical material is identical with the naturally occurring flavonol called kaempferol.

We desire to thank the Royal Society for a grant which has defrayed a part of the cost of this investigation.



THE UNIVERSITY, MANCHESTER. [*Received, June 23rd*, 1925.]



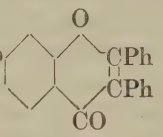
CCLXVI.—*Synthetical Experiments in the* iso*Flavone Group. Part I.*

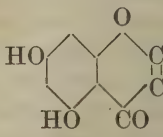
By Wilson Baker and Robert Robinson.

Whilst derivatives of 2-phenylchromone (flavone) and related substances in various states of oxidation (catechins, cyanomaclurin, butein, hyssopinaglykone, the anthocyanins and anthoxanthins) are found widespread in nature, the occurrence of derivatives of 3-phenylchromone (*iso*flavone) has not yet been definitely proved in any single instance. Nevertheless Finnemore has suggested (*Pharm. J.*, 1910, **31**, 604) that prunetin, $C_{16}H_{12}O_5$, obtained by hydrolysis of the glucoside prunetrin is the methyl ether of a trihydroxy*iso*flavone (I) and the isolation of *p*-hydroxyphenylacetic acid and phloroglucinol from the products of fusion with potassium hydroxide is strong evidence that this view is correct. On demethylation prunetin yields prunetol, $C_{15}H_{10}O_5$, and we are informed by Professor A. G. Perkin that there is a possibility that this substance is identical with genistein, the colouring matter of Dyer's Broom (*Genista tinctoria*) (Perkin and Newbury, J., 1899, **75**, 830; Perkin and Horsfall, J., 1900, **77**, 1310). The following comparison will serve to make clear the basis of this suggestion. Genistein; long, colourless needles from aqueous alcohol, m. p. 291—293°; prunetol, colourless needles from aqueous alcohol, m. p. *ca.* 290° (decomp.): triacetylgenistein, m. p. 197—201°; triacetylprunetol, m. p. 205°: genistein dimethyl ether, colourless leaflets from alcohol, m. p. 137—139°; prunetin monomethyl ether, flat needles, m. p. 145°: acetyl derivative of genistein dimethyl ether, colourless needles, m. p. 202—204°; acetyl derivative of prunetin monomethyl ether, colourless needles, m. p. 202°. In addition it was found that genistein dimethyl ether yields *p*-methoxyphenylacetic acid by hydrolysis with alcoholic potassium hydroxide.

A synthesis of the compound (I) would clearly be of considerable interest and we have decided to attempt it. The present communication is a record of the necessary preliminary investigation of the methods available, and it has been found that though *iso*flavones substituted in position 2 are easy to prepare, the contrary is the case when it is desired to leave this position unsubstituted.

(I.) 

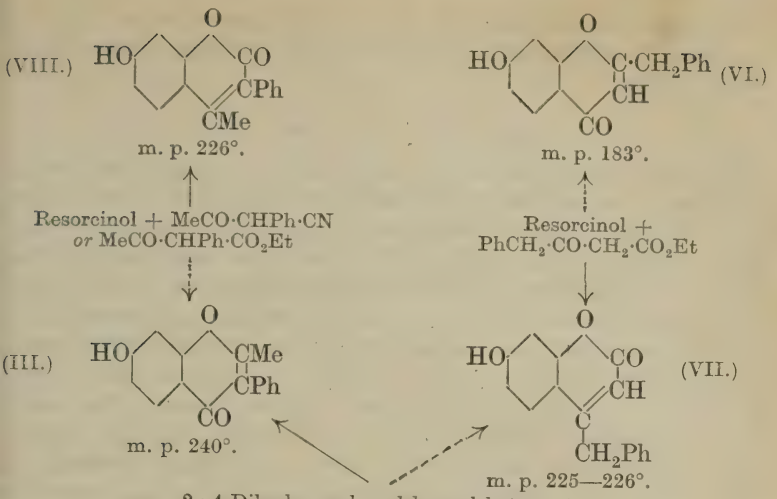




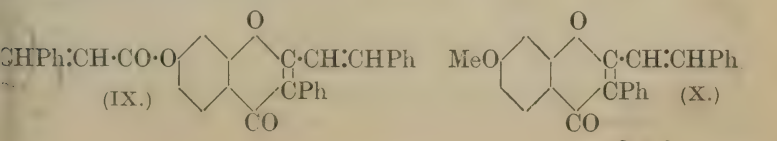
(II.)

The problem is analogous to that presented by the synthesis of

anhydrobrazilic acid, which is also a 3-substituted chromone derivative, but the method which was successful in that case (Perkin and Robinson, J., 1908, **93**, 503) was found to be inapplicable in the present instance. Ultimately 7-methoxy*iso*flavone (II) was synthesised by degradation of its 2-styryl derivative (X) by oxidation with potassium permanganate in pyridine solution and thermal decomposition of the resulting 7-methoxy*iso*flavone-2-carboxylic acid. A synthesis of (I) is thus rendered feasible. 2-Substituted *iso*flavones are quite readily obtained by the interaction of 2 : 4-dihydroxyphenyl benzyl ketone or the corresponding phloroglucinol derivative with a mixture of the anhydrides and sodium salts of carboxylic acids at 170—180° in accordance with a general method. For example, interaction of the former ketone and acetic anhydride and sodium acetate followed by hydrolysis of the product yields 7-*hydroxy*-2-*methyl*iso*flavone* (III), 7-*hydroxy*-3-*phenyl*-*flavone* (IV) is similarly obtained by means of benzoic anhydride and sodium benzoate, whilst 2 : 4 : 6-trihydroxyphenyl benzyl ketone, acetic anhydride, and sodium acetate yield ultimately the iso*flavone* (V).



(IV.)



(V.)

A substance which, it was claimed, had the formula (III) has been obtained by Ghosh (J., 1916, **109**, 105) and formulæ (IV) and (V) have been assigned by Jacobson and Ghosh (J., 1915, **107**, 1051) to compounds prepared by them, but the properties of the substances as recorded by these authors do not tally, even approximately, with our observations and there appears to be no possibility that the specimens prepared by the two methods can be identical. Since the synthetical process employed by Ghosh and by Jacobson and Ghosh is essentially that due to von Pechmann and was originally devised for the synthesis of coumarins, it seems possible that all these compounds, including eleven alleged *iso*flavones, are α-pyrones. In regard to the three substances already mentioned, this conclusion is inevitable unless it can be shown that we have taken a wrong view of the course of the reactions described in this communication. No alternative, however, is possible in the case of the compound (IV) and in regard to (III) (with which V is doubtless strictly analogous) the relations included in the annexed scheme demonstrate the correctness of our hypothesis. The dotted arrows show possible courses of the reactions and the full arrows the direction in which they actually proceed :

The condensation of ethyl β-keto-γ-phenylbutyrate and resorcinol yields 7-*hydroxy*-4-*benzylcoumarin* (VII), because the product of the reaction is not identical with the 7-hydroxy-2-benzylchromone (VI) synthesised by Hannach and Kostanecki (*Ber.*, 1902, **35**, 867). The non-identity of (III) and (VII) disposes of the only alternative for (III) and therefore the compound obtained by Ghosh from acetylphenylacetonitrile and resorcinol must have the constitution (VIII). It is possible that the whole of the compounds described by Jacobson and Ghosh and by Ghosh in four papers (*loc. cit.* and J., 1915, **107**, 424, 959) as γ-pyrones are in fact α-pyrones. A further critical examination of this subject is in progress. The question of the mechanism of the chromone synthesis is to some extent answered as the result of the observation that the di-*o*-acetyl derivative of 2 : 4-dihydroxyphenyl benzyl ketone, which is stable to acetic anhydride alone, suffers ring closure under the influence of acetic anhydride and sodium acetate.

The action of cinnamic anhydride and sodium cinnamate (compare the preceding paper) on 2 : 4-dihydroxyphenyl benzyl ketone gave rise to 7-*cinnamoyloxy*-2-*styryl*iso*flavone* (IX), from which (X) and then, as already stated, (II) were derived. The investigation is being extended.

The alkali-metal salts of (IV) exhibit phenomenal colloidal properties, a preliminary account of which is given in the experimental section.

Experimental.

7-*Hydroxy*-2-*methyl*isoflavone (III).—The red solution exhibiting green fluorescence which is obtained after boiling the acetyl derivative (see below) with an excess of dilute aqueous sodium carbonate for 2 hours was acidified and the crystalline precipitate collected (yield—over 90% from 2 : 4-dihydroxyphenyl benzyl ketone). The substance separates from methyl alcohol containing a few drops of water in very pale brownish-yellow needles melting at 240° when rapidly heated (Found : C, 76·3; H, 4·8. $C_{16}H_{12}O_3$ requires C, 76·2; H, 4·8%). The colourless solutions in aqueous sodium hydroxide and concentrated sulphuric acid exhibit weak blue and bluish-violet fluorescences respectively. The *methyl* ether obtained by interaction with methyl sulphate in aqueous potassium hydroxide solution at about 60° crystallised from aqueous alcohol in nearly colourless needles, m. p. 135·5° (Found : C, 76·7; H, 5·3. $C_{17}H_{14}O_3$ requires C, 76·7; H, 5·3%). The *acetyl* derivative was prepared by heating (oil-bath at 170—180°) a mixture of 2 : 4-dihydroxyphenyl benzyl ketone (10 g.) (Chapman and Stephen, J., 1923, **123**, 404), acetic anhydride (40 c.c.), and anhydrous sodium acetate (10 g.) under reflux for 12 hours. The product was shaken with dilute hydrochloric acid, and the solid crystallised from alcohol in colourless prisms, m. p. 162° (Found : C, 73·6; H, 4·8. $C_{18}H_{14}O_4$ requires C, 73·4; H, 4·8%). The same compound was obtained from 2 : 4-diacetoxyphenyl benzyl ketone (Chapman and Stephen, *loc. cit.*) in a precisely similar manner.

7-*Hydroxy*-4-*benzylcoumarin* (VII).—A solution of resorcinol (2 g.) and ethyl β-keto-γ-phenylbutyrate (2 g.) (Attwood, Stevenson, and Thorpe, J., 1923, **123**, 1762) in concentrated sulphuric acid (10 c.c.) was heated on the steam-bath for 20 minutes. The solid isolated after the addition of water crystallised from alcohol in faintly brown prisms, m. p. 225—226° (Found : C, 76·2; H, 4·9. $C_{16}H_{12}O_3$ requires C, 76·2; H, 4·8%). The yellow solution in aqueous sodium hydroxide has a blue fluorescence and the colourless solution in sulphuric acid fluoresces bluish-violet.

5 : 7-*Dihydroxy*-2-*methyl*isoflavone (V).—This substance and its derivatives were obtained, in the first place from 2 : 4 : 6-trihydroxyphenyl benzyl ketone (Chapman and Stephen, *loc. cit.*), by methods entirely similar to those used in the case of the resorcinol analogue. The substance crystallises from concentrated alcoholic solution in faintly yellowish-brown prisms, m. p. 228° (Found : C, 71·7;

H, 4·7. $C_{16}H_{12}O_4$ requires C, 71·6; H, 4·5%). The yellow solution in aqueous alkalis does not exhibit fluorescence.

The *diacetyl* derivative crystallises from alcohol in colourless, silky needles, m. p. 169° (Found: C, 68·0; H, 4·6. $C_{20}H_{16}O_6$ requires C, 68·2; H, 4·6%). The 7-*monomethyl* ether crystallises from methyl alcohol in glistening, colourless needles, m. p. 186—187°, insoluble in aqueous sodium hydroxide but giving a bluish-green coloration with ferric chloride in alcoholic solution. The solutions in concentrated sulphuric acid of this and the two substances last described exhibit weak bluish-green fluorescence.

7-*Hydroxy*-3-*phenylflavone* (7-*Hydroxy*-2-*phenyl*iso*flavone*) (IV).—A mixture of 2 : 4-dihydroxyphenyl benzyl ketone (20 g.), benzoic anhydride (100 g.), and sodium benzoate (10 g.) was heated (oil-bath at 180—190°) for 12 hours, and the product dissolved in alcohol (250 c.c.) and water (50 c.c.) by heating on the steam-bath. A solution of potassium hydroxide (60 g.) in water (100 c.c.) was added, and heating on the steam-bath continued for 15 minutes, after which water (500 c.c.) was added and the phenol precipitated by saturating the solution with carbon dioxide. It is important to follow the above directions in order to ensure the avoidance of the formation of a thick gel through which the gas cannot be passed. The crude product crystallised from ethyl alcohol (800 c.c.) in microscopic needles and on recrystallisation separated in glistening, pale yellow plates, m. p. 270—271° (yield of fully purified material, 20 g.) (Found: C, 80·3; H, 4·6. $C_{21}H_{14}O_3$ requires C, 80·2; H, 4·5%). The pale yellow solution in sulphuric acid exhibits a bluish-green fluorescence. The substance does not appear to dissolve in cold aqueous potassium hydroxide, but this is due to the formation of a gel round each crystal. On heating, a greenish-yellow solution is produced and this sets on cooling to a clear gel. A 1% solution sets to a stiff gel which is with difficulty shaken from a test-tube, whilst even a 0·1% solution gives a weak gel which, with an excess of alkali, will almost permit the inversion of the tube without displacement of the contents. The nature of the gels is very much affected by the concentration of the alkali. The *acetyl* derivative, prepared from the phenol by the action of boiling acetic anhydride for 4 hours, crystallised from acetic acid in pale yellow prisms, m. p. 208—209° (Found: C, 77·4; H, 4·5. $C_{23}H_{16}O_4$ requires C, 77·5; H, 4·5%).

7-*Cinnamoyloxy*-2-*styryl*iso*flavone* (IX).—A mixture of 2 : 4-dihydroxyphenyl benzyl ketone (10 g.), cinnamic anhydride (40 g.), and sodium cinnamate (10 g.) was heated (oil-bath at 170—180°, finally at 215°) for 5 hours. The cooled, ground product was washed with dilute aqueous sodium hydroxide, and the cinnamic anhydride

decomposed by heating on the steam-bath for an hour with alcohol (100 c.c.), water (20 c.c.), and concentrated sulphuric acid (1 c.c.). The solid then obtained on the addition of water was collected, washed with aqueous sodium hydroxide, and crystallised from acetic acid, in which it was sparingly soluble. The pale yellowish-brown prisms, m. p. 213—214°, dissolved in sulphuric acid to an intensely yellow solution exhibiting green fluorescence (Found : C, 81·6; H, 4·8. $C_{32}H_{22}O_4$ requires C, 81·7; H, 4·7%).

7-*Methoxy*-2-*styryl*iso*flavone* (X).—The crude cinnamoyloxy-styryl*iso*flavone from 10 g. of 2 : 4-dihydroxyphenyl benzyl ketone was added to alcohol (100 c.c.) and potassium hydroxide (7·5 g.) dissolved in a little water, and the whole heated for 5 minutes on the steam-bath. Water (100 c.c.) * was added and the phenol contained in the solution was methylated at 60° by the alternate addition of methyl sulphate and concentrated aqueous potassium hydroxide. After the addition of more water the methyl ether was collected (13·9 g.). It crystallised from ethyl alcohol, in which it was sparingly soluble, in pale yellow needles, m. p. 204—205° (Found : C, 81·4; H, 5·0. $C_{24}H_{18}O_3$ requires C, 81·3; H, 5·1%). The deep yellow solution in sulphuric acid has a green fluorescence.

7-*Methoxy*iso*flavone* (II).—7-Methoxy-2-styryl*iso*flavone (2 g.) dissolved in pure pyridine (20 c.c.) was oxidised at 0° in the course of an hour by the slow addition, with stirring and passage of carbon dioxide, of aqueous potassium permanganate (100 c.c. saturated at 15°). The manganese precipitate was brought into solution by sulphur dioxide and after the addition of dilute hydrochloric acid the ether-soluble contents of the liquid were isolated. The crude product was extracted with warm sodium bicarbonate solution, the filtrate acidified, and the organic acids were again collected by ether. The residue mixed with a little copper powder was cautiously heated over a free flame until evolution of carbon dioxide ceased, and the product shaken with aqueous sodium bicarbonate and ether. The neutral oil obtained from the ethereal solution solidified on stirring and the substance crystallised from not too much alcohol in needles, m. p. 155° (Found : C, 75·7; H, 5·1. $C_{16}H_{12}O_3$ requires C, 76·1; H, 4·8%). The colourless solution in sulphuric acid exhibits a blue fluorescence.

The authors desire to thank the Chemical Society for a grant which has defrayed a part of the cost of this investigation.

THE UNIVERSITY, MANCHESTER. [*Received, June 23rd*, 1925.]

* If more water is added, a thick, mucilaginous, colloidal solution results.

CCLXVII.—*Oxidation Products of Oleic Acid. Part II. Degradation of Dihydroxystearic Acid.*

By Arthur Lapworth and Edward Neville Mottram.

Spirondonov (*J. Russ. Chem. Soc.*, 1887, **19**, 646) oxidised dihydroxystearic acid with potassium permanganate, and an examination of the degradation products led to the separation of *n*-octoic, suberic and azelaic acids. Edmed (J., 1898, **73**, 628) carried out further investigations in this direction, but obtained no evidence of the formation of either suberic or *n*-octoic acid. He isolated three main products, namely azelaic, *n*-nonoic and oxalic acids, and assumed that the last-named was produced by the oxidation of the chain of carbon atoms which otherwise would have yielded pelargonic acid. Edmed's conclusion has been generally accepted, but the evidence obtained by the present authors does not support his view. In dilute alkaline solution at the ordinary temperature, *n*-octoic, suberic, and oxalic acids are the main oxidation products in several experiments, and it is necessary to conclude that the oxalic acid is a primary product in the degradation of dihydroxystearic acid and is formed by a splitting between the 8—9 and 10—11 carbon atoms as indicated below.

$$CH_3\cdot[CH_2]_6\cdot CH_2\cdot CH(OH)\cdot CH(OH)\cdot CH_2\cdot[CH_2]_6\cdot CO_2H$$

$CH_3\cdot[CH_2]_6\cdot CO_2H$	$CO_2H\cdot CO_2H$	$CO_2H\cdot[CH_2]_6\cdot CO_2H$
n-Octoic acid.	Oxalic acid.	Suberic acid.

In the conditions employed by Edmed, it appears that this mode of oxidation takes place simultaneously with that of the better known type

$$CH_3\cdot[CH_2]_7\cdot CH(OH)\cdot CH(OH)\cdot[CH_2]_7\cdot CO_2H$$

$CH_3\cdot[CH_2]_7\cdot CO_2H$	$CO_2H\cdot[CH_2]_7\cdot CO_2H$
n-Nonoic acid.	Azelaic acid.

Experimental.

1. (a) *Oxidation.* A solution of dihydroxystearic acid (5·0 g.) and caustic soda (10 g.) in water (1000 c.c.) was cooled, ice-cold water (3000 c.c.) added, and the whole well shaken during the addition of 1% aqueous potassium permanganate (2000 c.c.). Oxidation having proceeded at the ordinary temperature for 2½ hours, the solution was decolorised by sulphur dioxide, concentrated hydrochloric acid (100 c.c.) added, and the white, flocculent precipitate of unchanged dihydroxystearic acid filtered off, and washed with water. Traces of liquid fatty acids were removed from the drained

precipitate by washing with a little light petroleum (b. p. 40—60°) and the unchanged dihydroxystearic acid (0·40 g., m. p. 130°) was recovered.

The aqueous filtrate was neutralised with sodium carbonate, concentrated to about 500 c.c., and excess of hydrochloric acid added. The liberated mixed acids, isolated by means of ether,* were distilled with steam to separate the volatile portion; on cooling, the aqueous solution (75 c.c.) in the distillation flask deposited 1·6 g. of crystalline suberic acid, m. p. 137—138°. The mother-liquor on evaporation yielded further small quantities of suberic acid (0·3 g.). The total yield of suberic acid obtained was 1·90 g. (Theory requires 2·47 g.) and the equivalent found was 87·9 ($C_8H_{14}O_4$ requires 87·0), this slightly high value being almost certainly due to traces of octoic acid.

(b) *Examination of dibasic acid for azelaic acid.* The whole of the dibasic acid was warmed with 20—30 c.c. of ether, and the solution allowed to crystallise. The solid which separated (1·5 g.) was removed by filtration, and the mother-liquor evaporated to dryness. This solid was dissolved in water and treated with magnesium carbonate. (The magnesium salt of azelaic acid is much less soluble in water than that of suberic acid.) The most insoluble fraction of magnesium salt was treated with dilute hydrochloric acid, and the free dibasic acid extracted with ether. The acid obtained in this way melted at 139°, so that more than traces of azelaic acid could not have been present.†

(c) *Isolation of monobasic acid formed.* The aqueous distillate containing the liquid fatty acid was extracted with petroleum (b. p. 40—60°), and the solution dried with sodium sulphate. The liquid left after recovering solvent was freed from traces of petroleum by gently warming under reduced pressure and on cooling to 9° the acid solidified in colourless laminæ, m. p. 14°; the yield of monobasic acid was 1·4 g. (Theory for octoic acid is 2·05 g.) In conjunction with the results mentioned in the footnote,‡ these observations show that the greater part of the monobasic acid was octoic acid.

(d) *Estimation of oxalic acid formed.* The calcium oxalate precipi-

* The light petroleum washings from unchanged dihydroxystearic acid were reserved and added to the ethereal solution of oxidation products.

† In another experiment, the dibasic acid (6·5 g.) obtained from a larger quantity of dihydroxystearic acid was examined according to the above method and no azelaic acid was detected.

‡ In another experiment, starting from 16 g. of dihydroxystearic acid, 4·75 g. of fluid fatty acid distilled steadily at 233—235° at ordinary pressure. (Octoic acid boils at 236–237° and nonoic acid at 253–254°.) The equivalent found was 142·2; $C_8H_{16}O_2$ requires 144·0.

tated from the aqueous liquor from (c), made alkaline with ammonia, by the addition of calcium sulphate solution, was collected after 12 hours and treated with warm acetic acid. The residue was washed with water, and the oxalic acid estimated by titration with 1% potassium permanganate at 60° (Found : 0·86 g. ; calc., 1·28 g.). This quantitative result is, however, not offered with the same degree of confidence as those for octoic and suberic acids.

Oxidation of Dihydroxystearic Acid by Edmed's Method.—To a hot solution of dihydroxystearic acid (6·0 g.) in 150 c.c. of 1% caustic potash, 8·2 g. of potassium permanganate dissolved in 450 c.c. of water were added and oxidation was continued until the potassium manganate first formed was completely reduced (about 10 minutes). Manganese dioxide was filtered off, the filtrate acidified with sulphuric acid, and unchanged dihydroxystearic acid (3·0 g.) was filtered off. The oxidation products were isolated from the filtrate as in the above experiments.

The extracted dibasic acid (1·3 g.) was treated with cold ether, and the more soluble fraction (0·9 g.) converted into magnesium salt as in 1 (b) above. The most insoluble fraction of the latter yielded almost pure azelaic acid (m. p. 105°) (Equivalent found, 93·8; required, 94·0).

The fraction of dibasic acid less soluble in ether melted at 137—138° and had the equivalent 87·5. It was therefore mainly suberic acid.

Conclusions.—(1) The oxidation of dihydroxystearic acid by the method described in 1 (a) therefore leads to the formation of : suberic acid, in amount at least 80% of the theoretical; octoic acid, in amount at least 70% of the theoretical; and oxalic acid.

(2) By Edmed's original method, both suberic and azelaic acid are formed.

This work was carried out in continuation of researches begun under the auspices of the Food Investigation Board of the Department of Scientific and Industrial Research.

A grant from the Department of Scientific and Industrial Research to one of us (E. N. M.) rendered it possible for him to take part in the research and is gratefully acknowledged.

CCLXVIII.—*The Effect of Ultra-violet Light on Dried Hydrogen and Oxygen.*

By Herbert Brereton Baker and Margaret Carlton.

In 1922 Coehn and Tramm (*Ber.*, **56**, 455), working with an "electrolytic" mixture of hydrogen and oxygen, found that the gases interacted at the same rate when exposed to the light from a quartz mercury lamp whether they were dry or moist. This conclusion, if confirmed, would have an important bearing on the theory of the determining effect of water vapour. It was thought necessary to repeat the experiments, since these authors had not succeeded in attaining the same degree of resistance to the effect of heat on the dried gases as had been attained by one of us (Baker, J., 1902, **81**, 400). In these experiments, it was shown that the highly dried, "pure" gas mixture could be heated to redness and a silver wire melted in it without measurable action. Coehn and Tramm have succeeded in obtaining the gases so pure and dry that no explosion took place on heating to redness, but slow combination only. It is impossible to say why their gases did not give the same results as those described in 1902. Their work, as described, seems to have been most carefully carried out. The only point in their apparatus to which objection might be taken is the presence of two greased taps. The interaction of hydrogen and oxygen is one of those most susceptible to the slightest trace of impurity; it is possible that a few molecules of vapour from the lubricant used may have produced a diminution in the resistance to chemical action.

In our experiments the gases were produced by the electrolysis of a solution of barium hydroxide which had been recrystallised fifteen times. The reaction tubes were of the clearest fused quartz bent into L shape. The shorter arm was closed. The tubes were boiled in a mixture of chromic and nitric acids; after washing with distilled water, they were roughly dried in an electric oven and heated to bright redness after being exhausted. Air dried by phosphorus pentoxide was admitted after heating, the process being repeated six times.

The tubes were then filled with highly purified and dried mercury and the gaseous mixture was admitted over a mercury trough. It had been found, in the previous work, that the gases evolved during the electrolysis were not as resistant to chemical action in the first as in the later stages. The gaseous mixture was therefore allowed to escape during 3 days before being collected in the quartz tubes. Pairs of tubes, similar in diameter and in shape,

were filled at the same time. Into one of the pair was introduced a plug of phosphorus pentoxide which had been distilled in oxygen, the other being left in the undried condition. Both tubes, mounted on a special stand, were left in the dark room during the time specified.

The pair of tubes was then arranged symmetrically near a quartz mercury vapour lamp, so that both were exposed, as nearly as possible, to the same radiation. The part of the tube containing the phosphorus pentoxide was shielded from the direct rays of the lamp. The amount of chemical action was estimated by measurement of the rise of the mercury column in each tube, the temperature and pressure being noted at the same time.

In all, six pairs of tubes have been tested, prepared in the same way but with different lengths of time allowed for drying. In every case, there was a marked difference between the wet and the dry tubes, the latter showing in some cases no measurable action.

The following table is a summary of the results.

	Period of drying.	Time of exposure to light (hours).	Rise in mercury column (mm.). Dry.	Wet.
1	2 weeks	7	4	14
2	3 weeks	5	4	30
	After 12 hours' interval	6	9	43
3	4 weeks	5	0	6·1
	After 12 hours' interval	3	1	4·5
	After 12 hours' interval	5	6·5	7·2
4	7 weeks	6¼	0	2·3
	After 12 hours' interval	6½	0·35	6·5
5	8 weeks	5	0·5	5
	After 12 hours' interval	5	0·1	5
6	8 weeks	5	0	6·1
	After 12 hours' interval	6	0	6·2
	After 12 hours' interval	9	0·5	9·1
	After 12 hours' interval	8½	1·5	10
	After 12 hours' interval	6	10	12·5

Note, added August 1st.—One tube, dried for 12 weeks, was exposed at a distance of 2 cm. from the quartz mercury lamp for 13 hours without showing any measurable contraction.

It should be noticed that during the 12-hour intervals renewed drying is taking place, so that it is probable that only a fraction of the water produced (if any) during a day's exposure is available for promoting the chemical action on the next day.

It is also noticeable that in experiments 3 and 6 there is a sudden rise in the amount of gas combined in the dry tubes. This seems to be due to the amount of water formed during the previous day being too great to be absorbed by the drying agent during the night, so that the gases start in a comparatively moist condition.

It was found impracticable to leave the lamp running all night,

as it had a tendency, after some hours' run, to go out. On two occasions it was found that an exposure of 5 hours to the light had produced no action in either the wet or the dry tube. On examination it was found that a purple film had formed on the inside of the quartz tube of the lamp. Professor R. Wood (*Proc. Roy. Soc.*, 1924, *A*, 688) noticed the same phenomenon and he recommended the opening of the tube and the polishing of the interior with rouge. We found, however, that the full activity of the lamp could be restored by strongly heating the quartz tube of the lamp with a hot bunsen burner.

It was noteworthy that, in none of the tubes, wet or dry, was any tailing of the mercury observed; ozone therefore was not formed. The loss of mobility of mercury exposed to ozone forms one of the most delicate tests known. In two cases, both of wet tubes, a yellow film was formed. This proved to be mercuric oxide and amounted in the one tube in which it was determined to 4·1 mg. Its formation could not have been due to ozone, which produces mercurous oxide, never mercuric oxide.

Professor Bone (private communication) considers that phosphorus pentoxide cannot exert its full drying power when its temperature is allowed to rise above 25°. In the experiments described above, the gases generally reach a temperature of above 30°. In two of them the part of the tube containing the pentoxide was kept surrounded by ice during the whole of the run. The rate of union was not found to be altered by this treatment.

We wish to express our thanks to Messrs. Brunner Mond and Co. for a grant for the purchase of apparatus.

CCLXIX.—*Imino-aryl Ethers. Part III. The Molecular Rearrangement of N-Phenylbenziminophenyl Ether.*

By ARTHUR WILLIAM CHAPMAN.

IT is on record (Mumm, Hesse, and Volquartz, *Ber.*, 1915, **48**, 379) that benzoyldiphenylamine (II) may be obtained by heating *N*-phenylbenziminophenyl ether (I) at 240° for 1 hour.

$$\text{(I.)}\quad \text{PhO·CPh:NPh} \xrightarrow{\text{heat}} \text{O:CPh·NPh}_2 \quad \text{(II.)}$$

On repeating this experiment, unchanged material only could be recovered. However, benzoyldiphenylamine was obtained

after heating at 270—300° for 2 hours. The transformation had apparently occurred completely and without the formation of by-products, and therefore merited further investigation, especially as no quantitative study seems to have been made of any of the isomeric changes among imino-ethers of the aliphatic series and imino-esters (Pinner, "Die Imidoaether," 1892; Wislicenus and Goldschmidt, *Ber.*, 1900, **33**, 1470; Lander, J., 1903, **83**, 406; Wheeler and Johnson, *Amer. Chem. J.*, 1903, **30**, 24; Busch, Blume, and Pungs, *J. pr. Chem.*, 1909, **79**, 513; Kuhara, *Cent.*, 1911, I, 1514; Short and Smith, J., 1922, **121**, 1803).

The dynamics of the reaction were first studied. The purified imino-ether was heated in a thermostat maintained at various temperatures between 220° and 300°, and the product was submitted to thermal analysis (Hollemann, "Direkte Einfuhrung von Substituenten in den Benzolkern," 1910, p. 26). The freezing-point curve of mixtures of the two components was drawn from the following observations on mixtures of *N*-phenylbenziminophenyl ether with known quantities (*a*) of benzoyldiphenylamine.

a%	20	30	40	50	60	70	80	90	95	100
F. p.	107·8°	123·8°	134·8°	144·8°	152·7°	159·7°	165·6°	171·6°	174·6°	176·7°

The freezing points of mixtures containing less than 20% of benzoyldiphenylamine could not be determined accurately.

The progress of the transformation agreed closely with that required by the unimolecular formula; a typical series of observations is the following, t being the time of heating in minutes, x the percentage of benzoyldiphenylamine formed, and the temperature 262°:

t	32	60	120	181	240	300	360	
x	33	54	80	90	94	98	99·5	
$k \times 10^3$	5·4	5·6	5·8	5·5	5·1	5·7	5·6	Mean 5·5

The velocity coefficients at different temperatures are:

Temp.	228°	246—247°	262°	272°	278°	282°	287—288°	292—293°
$k \times 10^3$	0·1—0·2	1·6	5·5	11	18	23	34	45

The mean temperature coefficient between 246° and 292° was 2·06 per 10°.

N-Phenylbenzimino-*o*-chlorophenyl ether and *N*-phenylbenzimino-*p*-chlorophenyl ether, heated at 270—290° for 2 hours, gave benzoyl-*o*- and -*p*-chlorodiphenylamine, respectively, by changes corresponding to that of (I) into (II).

The mobile group must therefore have become attached to the nitrogen atom by the nuclear carbon atom originally attached to the oxygen (compare Montagne, *Ber.*, 1918, **51**, 1479).

The assumption has frequently been made that in changes of this character the migration of the mobile atom or group is preceded by its partial dissociation from the remainder of the molecule, followed by a redistribution of the valency bonds and recombination to form the isomeric compound; some workers have assumed complete dissociation (Brühl, *Ber.*, 1899, **32**, 2326; Lapworth, J., 1901, **79**, 1265; Nef, *J. Amer. Chem. Soc.*, 1904, **26**, 1549). The absence of by-products formed by the combination of two similar free radicals could be accounted for by regarding the dissociation as ionic in character. Recently Meerwein and van Emster (*Ber.*, 1922, **55**, 2500; compare also *Annalen*, 1923, **435**, 190, 207) have applied this view to the interpretation of the isomeric change of camphene hydrochloride into bornyl chloride, and have shown that the velocities of the transformation in different solvents are proportional to the ionising powers of the latter. Others, however, have preferred to express the course of such transformations in terms of partial valencies without assuming the formation of ions or free radicals (Robinson, *Mem. Manc. Lit. Phil. Soc.*, 1920, **64**, No. 4; Tiffeneau, *Rev. Gen. Sci.*, 1907, 583; Stark, "Prinzipien der Atomdynamik," 1915, III, 156; Mumm, Hesse, and Volquartz, *loc. cit.*).

It seemed desirable to test the validity of the ionic hypothesis in the present instance, and a number of measurements were made of the electrical conductivity of the imino-ether and its isomeride before, during, and after the completion of the isomeric change. The results obtained were mainly comparative. The specific conductivity of the imino-ether between 250° and 280° was of the order 10^{-8} to 10^{-9}. The low conductivity of the imino-ether remained constant so long as no appreciable isomeric change occurred, as was shown by heating the ether at 200° for several hours. When the imino-ether was heated at a higher temperature, an increase in conductivity occurred simultaneously with the isomeric change. At first rapid, it became slower, and finally the conductivity remained constant, the end of the increase coinciding with the completion of the isomeric change. Samples of benzoyldiphenylamine had identical conductivities within the range of experimental error whether prepared (*a*) by heating the imino-ether, or (*b*) as in (*a*) but subsequently crystallised from alcohol and dried, or (*c*) from diphenylamine and benzoyl chloride. The specific conductivity was of the order of 10^{-6} to 10^{-7} at 250—280°.

These observations can readily be explained in terms of the ionic hypothesis by supposing that the first stage consists in the rupture of the bond between the phenyl radical and the oxygen atom, a phenyl ion and an ionised residue being produced; re-

arrangement of the linkings in the residue follows, and combination of the phenyl ion with the nitrogen atom :

$$\mathrm{PhC}\lessdot^{\mathrm{NPh}}_{\mathrm{OPh}} \longrightarrow \mathrm{PhC}\lessdot^{\mathrm{NPh}}_{\mathrm{O}\cdots} + \mathrm{Ph}\cdots \longrightarrow$$

$$\mathrm{PhC}\lessdot^{\mathrm{NPh}\cdots}_{\mathrm{O}} + \mathrm{Ph}\cdots \rightleftharpoons \mathrm{PhC}\lessdot^{\mathrm{NPh}_2}_{\mathrm{O}}.$$

The first stage would give the reaction its unimolecular character, the succeeding ones being comparatively very rapid. The final stage would result in an equilibrium between ionised and non-ionised benzoyldiphenylamine.

The results of the determinations with different samples of benzoyldiphenylamine rendered it unlikely that the observed conductivity change was due to a trace of a by-product formed during the transformation; but the possibility was not excluded that it might arise from the constant presence of a trace of impurity in the changing medium of the molten mixture. Such a source of error—which might arise from the liberation of water adsorbed on the glass walls of the cell, as well as from the presence of impurities in the substances used—could be guarded against only partially by careful purification of material and apparatus, and hence it was decided to employ a more trustworthy test of the ionisation of the materials undergoing change.

N-*p*-Tolylbenzimino-*p*-tolyl ether undergoes rearrangement at the same temperatures as *N*-phenylbenziminophenyl ether. If the change is ionic in the one case, it should be so in the other, and if a mixture of these two imino-ethers were heated at the transformation temperature a certain amount of benzoylphenyl-*p*-tolylamine should be formed by exchange of the mobile groups, in addition to the two symmetrical products.

$$\mathrm{PhC(:NPh)\cdot OPh} \longrightarrow \mathrm{PhCO\cdot NPh}\cdots + \mathrm{Ph}\cdots \rightleftharpoons \mathrm{PhCO\cdot NPh_2}$$

$$\rightleftharpoons \mathrm{PhCO\cdot NPh(C_7H_7)}$$

$$\mathrm{PhC(:N\cdot C_7H_7)\cdot O\cdot C_7H_7} \rightarrow \mathrm{PhCO\cdot N\cdot C_7H_7}\cdots + \mathrm{C_7H_7}\cdots \rightleftharpoons \mathrm{PhCO\cdot N(C_7H_7)_2}$$

A mixture of *N*-phenylbenziminophenyl ether and *N*-*p*-tolylbenzimino-*p*-tolyl ether in equal molecular proportions was heated at 290° until the freezing point of the product was constant (139·8°). This freezing point was identical with that of a freshly made mixture of benzoyldiphenylamine and benzoyldi-*p*-tolylamine in equal molecular proportions. After the latter mixture had been heated for several hours at 250—290°, the freezing point was unchanged, showing that here again no third substance was produced. Inter-

change of groups to form benzoylphenyl-*p*-tolylamine had therefore not taken place.

The conclusion cannot be resisted, in view of this evidence, that the isomeric change of an imino-ether into a substituted amide is not ionic in character. This conclusion can probably be extended to other isomeric changes, where, under the influence of heat, an aryl group migrates to a different position in the molecule, and serves to confirm the view, recently expressed (*Ann. Rep.*, 1924, 98), that the ionic hypothesis should be applied only to those structures which exhibit independent evidence of capacity to ionise.

Experimental.

Preparation and Purification of Materials.—The *N*-phenylbenziminophenyl ether was prepared by the same method as *N*-phenylbenzimino-*m*-hydroxyphenyl ether (J., 1922, **121**, 1679). It was recrystallised from alcohol until both the m. p. (105°) and the velocity of isomeric change were constant. Further recrystallisation from benzene produced no effect on either property.

The benzoyldiphenylamine prepared from diphenylamine and benzoyl chloride was recrystallised from alcohol until the m. p. was constant.

Dynamical Experiments.—Five grams of imino-ether were used for each determination. The material, in a test-tube, was rapidly heated to approximately the required temperature in a separate oil-bath and then quickly transferred to an electrically heated, oil-filled thermostat maintained within 0·5° of the temperature of the experiment. At the end of the required time the tube was removed; the cooled melt could then be analysed at leisure.

The freezing-point determinations were conducted in the same tube, which was enclosed in a wider tube, itself immersed in an oil-bath maintained a few degrees below the freezing point of the mixture. Readings were easily obtained concordant to 0·25°, corresponding to an accuracy of 0·5%.

The freedom of the benzoyldiphenylamine from impurity when obtained by prolonged heating of the imino-ether (10 g., heated at 280° for 3 hours and then at 290° for 50 minutes) was proved by the identity of its freezing point with that of pure benzoyldiphenylamine (176·7°). A special thermometer was used which could be read to 0·05°.

Isomeric Change of Chloro-substituted Imino-ethers.—These compounds were prepared from *o*- and *p*-chlorophenols by the method referred to above.

N-*Phenylbenzimino*-o-*chlorophenyl ether* crystallises from alcohol in almost colourless, stout prisms, m. p. 88°. It is very soluble in hot

alcohol, but only sparingly soluble in cold (Found: N, 4·6. $C_{19}H_{14}ONCl$ requires N, 4·55%).

When heated at 270—280° for 1 hour and then crystallised from alcohol, it yielded hard crusts of constant m. p. 95—96°, which did not depress the m. p. of benzoyl-*o*-chlorodiphenylamine prepared as described below (Found: N, 4·7. $C_{19}H_{14}ONCl$ requires N, 4·55%).

N-*Phenylbenzimino*-p-*chlorophenyl ether* crystallised from alcohol in pale yellow, long prisms, m. p. 92—93° (Found: N, 4·75%). Hydrolysis with 50% sulphuric acid yielded *p*-chlorophenyl benzoate (m. p. 88—88·5°) identical with a sample prepared from *p*-chlorophenol. When heated at 280—290° for 2 hours and then recrystallised from alcohol, it yielded long prisms of constant m. p. 109—110° which did not depress the m. p. of benzoyl-*p*-chlorodiphenylamine prepared as described below (Found: N, 4·7%).

Benzoyl-o-, -m-, and -p-*chlorodiphenylamines* were prepared as described by Ullmann (*Annalen*, 1907, **355**, 338) by heating the corresponding chlorophenylanthranilic acids. o-*Chlorodiphenylamine* was obtained only after heating *o*-chlorophenylanthranilic acid at 300—320° for 5 hours. It is a pale yellow oil, b. p. 300—303°/753 mm.

The bases were benzoylated by heating with benzoyl chloride, and the benzoyl derivatives crystallised from alcohol.

Benzoyl-o-*chlorodiphenylamine*, m. p. 95° (Found: N, 4·6%), and *benzoyl*-m-*chlorodiphenylamine*, m. p. 101—102° (Found: N, 4·6%), crystallise in hard crusts; the m. p. of the latter was depressed by the addition of either of the substances prepared by heating the *o*- and *p*-chloro-iminoethers. *Benzoyl*-p-*chlorodiphenylamine* crystallises in prisms, m. p. 109—109·5° (Found: N, 4·7%).

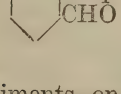
Measurements of Electrical Conductivity.—The electrodes were bright platinum foil cylinders 1·0 and 0·7 cm. respectively in diameter and 1 cm. high, secured in position one inside the other by sealing their platinum stems through two rigidly connected glass tubes. The constant of the cell was approximately $2·4 \times 10^{-2}$ at 21°, and no appreciable leak could be detected at 275°.

As the resistances to be measured were very high (10^5 to 10^7 ohms), the arrangement devised by Ambronn (*Ann. Physik*, 1919, **58**, 139) was employed, consisting of a battery and galvanometer connected to the conductivity cell through a rotating commutator which reversed the current through the cell about 100 times per second. The apparatus was calibrated by comparison with a series of standard high resistances.

The samples (5 g. in each case) were well dried and heated as in the dynamical experiments. The electrodes were immersed in the

fused material, and readings taken from time to time throughout the whole period of the transformation. The temperatures employed varied from 260° to 280°.

N-p-*Tolylbenzimino*-p-*tolyl ether*, prepared from benz-*p*-toluidide-iminochloride and *p*-cresol by the method already described, formed very pale yellow prisms, m. p. 65—66° (Found : N, 4·75. $C_{21}H_{19}ON$ requires N, 4·65%). When heated at 270—300° for 2 hours, it yielded *benzoyldi*-p-*tolylamine ;* this, prepared also from di-*p*-tolylamine and benzoyl chloride, formed nearly colourless prisms, m. p. 124—125° (Found : N, 4·7. $C_{21}H_{19}ON$ requires N, 4·65%).



The author wishes to express his indebtedness to the Chemical Society for a grant which has defrayed part of the expenses of this investigation, and to Messrs. Metropolitan-Vickers Electrical Company, Ltd., for the loan of the rotating commutator.

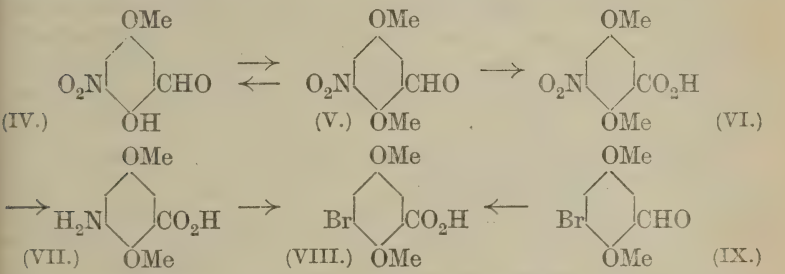
The University, Sheffield. [*Received, June 20th,* 1925.]

CCLXX.—*Substitution in Derivatives of Quinol Ethers.*

By Leon Rubenstein.

The investigation of substitution in the case of dialkyloxy vicinal benzene derivatives of type I (Davies and Rubenstein, J., 1923, **123**, 2830) showed that during nitration each alkyloxy-group OR,OR_1 exerts its para-directing influence independently of the other, whereas during bromination only the group –OR is potent in determining the orientation of the brominated product. The relative amounts of the isomerides produced in the nitration experiments, which could not then be estimated, have now been determined in the case of *o*-veratraldehyde (Perkin, Robinson, and Stoyle, J., 1924, **125**, 2355). The results obtained in those investigations made it desirable to examine the nitration and bromination of substances of type II in which only ortho-substitution with respect to the alkyloxy-groups can take place.

(I.) 



(II.)

(III.)

Experiments on the nitration of 2-hydroxy-5-methoxybenzaldehyde (III) indicate that the substance formed is the 3-nitro-benzaldehyde (IV), for when its methylation product (V) is hydrolysed 3-*nitro*-2-*hydroxy*-5-*methoxybenzaldehyde* is reformed. The bromin-

ation of 2-hydroxy-5-methoxybenzaldehyde yields the 3-bromobenzaldehyde, as is shown in the following manner: 3-*Nitro*-2 : 5-*dimethoxybenzaldehyde* (V) is oxidised to 3-*nitro*-2 : 5-*dimethoxybenzoic acid* (VI), which is reduced to 3-*amino*-2 : 5-*dimethoxybenzoic acid* (VII); from this by the Sandmeyer process is produced 3-*bromo*-2 : 5-*dimethoxybenzoic acid* (VIII), identical with the acid obtained by oxidising bromo-2-hydroxy-5-methoxybenzaldehyde after methylation (IX).

The nitration of 2 : 5-dimethoxybenzaldehyde gives a mixture of 6-*nitro*-2 : 5-*dimethoxybenzaldehyde* (80%) and 3-*nitro*-2 : 5-*dimethoxybenzaldehyde* (20%). The former substance has its nitro-group in the ortho-position with respect to the aldehyde group, for it gives an indigotin derivative when treated with acetone and alkali. It yields 6-nitro-2 : 5-dimethoxybenzoic acid on oxidation. The bromination of 2 : 5-dimethoxybenzaldehyde gives 6-*bromo*-2 : 5-*dimethoxybenzaldehyde* as the only product, and from this 6-*bromo*-2 : 5-*dimethoxybenzoic acid* is obtained by oxidation.

The remaining portion of the work consists in the investigation of the nitration and the bromination of 2 : 5-dimethoxyacetanilide. The nitration of this substance yields 4-*nitro*-2 : 5-*dimethoxyacetanilide*, as is shown by the fact that hydrolysis converts it into the nitro-2 : 5-dimethoxyaniline which on diazotisation and subsequent treatment in the Sandmeyer manner yields 3-*bromo*-6-*nitroquinol dimethyl ether*. On bromination, 2 : 5-dimethoxyacetanilide yields 4-*bromo*-2 : 5-*dimethoxyacetanilide*, the usual proof being applied, namely, conversion into the 4-*bromo*-2 : 5-*dimethoxyaniline*, diazotisation, and treatment with cuprous bromide to give dibromoquinol dimethyl ether.

Experimental.

2-Hydroxy-5-methoxybenzaldehyde was obtained by Tiemann and Müller (*Ber.*, 1881, **14**, 1990) in small yield, but the following modification gives much better results. Quinol monomethyl ether (40 g.) dissolved in a concentrated aqueous solution of sodium hydroxide (19 g. in 55 c.c. of water) is heated on a water-bath

while chloroform (42 g.) and sodium hydroxide solution (56 g. in 60 c.c. of water) are added alternately during 2 hours. The mixture is then heated for 1 hour, the sodium salt of the aldehyde separating in yellow, metallic crystals. The whole is strongly acidified, steam-distilled, the distillate extracted with ether, and the ethereal extract kept for some time over a concentrated solution of sodium bisulphite. The major portion of the ether is distilled off and the bisulphite compound of the aldehyde, which separates, is removed, decomposed by hot dilute sulphuric acid, and the aldehyde extracted with ether. The ether is removed and the residue distilled under reduced pressure, when 2-hydroxy-5-methoxybenzaldehyde is obtained as a light yellow, refracting liquid, b. p. 124°/12 mm. (yield 8·5 g., *i.e.*, 25%).

3-*Nitro*-2-*hydroxy*-5-*methoxybenzaldehyde*.—To a cold solution of 2-hydroxy-5-methoxybenzaldehyde (10 g.) in glacial acetic acid (50 c.c.) is added with cooling and stirring a solution of nitric acid (50 c.c.; *d* 1·42) in glacial acetic acid (50 c.c.), the temperature being maintained between 10° and 20°. 3-Nitro-2-hydroxy-5-methoxybenzaldehyde, which soon begins to separate, is collected after a few hours (yield 6·5 g.; m. p. 127°). The glacial acetic acid solution is diluted with water, neutralised with sodium bicarbonate, and extracted with ether; from the extract a further 4·5 g. of the substance is obtained (total yield 88%). 3-Nitro-2-hydroxy-5-methoxybenzaldehyde crystallises in bright yellow needles, m. p. 132°. It does not yield an indigotin derivative when treated with acetone and sodium hydroxide solution. With ferric chloride solution, it gives a red coloration (Found: N, 7·2. $C_8H_7O_5N$ requires N, 7·1%).

The p-*nitrophenylhydrazone* crystallises in scarlet prisms, decomp. 250°.

3-*Nitro*-2 : 5-*dimethoxybenzaldehyde*.—A solution of 3-nitro-2-hydroxy-5-methoxybenzaldehyde (6 g.) in dry chloroform (20 c.c.) and methyl iodide (10 c.c.) is heated on a water-bath while finely powdered silver oxide (6 g.) is added during 2 hours. After being heated for a further 1 hour, the mixture is filtered hot, some of the chloroform evaporated, and the solution cooled; 3-nitro-2 : 5-dimethoxybenzaldehyde then crystallises in pale yellow needles, m. p. 113°. More of the substance is obtained from the mother-liquors (yield almost theoretical) (Found: N, 6·85. $C_9H_9O_5N$ requires N, 6·7%). When it is boiled for a short time with 10% sodium hydroxide, and the solution is acidified, 3-nitro-2-hydroxy-5-methoxybenzaldehyde can be extracted from the precipitate obtained.

3-*Bromo*-2-*hydroxy*-5-*methoxybenzaldehyde*.—2-Hydroxy-5-meth-

oxybenzaldehyde (6 g.) is dissolved in glacial acetic acid (30 c.c.), and powdered, freshly-fused sodium acetate (3·6 g.) added. The suspension is well stirred, cooled to 5°, and treated with a solution of bromine (6 g.) in glacial acetic acid (12 c.c.), when 3-*bromo*-2-*hydroxy*-5-*methoxybenzaldehyde* rapidly separates. After remaining for a few hours, the mixture is diluted with water and the solid collected (yield 7·3 g. or 80%). It crystallises from aqueous alcohol in light brown needles, m. p. 107° (Found : Br, 35·0. $C_8H_7O_3Br$ requires Br, 34·6%). The p-*nitrophenylhydrazone* forms scarlet prisms, decomp. above 250°.

3-*Bromo*-2 : 5-*dimethoxybenzaldehyde*.—A solution of 3-bromo-2-hydroxy-5-methoxybenzaldehyde (6·5 g.) in alcohol (59 c.c.) is boiled under reflux during the gradual addition of methyl *p*-toluenesulphonate (10·5 g.) and 30% sodium hydroxide solution (4 c.c.). After boiling for 3 hours, the red alcoholic solution is diluted with water and the solid collected; after twice crystallising from aqueous alcohol, it forms needles, m. p. 63° (Found : Br, 32·3. $C_9H_9O_3Br$ requires Br, 32·6%).

Nitration of 2 : 5-*Dimethoxybenzaldehyde*.—Finely-powdered 2 : 5-dimethoxybenzaldehyde (3 g.) was added with cooling and stirring to cold nitric acid (12 c.c.; *d* 1·42). After remaining at room temperature for several hours, the mixture was diluted with water, and the solid (3·4 g.) collected. The mixture, m. p. 130—153°, was fractionally crystallised from alcohol, the main product being 6-*nitro*-2 : 5-*dimethoxybenzaldehyde* (*vide ante*), m. p. 159°. The mother-liquors deposited a small amount of 3-*nitro*-2 : 5-*dimethoxybenzaldehyde* (m. p. 113°), which gave no depression of melting point when mixed with a sample of 3-nitro-2 : 5-dimethoxybenzaldehyde prepared by the methylation of 3-nitro-2-hydroxy-5-methoxybenzaldehyde (p. 2000).

6-Nitro-2 : 5-dimethoxybenzaldehyde crystallises from alcohol in pale yellow needles, m. p. 159° (Found : N, 6·8. $C_9H_9O_5N$ requires N, 6·7%). The p-*nitrophenylhydrazone* forms scarlet prisms, m. p. 245—250° (decomp.).

6-*Bromo*-2 : 5-*dimethoxybenzaldehyde*.—A cooled solution of 2 : 5-dimethoxybenzaldehyde (2·8 g.) in glacial acetic acid (16 c.c.) is treated with bromine (2·8 g.) in glacial acetic acid (8 c.c.), kept for 2 days, and diluted with water; an oil then separates which rapidly solidifies. It crystallises from alcohol in pale grey needles, m. p. 125—126°, which become pink on exposure to the air (Found : Br, 29·1. $C_9H_9O_3Br$ requires Br, 28·7%). The p-*nitrophenylhydrazone* consists of hexagonal, scarlet prisms, m. p. 204—206°.

3-*Nitro*-2 : 5-*dimethoxybenzoic Acid*.—3-Nitro-2 : 5-dimethoxybenzaldehyde (6 g.) is added to water (60 c.c.) containing potassium

bicarbonate (4·2 g.), and boiled during the addition of potassium permanganate solution (6 g. in 60 c.c. of water). The hot solution is filtered, allowed to cool, and unchanged aldehyde collected. The reddish-yellow aqueous solution is acidified with dilute hydrochloric acid, when 3-nitro-2 : 5-dimethoxybenzoic acid (3·5 g.) is precipitated. It crystallises from hot water in long needles, m. p. 182—183° (Equiv. : found, 225; calc., 227).

6-*Nitro*-2 : 5-*dimethoxybenzoic Acid.* — 6-Nitro-2 : 5-dimethoxybenzaldehyde is oxidised as described above. The acid crystallises from hot water in pale yellow prisms, m. p. 192° (Equiv. : found, 229; calc., 227).

3-*Amino*-2 : 5-*dimethoxybenzoic Acid.*—A mixture of 3-nitro-2 : 5-dimethoxybenzoic acid (7 g.) and concentrated hydrochloric acid (24 c.c.) is gradually treated with tin (7 g.) and heated on a water-bath for 3 hours, water (50 c.c.) is added, and the tin removed from the hot solution as sulphide. The colourless filtrate is evaporated under reduced pressure, when the *hydrochloride* of 3-*amino*-2 : 5-*dimethoxybenzoic acid* separates in long, white needles (yield 5 g. or 80%).

The hydrochloride is easily soluble in water or alcohol, more difficultly soluble in concentrated hydrochloric acid, from which it can be crystallised. The solutions turn pink and then red on exposure to the air. When heated, the solid becomes very dark at 170° and decomposes at 215°. 3-*Amino*-2 : 5-*dimethoxybenzoic acid* is obtained by treating a solution of the hydrochloride in a small quantity of water with solid sodium carbonate until it is just acid to Congo-red, and evaporating under reduced pressure; after a long time, the acid separates in white, slender needles which turn black at 170° and decompose at 210—215°. It is soluble in acids, alkalis, and hot water; the latter two solutions turn green on exposure to the air (Found : N, 6·9. $C_9H_{12}O_4N$ requires N, 7·0%).

3-*Bromo*-2 : 5-*dimethoxybenzoic Acid.*—A mixture of 3-bromo-2 : 5-dimethoxybenzaldehyde (5·5 g.), water (55 c.c.), and potassium bicarbonate (3·8 g.) is boiled during the addition of 10% potassium permanganate (55 c.c.), filtered hot, cooled, and again filtered. The colourless filtrate is acidified with dilute hydrochloric acid, and the precipitated 3-*bromo*-2 : 5-*dimethoxybenzoic acid* (yield 4·5 g. or 85%) is crystallised from aqueous alcohol, when it is obtained in white, microscopic prisms, m. p. 132° (Equiv. : found, 258; calc., 261).

6-*Bromo*-2 : 5-*dimethoxybenzoic Acid.*—6-Bromo-2 : 5-dimethoxybenzaldehyde is oxidised as described above. The acid crystallises from aqueous alcohol in white, microscopic prisms, m. p. 164—165° (Equiv. : found, 259; calc., 261).

4 : 4′ : 7 : 7′-*Tetramethoxyindigotin*.—Aqueous potash (1 c.c. of 10%) is added to a solution of 6-nitro-2 : 5-dimethoxybenzaldehyde (0·4 g.) in acetone (2 c.c.). The deep blue liquid is mixed with water (20 c.c.) and boiled for a few minutes; the indigotin then separates. It has a rich deep blue appearance and crystallises from nitrobenzene in deep purple rhombs which sublime at 350°.

4-*Bromo*-2 : 5-*dimethoxyacetanilide*.—When 2 : 5-dimethoxyacetanilide (5 g.) dissolved in glacial acetic acid (25 c.c.) is treated with bromine (3·3 g.) in 4 c.c. of glacial acetic acid, 4-*bromo*-2 : 5-*dimethoxyacetanilide* soon separates from the well-cooled solution. After the mixture has been diluted with water, and the acetic acid neutralised with sodium carbonate, ether extracts the product, which crystallises from dilute alcohol in pale pink rhombs, m. p. 122° (yield 5·6 g. or 80%) (Found: Br, 29·3. $C_{10}H_{12}O_3NBr$ requires Br, 29·1%).

4-*Bromo*-2 : 5-*dimethoxyaniline Hydrochloride*.—4-Bromo-2 : 5-dimethoxyacetanilide (12 g.) is boiled with 20% alcoholic hydrochloric acid (20 c.c.) for 15 minutes; the 4-*bromo*-2 : 5-*dimethoxyaniline hydrochloride* which separates crystallises from alcohol in white, microscopic plates which become blue at 160° and decompose above 300°.

4-*Bromo*-2 : 5-*dimethoxyaniline* forms pale pink prisms, m. p. 106°. The *hydrobromide* is obtained by keeping an ethereal solution of the base in contact with hydrobromic acid (*d* 1·5), when it slowly separates in fine, yellow needles which turn blue at 160° and decompose slowly above this temperature.

Diazotisation. Methyl nitrite is passed through a solution of 4-bromo-2 : 5-dimethoxyaniline hydrobromide (20 g.) in glacial acetic acid (60 c.c.) at 10°. The deep brown solution of 4-bromo-2 : 5-dimethoxybenzenediazonium bromide is poured into dry ether, the ether decanted off, and the solid diazonium salt dissolved in ice-cold water (40 c.c.). The aqueous solution is added cautiously to a solution of cuprous bromide in concentrated hydrobromic acid and heated on a water-bath; nitrogen is then evolved and 2 : 5-dibromoquinol dimethyl ether separates. This crystallises from alcohol in colourless needles, m. p. 143°, not depressed on admixture with the dibromoquinol dimethyl ether prepared by the bromination of quinol dimethyl ether.

4-*Nitro*-2 : 5-*dimethoxyacetanilide*.—A solution of 2 : 5-dimethoxyacetanilide (10 g.) in glacial acetic acid (50 c.c.) is treated at 5° with nitric acid (*d* 1·42; 10 c.c. in 50 c.c. of glacial acetic acid). After 1 hour, water is added. The 4-*nitro*-2 : 5-*dimethoxyacetanilide* which separates (yield 11 g. or 90%) crystallises from alcohol in yellow prisms, m. p. 165° (Found: N, 11·8. $C_{10}H_{12}O_5N_2$ requires N, 11·7%).

4-*Nitro*-2 : 5-*dimethoxyaniline Hydrochloride*.—4-Nitro-2 : 5-dimethoxyacetanilide (10 g.) is boiled with 20% alcoholic hydrochloric acid (25 c.c.) for 1 hour. The grey crystals of the *hydrochloride* that separate on cooling (yield theoretical) crystallise from alcohol in yellow, metallic prisms, m. p. 160° (decomp.) (Found: N, 12·1. $C_8H_{11}O_4N_2Cl$ requires N, 11·9%).

4-*Nitro*-2 : 5-*dimethoxyaniline* forms yellow prisms, m. p. 153°.

Diazotisation of 4-*Nitro*-2 : 5-*dimethoxyaniline Hydrobromide*.—The solution obtained by diazotising 4-nitro-2 : 5-dimethoxyaniline hydrobromide (4 g.) in concentrated hydrobromic acid (20 c.c.) and water (25 c.c.) at 0° with 2·5 c.c. of 40% sodium nitrite is filtered, added cautiously to a solution of cuprous bromide in concentrated hydrobromic acid, and the mixture heated on a water-bath for a short time. The 2-bromo-5-nitroquinol dimethyl ether that separates is washed with concentrated hydrobromic acid and with water and crystallised from alcohol. The product, pale yellow prisms, m. p. 154°, does not depress the m. p. of 2-bromo-5-nitroquinol dimethyl ether obtained by bromination of nitroquinol dimethyl ether.

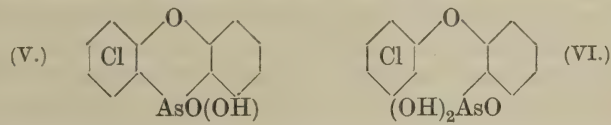
CCLXXI.—*The Relative Rates of Conversion of Phenoxyphenyldichloroarsine and its Chloro-derivatives into Chlorophenoxarsines.*

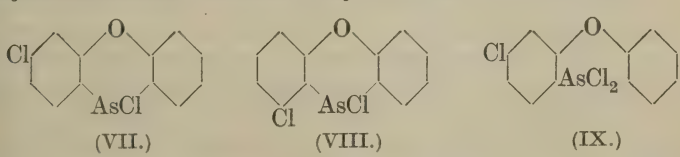
By ELWYN ROBERTS and EUSTACE EBENEZER TURNER.

IT was previously shown (Turner and Sheppard, this vol., p. 544) that *o*-phenoxyphenyldichloroarsine readily passes into 5-chlorophenoxarsine (there named 6-chlorophenoxarsine) when distilled under diminished pressure, and it was suggested that polarity effects might account for this then unusual ring-closure. It was therefore decided to test the effect, on the ring-closure, of a polar substituent in the dichloroarsine. In starting the work, the present authors were unaware of the fact that diphenylyl-*o*-arsenious chloride is readily converted into *oo'*-diphenylylenearsenious chloride (Aeschlimann, Lees, McCleland, and Nicklin, this vol., p. 66).



It having been found that *o*-phenoxyphenyldichloroarsine under-

went ring-closure at a readily measurable rate when heated at 200° in a current of carbon dioxide, it was decided to compare, under these conditions, the rate of ring-closure of the parent *o*-phenoxy-compound (I) and its *ortho*- (II), *meta*- (III), and *para*- (IV) chloro-derivatives :



Compounds (II), (III) and (IV) were synthesised from the appropriate chlorophenol by processes similar to that originally used for the synthesis of (I). Preliminary experiments showed that whilst the compounds (II) and (IV) could be distilled under diminished pressure with only partial decomposition, compound (III) underwent very considerable ring-closure, a result which at first sight appeared to support the alternate polarities theory.

5 : 8- (see below) and 5 : 7-*Dichlorophenoxarsines* were prepared in two ways; first, by prolonged boiling of dichloroarsines (III) and (IV) under diminished pressure, and secondly by the reduction (hydrochloric–hydriodic–sulphurous acid method) of the corresponding chlorophenoxarsinic acids (V), the latter being obtained by the action of warm concentrated sulphuric acid on the corresponding chlorophenoxyphenylarsinic acids (VI) :

5 : 9-*Dichlorophenoxarsine* was prepared by boiling the corresponding phenoxydichloroarsine under diminished pressure.

The constitutions of three of the chlorophenoxarsines follow from their mode of formation from the corresponding dichloroarsines. That of the chlorophenoxarsine obtained from 2-m-*chlorophenoxyphenyldichloroarsine*, however, may be either (VII) or (VIII) :

5 : 8-Dichlorophenoxarsine (VII) has therefore been synthesised by a process which leaves no doubt as to its constitution. When 2 : 4-dichloronitrobenzene is warmed with 1 mol. of potassium phenoxide in phenol as solvent, the 2-chlorine atom is displaced by

phenoxyl. The resulting *5-chloro-2-nitrodiphenyl ether* is readily converted by the usual series of reactions into *4-chloro-2-phenoxyphenyldichloroarsine* (IX), and the latter, when heated at 200° in a current of carbon dioxide affords 5 : 8-dichlorophenoxarsine, identical in all respects with the product obtained from 2-*m*-chlorophenoxyphenyldichloroarsine. It also follows that the substance obtained by heating 2-m-*chlorophenoxyphenylarsinic acid* with concentrated sulphuric acid is 5 : 8-*dichlorophenoxarsinic acid*.

In order to compare their rates of ring-closure, the four dichloroarsines were heated simultaneously in the same bath kept at 200°. Through each dichloroarsine carbon dioxide was bubbled at the same rate, and the hydrogen chloride liberated was determined at intervals. In this way it was found (see p. 2012) that *o*-phenoxyphenyldichloroarsine (I) undergoes ring-closure much more readily than does its *m*-chloro-derivative (III), whilst the latter in turn undergoes ring-closure much more rapidly than the ortho- (II) or para- (IV) derivative, the last two compounds undergoing ring-closure at approximately equal rates.

This result appears to show conclusively that the polarising effect of the chlorine atom is not the sole determining influence affecting ring-closures of dichloroarsines to chlorophenoxarsines, just as the polarising effect of the oxygen atom can no longer be regarded as the main determining influence causing the ready formation of 5-chlorophenoxarsine itself.

The theory of alternate latent polarities requires compound (III) (combined effects of chlorine and oxygen) to pass more readily than (I) into a phenoxarsine, and (II) and (IV) to undergo ring-closure much less readily (opposed effects of chlorine and oxygen). A purely steric effect on the part of the chlorine atom would account for the observed fact that compound (I) undergoes ring-closure more readily than compound (III), but scarcely explains why (II) and (IV) pass into chlorophenoxarsines so much less readily. The main determining factor appears to be a steric one, modified by polar effects. In the case of compound (III), the steric outweighs the polar effect of the chlorine atom, whilst in the case of (II) and (IV) it enhances this effect. 4-Chloro-2-phenoxyphenyldichloroarsine (IX) (see below) is apparently even more readily converted into a phenoxarsine than *o*-phenoxyphenyldichloroarsine itself. This is in full agreement with a combined steric and polarity effect. In explaining the results obtained, Flürscheim's theory does not appear to present any advantages over the theory of alternate latent polarities, which, on this occasion at any rate, seems to be capable of definite interpretation, whilst the more subtle alternation of free affinity is not readily dealt with in the case of two key-atoms

having opposite effects. The observations of Altschul in connexion with the coupling of diazo-solutions with the isomeric nitrophenols are of interest in comparison with the present results (*Chem.-Ztg.*, 1898, **22**, 115).

When *o*-phenoxy- or 2-*o*-chlorophenoxy-phenylarsinic acid is heated with concentrated sulphuric acid, the corresponding phenoxarsinic acid is not obtained. Since each phenyl nucleus in diphenyl ether is readily monosulphonated, the different behaviour of the four phenoxyphenylarsinic acids may be explained as follows: Phenoxyphenylarsinic acid itself readily undergoes sulphonation in the unsubstituted phenyl nucleus, so that the final product is a sulphonic acid of the simple arsinic acid or of the phenoxarsinic acid. 2-*o*-Chlorophenoxyphenylarsinic acid, owing to combined polar and steric effects of the chlorine atom, undergoes sulphonation more rapidly than ring-closure. 2-*m*-Chlorophenoxyphenylarsinic acid shows a greater tendency to undergo ring-closure than to sulphonate, owing to the steric effect, on sulphonation, of the chlorine atom, whilst 2-*p*-chlorophenoxyphenylarsinic acid is readily converted into a phenoxarsinic acid, owing to the presence of a chlorine atom in the position at which sulphonation would occur.

The mechanism of the hydrochloric–hydriodic–sulphurous acid reduction of arsinic acids to dichloroarsines is imperfectly understood. In the reduction of 4-chloro-2-phenoxyphenylarsinic acid, free iodine is liberated as reduction proceeds, and appears as a surface film, which, although readily broken up by agitation, continually reappears, whilst any arsinic acid remains unreduced. Suddenly the oily dichloroarsine–oxychloride–acid mixture solidifies, owing to its conversion into dichloroarsine, and at once the iodine film disappears. Similar, although less definite, changes occur in other cases, and it would therefore appear clear that hydriodic acid is the essential reducing agent, being immediately oxidised in presence of even small quantities of an arsinic acid.

Experimental.

Preparation of 2-, 3-, *and* 4-*Chloro*-2′-*nitrodiphenyl Ethers.*—The method adopted for the preparation of these compounds has been that previously employed, using *o*-chloronitrobenzene (1 mol.), a phenol (2 mols.), potassium hydroxide (1 mol.), and water (0·3 mol.) in presence of copper bronze. The yields given below are calculated on the chloronitrobenzene. If the proportion of alkali be increased (say, to 1·5 mols.), unworkable tars result, but in the case of the condensation with *m*-chlorophenol, a substance only obtainable with difficulty, the proportion of phenol may be reduced to 1 mol. without seriously decreasing the yield.

2-*Chloro*-2′-*nitrodiphenyl ether* was obtained in 55% yield, forms yellow, hexagonal prisms or plates from alcohol, and has m.p. 48°, b. p. 209°/9 mm. (Found: NO_2, 18·8. $C_{12}H_8O_3NCl$ requires NO_2, 18·4%).

3-*Chloro*-2′-*nitrodiphenyl ether*, obtained in 58% yield, is a yellow oil, b. p. 204°/8 mm. [Found (crude substance) NO_2, 17·3%]. The *m*-chlorophenol required was obtained by Hodgson's method (*Brit. Pat.* 200714) from *m*-chloroaniline. The addition of copper sulphate to the diazo-solution appears to improve the yield (94%) slightly. The *m*-chloroaniline used was readily prepared in almost theoretical yield by reducing *m*-chloronitrobenzene by the iron–ferric chloride method (below).

4-*Chloro*-2′-*nitrodiphenyl ether*, obtained in 75% yield, separates from alcohol in yellow needles, m. p. 44—45°, b. p. 208°/11 mm., or 220°/20 mm. (Found: Cl, 14·7; NO_2, 18·9. $C_{12}H_8O_3NCl$ requires Cl, 14·2; NO_2, 18·4%).

Preparation of Aminodiphenyl Ethers.—The method previously adopted for the reduction of nitrodiphenyl ethers has been abandoned in favour of the following, which gives excellent yields. A mixture of nitro-compound (1 part), iron filings (1·5 parts), and water (1 part) was heated for about 10 minutes in boiling water, with thorough shaking. A gram of ferric chloride for each 100 g. of iron was then added and the whole shaken and heated until a reaction set in. The reaction was controlled if necessary by removal from the bath, and finally completed by heating in boiling water for an hour. The cooled product was shaken with ether, filtered, and the iron residue washed with ether. The ethereal solution was shaken with an excess of hydrochloric acid, when the base separated as the hydrochloride. The iron residues become warm on exposure to air, owing to rapid oxidation.

All the amino-compounds are stable, and distil unchanged in a vacuum.

o-*Aminodiphenyl ether*, obtained in almost theoretical yield, forms an *acetyl* derivative, colourless prisms from light petroleum (b. p. 80—100°) (Found: N, 6·4. $C_{14}H_{13}O_2N$ requires N, 6·2%).

2-*Chloro*-2′-*aminodiphenyl ether*, obtained in 90% yield, separates from light petroleum (b. p. 80—100°) in white prisms, m. p. 44—45°, b. p. 185°/9 mm. The *hydrochloride* forms colourless, irregular plates, m. p. 171—173° (Found: HCl, 14·6. $C_{12}H_{10}ONCl,HCl$ requires HCl, 14·3%).

3-*Chloro*-2′-*aminodiphenyl ether* was obtained in 91% yield, and is a colourless oil, b. p. 195°/13 mm. The *hydrochloride*, colourless aggregates of prisms, has m. p. 149—151° (Found: HCl, 14·4%).

The *benzoyl* derivative separates from dilute alcohol in clusters of needles, m. p. 106°.

4-*Chloro*-2′-*aminodiphenyl ether*, obtained in 94% yield by the iron method, and in 84% yield by the alcoholic stannous chloride method, is a yellow oil, b. p. 202°/15 mm. The *hydrochloride* forms colourless prisms, m. p. 190—191° (Found : HCl, 14·3%), and the *benzoyl* derivative, hair-like needles from dilute alcohol, m. p. 108—109°.

Preparation of Phenoxyphenylarsinic Acids.—These acids were prepared by the following modification of the usual method :

The diazo-solution obtained from amine hydrochloride (1 mol.), and hydrochloric acid (1·5 mols.), etc., was neutralised with sodium hydrogen carbonate (0·5 mol.), and treated with a little copper sulphate solution. This solution was then slowly added to an arsenite solution (at 50—60°), containing arsenious oxide (0·75 mol.), sodium hydroxide (2 mols.), sodium carbonate (0·7 mol.), water (7 mols.), and a little copper sulphate. It was found advantageous not to use benzene to prevent frothing, because the by-products were obtained as brown solids which could readily be removed by filtration, the filtrate affording pure arsinic acids after acidification. The acids were dried at 100° before analysis.

o-*Phenoxyphenylarsinic acid* was obtained in 32% yield and separates from alcohol in needles, m. p. 167—168°.

2-o-*Chlorophenoxyphenylarsinic acid*, obtained in 18% yield, crystallises from alcohol or water in needles, m. p. 195—195·5° (Found : As, 22·8. $C_{12}H_{10}O_4ClAs$ requires As, 22·8%).

2-m-*Chlorophenoxyphenylarsinic acid* (yield, 18%) separates from dilute alcohol in rounded, hexagonal plates, m. p. 177—179° (Found : As, 23·0%).

2-p-*Chlorophenoxyphenylarsinic acid* was obtained in 24% yield, and forms cubes (from alcohol), m. p. 187—188° (Found : As, 22·8%).

Preparation of Chlorophenoxyphenyldichloroarsines.—The arsinic acids were reduced in warm concentrated hydrochloric acid suspension with sulphur dioxide in presence of a little potassium iodide. The crude dichloroarsines were converted into the corresponding oxides by dissolving in alcoholic sodium hydroxide containing sodium sulphite, and pouring the product into dilute sulphuric acid. In this way, all traces of iodine were removed, and the oxides, when warmed with concentrated hydrochloric acid, afforded pure dichloroarsines. The yields were almost theoretical.

2-o-*Chlorophenoxyphenyldichloroarsine* is a pale yellow oil, boiling with only partial decomposition at about 217°/8 mm. [Found : Cl (attached to arsenic), 20·7. $C_{12}H_8OCl_3As$ requires Cl, 20·3%].

2-m-*Chlorophenoxyphenyldichloroarsine*, is a pale yellow oil boiling with advanced decomposition at about 220°/10 mm. [Found, Cl (attached to arsenic), 20·8%].

2-p-*Chlorophenoxyphenyldichloroarsine*, pale yellow, prismatic needles from petroleum (b. p. 80—100°), has m. p. 67—68°, and boils with only partial decomposition at about 220°/10 mm. [Found: Cl (attached to arsenic), 20·3%].

The analysis of the dichloroarsines and of the chlorophenoxarsines has been effected by a simplified method: The chloroarsine was dissolved in alcohol, a slight excess of sodium hydrogen carbonate added, the solution warmed, just acidified with dilute sulphuric acid, neutralised with precipitated calcium carbonate, and titrated against *N*/10-silver nitrate.

Preparation of Chlorophenoxarsinic Acids.—8-*Chlorophenoxarsinic acid.* Two grams of 2-*m*-chlorophenoxyphenylarsinic acid were heated with 15 c.c. of concentrated sulphuric acid at 100° for 15 minutes, the solution then poured into water, and the precipitate collected. It was found impossible to obtain a pure compound by recrystallisation, and purification was ultimately effected by adding excess of sodium hydroxide to a solution of the *sodium* salt (colourless leaflets), when the latter was precipitated in the pure state, and gave rise to an acid which crystallised from alcohol in prisms, m. p. 250—252° (Found: As, 24·3. $C_{12}H_8O_3ClAs$ requires As, 24·2%).

7-*Chlorophenoxarsinic acid.* This acid separated on diluting the concentrated sulphuric acid solution; it crystallised from alcohol in colourless plates or prisms, m. p. 240—242° (Found: As, 23·7%).

When *o*-phenoxyphenylarsinic acid or its *o*-chloro-derivative was heated with concentrated sulphuric acid and the product diluted, no separation of solid occurred, and neutralisation by barium carbonate, finally followed by treatment of the barium salt with sulphuric acid, gave deliquescent sulphonic acids, which were not further investigated.

Preparation of Dichlorophenoxarsines.—(a) *From chlorophenoxarsinic acids.* 8-Chlorophenoxarsinic acid, when reduced by the usual method in the warm, gave 5 : 8-*dichlorophenoxarsine*, which separates from petroleum (b. p. 80—100°) in colourless intersecting circular plates, m. p. 125° [Found: Cl (attached to arsenic), 11·5. $C_{12}H_7OCl_2As$ requires Cl, 11·3%].

7-Chlorophenoxarsinic acid, when similarly reduced, gave a mixture which was separated by repeated crystallisation from petroleum–chloroform solution. 5 : 7-*Dichlorophenoxarsine* was obtained as almost colourless rhombs, m. p. 144—145° [Found: Cl (attached to arsenic), 11·3%], together with an arsenic-free *substance* forming yellow laminæ, m. p. 119—120°.

(b) *From chlorophenoxyphenyldichloroarsines.* The dichloroarsines were either allowed to boil gently under reflux under diminished pressure for 6 hours, or heated for a similar period at 200° in a current of carbon dioxide, and the residual crude chlorophenoxarsine was crystallised from chloroform–petroleum mixtures.

5 : 9 - *Dichlorophenoxarsine,* from 2 - *o* - chlorophenoxyphenyldichloroarsine, forms pale yellow needles, m. p. 99° [Found : Cl (attached to arsenic), 11·3%].

Synthesis of 5 : 8 - *Dichlorophenoxarsine.* — 2 : 4-*Dichloronitrobenzene.* As details of the preparation of this substance are not to be found in the literature, they are given here : *m*-Dichlorobenzene (1 mol.) was dissolved in nitric acid (*d* 1·5; 4·5 mols.) with efficient cooling, and the solution then warmed for 10 minutes at 70°. On pouring into ice and water, the nitro-compound separated as a solid, which after being melted under hot water melted at 33° (Beilstein and Kurbatov, *Annalen*, 1876, **182**, 97, give the same figure).

5-*Chloro*-2-*nitrodiphenyl ether.* 2 : 4-Dichloronitrobenzene (1 mol.) was added to a warm solution containing potassium hydroxide (1 mol.), phenol (2 mols.), and water (0·3 mol.). A vigorous reaction at once set in, without addition of copper bronze, and was completed by heating at 100° for 10 minutes. The product, after being worked up as usual, afforded the theoretical yield of the chloronitrodiphenyl ether, which crystallises from alcohol or petroleum (b. p. 80—100°) in prisms, m. p. 85° (Found : Cl, 14·3; NO_2, 17·8. $C_{12}H_8O_3NCl$ requires Cl, 14·2; NO_2, 18·4%). Using half the above proportion of phenol, the same result was obtained.

5-*Chloro*-2-*aminodiphenyl ether.* The last-named nitro-compound was reduced by the iron–ferric chloride method, when the amine hydrochloride was obtained in 95% yield as needles of indefinite m. p. (Found : HCl, 14·2. $C_{12}H_{10}ONCl,HCl$ requires HCl, 14·3%).

4-*Chloro*-2-*phenoxyphenylarsinic acid.* This acid, obtained in 25% yield from the amine hydrochloride in the usual manner, forms colourless, hairy tufts of needles from dilute alcohol, and has m. p. 182° (Found : As, 22·3. $C_{12}H_{10}O_4ClAs$ requires As, 22·8%).

4-*Chloro*-2-*phenoxyphenyldichloroarsine* (see introduction), pale yellow, regular cubes or octahedra from petroleum (b. p. 80—100°), has m. p. 91—92°, and possesses an objectionable odour [Found : Cl (attached to arsenic), 20·1. $C_{12}H_8OCl_3As$ requires Cl, 20·3%].

5 : 8-*Dichlorophenoxarsine.* A weighed quantity of 4-chloro-2-phenoxyphenyldichloroarsine was heated at 200° in a current of pure carbon dioxide. Hydrogen chloride was evolved rapidly, the percentage conversion into dichlorophenoxarsine at the end of 2, 3, and 8 hours being about 45, 55, and 65, respectively. Heating was then discontinued. The product became solid on cooling, and

was once crystallised from light petroleum (b. p. 80—100°). It then melted at 125°, possessed the highly characteristic crystalline form of the dichloroarsine obtained from 2-*m*-chlorophenoxyphenyldichloroarsine, and did not depress the m. p. of this phenoxarsine [Found : Cl (attached to arsenic), 11·7%].

Rates of Conversion of Phenoxyphenyldichloroarsines into Chlorophenoxarsines.—About 1 g. of each of the four dichloroarsines (I—IV) was placed in a test-tube fitted as a wash-bottle, with a capillary carbon dioxide ingress tube passing to the bottom of the test-tube. The egress tube was connected to an absorption flask containing *N*/10-potassium hydroxide solution in each case. All four tubes were simultaneously plunged into a stirred oil-bath kept at 200° ± 1°, and an equal current of pure carbon dioxide allowed to bubble through each. At intervals of 1 hour, the absorption flasks were replaced by similar ones, this operation being carried out in a uniform routine manner, so that the exact time interval obtained for each substance. The results are expressed below in terms of percentage decomposition.

	Percentage decomposition.			
Time (hours).	I.	II.	III.	IV.
1	23·7	1·86	8·90	1·09
2	38·2	6·08	23·4	4·65
3	45·7	11·2	29·3	11·3
4	49·5	15·5	33·0	17·0
5	53·5	19·7	35·5	20·5
6	56·6	24·3	37·8	27·0

The expenses of this investigation were partly defrayed by a grant obtained from the Chemical Society, for which the authors desire to express their thanks.

East London College,
University of London. [*Received, June 12th,* 1925.]

CCLXXII.—2-*Amino*-4 : 5-*dimethylglyoxaline.*

By [the late] Richard Burtles and Frank Lee Pyman.

4(5)-Amino-5(4)-methylglyoxaline (Fargher, J., 1920, **117**, 668), 4-amino-1 : 5-dimethylglyoxaline, and 5-amino-1 : 4-dimethylglyoxaline (Pyman, J., 1922, **121**, 2616) behave like typical aromatic amines in yielding benzylidene derivatives, and diazo-solutions which couple with sodium β-naphthoxide. The so-called 2-aminoglyoxaline (I), however, neither yields a benzylidene derivative (Fargher and Pyman, J., 1919, **115**, 217) nor does it behave normally with sodium nitrite (Pyman and Timmis, *J. Soc. Dyers Col.*, 1922, **38**,

269). It seems, therefore, to react rather according to the alternative tautomeric formula, that of 2-imino-3 : 4-dihydroglyoxaline

(I.)

(II.)

(III.)

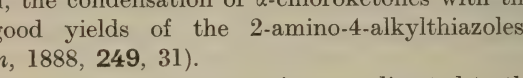
(II), put forward by Fargher and Pyman, and it may be noted that some other amino-compounds capable of similar tautomerism, for example, 2-aminopyridine, fail to react smoothly with nitrous acid.

On the other hand, the 8-aminopurines, for example, 8-aminoxanthine (III), which contain an amino-group in the 2-position of the glyoxaline nucleus, yield diazo-compounds which couple with R-salt (H. Fischer, *Z. physiol. Chem.*, 1909, **60**, 69). The 8-aminopurines differ from 2-aminoglyoxaline in that there is no possibility of substitution in their case at the 4- and 5-positions of the glyoxaline ring, and it seemed possible that this difference in structure might be the cause of the difference in behaviour. Some support appeared to be lent to this view by the fact that creatinine (IV) gives with nitric acid and sodium nitrite a mixture of oximinocreatinine (V) with oximinomethylhydantoin (Schmidt and Thumann, *Arch. Pharm.*, 1912, **250**, 352), and it was thought that the action of nitrous acid on 2-aminoglyoxaline might lead to the formation of an oximino-derivative (VI). To test this point, we have prepared

(IV.)

(V.)

(VI.)

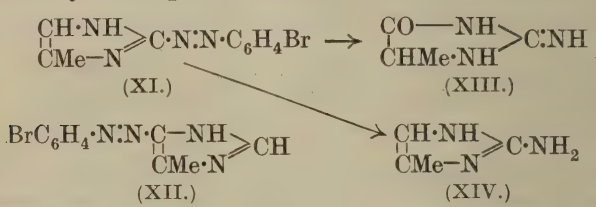


2-*amino*-4 : 5-*dimethylglyoxaline* (VIII), which cannot yield an oximino-compound of this type, and find that in general its behaviour towards nitrous acid in the presence of acid or alkali resembles that of 2-aminoglyoxaline. Consequently, the failure of 2-aminoglyoxaline to behave normally with nitrous acid cannot be attributed to the suggested cause.

The 2-amino-4 : 5-dimethylglyoxaline (VIII) required for this purpose was prepared by the reduction of 2-p-*bromobenzeneazo*-4 : 5-*dimethylglyoxaline* (VII), which was itself obtained by coupling diazotised *p*-bromoaniline with 4 : 5-dimethylglyoxaline. Since the

(VII.) (VIII.)

synthesis of 4 : 5-dimethylglyoxaline is long and tedious, an alternative method of preparing the amine was sought in the condensation



of α-bromoethyl methyl ketone (IX) with guanidine (X), but the required substance could not even be identified with certainty

(IX.) (X.)

amongst the products of the reaction, although an analogous reaction, the condensation of α-chloroketones with thiocarbamides, gives good yields of the 2-amino-4-alkylthiazoles (Traumann, *Annalen*, 1888, **249**, 31).

In these circumstances, attention was directed to the preparation of 2-*amino*-4(5)-*methylglyoxaline* (XIV), which, it was expected, could be made in quantity from the readily accessible 4(5)-methylglyoxaline. On treating this base with diazotised *p*-bromoaniline, the expected mixture of 2- and 5(4)-p-*bromobenzeneazo*-4(5)-*methylglyoxalines* (XI and XII) with the bis-azo-compound was obtained. The constitution of the 2-isomeride [and therefore of the 5(4)-isomeride also] was readily established through its reduction to alacreatinine (XIII) by means of zinc dust and acetic acid, but, unfortunately, attempts to reduce it smoothly to 2-amino-4(5)-methylglyoxaline, by means of stannous chloride, failed. Here again alacreatinine was obtained together with a substance which was probably the required amine.

(XI.) (XIII.)

(XII.) (XIV.)

Experimental.

2-p-*Bromobenzeneazo*-4 : 5-*dimethylglyoxaline* (VII).—4 : 5-Dimethylglyoxaline hydrochloride (4·12 g.) was added to an aqueous solution of hydrated sodium carbonate (59 g.) in water (300 c.c.), and to the turbid liquor, the product of diazotising *p*-bromoaniline (5·37 g.) in concentrated hydrochloric acid (32 c.c.) and water (100 c.c.) with sodium nitrite (3 g.) was added. After keeping over-night, the insoluble product was collected and crystallised from alcohol (7·15 g.; yield = 82%).

2-p-*Bromobenzeneazo*-4 : 5-*dimethylglyoxaline* crystallises from alcohol in light brown needles, m. p. 213—214° (corr.) (Found : N, 19·9; Br, 29·1. $C_{11}H_{11}N_4Br$ requires N, 20·1; Br, 28·7%). It seems to cause irritation of the skin and swelling of the eyelids.

On treatment with cold hydrochloric acid, it yields a sparingly soluble *hydrochloride* (orange-yellow needles, decomp. 135°), which resinifies when heated with dilute hydrochloric acid (Found : Cl, 11·6. $C_{11}H_{11}N_4Br,HCl$ requires Cl, 11·3%).

Reduction.—The above azo-compound (2·79 g.) was reduced by heating at 100° with stannous chloride (5·6 g. hydrated) in concentrated hydrochloric acid (13 c.c.) and water (50 c.c.) until almost completely decolorised. After removing tin by hydrogen sulphide, the solution was concentrated to low bulk, and made alkaline; *p*-bromoaniline was then partly precipitated and partly removed by ether. The mother-liquor was acidified with hydrochloric acid, evaporated to dryness, and extracted with alcohol; the extract gave on evaporation 2-amino-4 : 5-dimethylglyoxaline hydrochloride (1·02 g.; yield = 69%).

2-*Amino*-4 : 5-*dimethylglyoxaline hydrochloride* (VIII) crystallises from alcohol in fine, colourless needles, m. p. 289° (corr.) (Found : C, 40·4; H, 7·0; N, 28·1; Cl, 24·4. $C_5H_9N_3,HCl$ requires C, 40·7; H, 6·8; N, 28·5; Cl, 24·0%). It is very easily soluble in water or alcohol, and is best purified through the carbonate, which is precipitated on mixing this salt with sodium carbonate in strong aqueous solution, and may be recrystallised quickly from water. The *carbonate*, m. p. 144° (corr.), contains 1 H_2O, and is readily soluble in hot water, but much less soluble in cold water. It is insoluble or very sparingly soluble in most organic solvents. Its aqueous solution is alkaline and gradually darkens on heating, yielding resinous products [Found in air-dried substance : C, 43·4, 43·5; H, 7·2, 7·3; N, 28·1. $(C_5H_9N_3)_2,H_2CO_3,H_2O$ requires C, 43·7; H, 7·3; N, 27·8%]. The *picrate* crystallises from water in yellow needles, m. p. 245° (corr.) (Found : N, 24·5. $C_5H_9N_3,C_6H_3O_7N_3$ requires N, 24·7%).

Reactions with Nitrous Acid.—Both 2-amino-4 : 5-dimethylglyoxaline and 2-aminoglyoxaline react sluggishly with nitrous acid in the presence of dilute or concentrated hydrochloric acid or of 25% acetic acid, giving solutions from which neither the original material nor any useful quantity of other crystalline substances could be isolated, but which give deep colours on treatment with sodium hydroxide. A difference in behaviour, however, was observed where 23% nitric acid was employed, for here, after treatment with sodium nitrite and keeping for 2 days, the solution from 2-aminoglyoxaline deposited a red solid, the filtrate from which gave a purple solution with sodium hydroxide, whilst the solution from 2-amino-4 : 5-dimethylglyoxaline remained clear and gave a pale yellow solution with either sodium hydroxide or sodium β-naphthoxide. Both amines give deeply coloured solutions with

either sodium nitroprusside and aqueous sodium hydroxide, or with amyl nitrite and sodium ethoxide in alcoholic solution. Since solutions of both amines in aqueous sodium hydroxide gradually darken on keeping, it is possible that the main effect of nitrous acid upon them is one of oxidation, for both bases are readily oxidised; thus 2-amino-4 : 5-dimethylglyoxaline immediately reduces cold aqueous acid permanganate or ammoniacal silver nitrate.

2-*Acetylamino*-4 : 5-*dimethylglyoxaline*, prepared by boiling the above carbonate with acetic anhydride and fused sodium acetate for 1 hour, crystallised from water in colourless needles, m. p. 270° (corr.) (Found : N, 27·6. $C_7H_{11}ON_3$ requires N, 27·5%). It is soluble in dilute hydrochloric acid and in aqueous sodium hydroxide, but insoluble in aqueous sodium carbonate. After treatment with hydrochloric acid and sodium nitrite, it gives no coloration with sodium β-naphthoxide. It instantly decolorises cold aqueous potassium permanganate.

2-Amino-4 : 5-dimethylglyoxaline does not yield a benzylidene derivative.

p-*Bromobenzeneazo-derivatives of* 4(5)-*Methylglyoxaline*.—The diazo-solution from *p*-bromoaniline (34·4 g.), hydrochloric acid (260 c.c. conc.), water (600 c.c.), and sodium nitrite (14 g.) was added to a stirred ice-cold solution of 4(5)-methylglyoxaline (16·4 g.) and hydrated sodium carbonate (350 g.) in water (1·6 l.). After keeping over-night, the insoluble azo-compounds were collected, and the filtrate was treated with diazotised *p*-bromoaniline (2 g.) [to utilise the 4(5)-methylglyoxaline remaining in excess on account of the formation of the bis-azo-compound], when a further separation of azo-compounds occurred. The total material was extracted several times with cold 2·5% hydrochloric acid (240 c.c. each time), when the very dark-red bis-azo-compound (10 g., crude, m. p. 100—102°) remained undissolved. The filtrate was basified with sodium carbonate, and the product crystallised from alcohol, when nearly pure 2-*p*-bromobenzeneazo-4(5)-methylglyoxaline, *ca.* 20 g., m. p. 219°, separated, followed by crops of lower m. p. (204—210°). The latter were mixed with cold dilute hydrochloric acid, when the sparingly soluble 5(4)-*p*-bromobenzeneazo-4(5)-methylglyoxaline hydrochloride separated, and the filtrate from this, when basified, gave more of the crude 2-azo-compound. After repetition of these operations, there were obtained 25 g. of the 2-azo-compound (47%) and 7·5 g. of the hydrochloride of the 5(4)-azo-compound (12%).

2-p-*Bromobenzeneazo*-4(5)-*methylglyoxaline* (XI) crystallises from alcohol in fine yellow needles, m. p. 225—226° (corr.) (Found : C, 45·2; H, 3·6; N, 21·1. $C_{10}H_9N_4Br$ requires C, 45·3; H, 3·4

N, 21·1%). Its hydrochloride is very easily soluble in dilute hydrochloric acid.

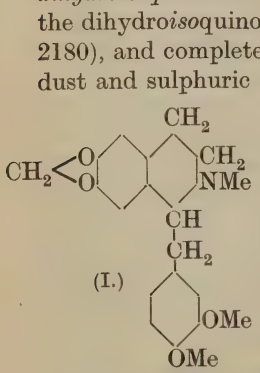
5(4)-p-*Bromobenzeneazo*-4(5)-*methylglyoxaline* (XII) crystallises from alcohol in irregular, brown prisms, m. p. 238° (corr.) (Found : C, 45·1 ; H, 3·6. $C_{10}H_9N_4Br$ requires C, 45·3 ; H, 3·4%). The *hydrochloride* is sparingly soluble in dilute hydrochloric acid, from which it crystallises in fine yellow needles or long, yellow-red prisms, m. p. 188° (decomp. ; corr.).

Reduction of 2-p-*Bromobenzeneazo*-4(5)-*methylglyoxaline*.—A. *With zinc dust and acetic acid.* Zinc dust (9 g.) was added gradually to a solution of the azo-compound (5·3 g.) in a boiling mixture of glacial acetic acid (20 c.c.) with water (40 c.c.). Zinc was removed by hydrogen sulphide, and the solution was mixed with hydrochloric acid and evaporated to dryness. After basifying with aqueous sodium carbonate, *p*-bromoaniline (2·3 g.) was collected by means of ether, and the aqueous solution was acidified with hydrochloric acid, evaporated to dryness, and extracted with alcohol, which left sodium chloride and some ammonium chloride undissolved. The alcoholic extract was mixed with alcoholic picric acid and gave 1·8 g. (yield 26%) of pure alacreatinine picrate, m. p. 212° (decomp. ; corr. : after sintering earlier) (Found : C, 35·3 ; H, 3·2. Calc. : C, 35·1 ; H, 2·9%). This identification was confirmed by the preparation of the hydrochloride, which had m. p. 202° (corr.) (compare Fargher and Pyman, *loc. cit.*).

B. *With hot stannous chloride.* Stannous chloride (33·6 g., hydrated) in concentrated hydrochloric acid (66 c.c.) was added to a hot solution of the azo-compound (15·9 g.) in hydrochloric acid (12 c.c.) and water (300 c.c.). Decoloration took place at once, and, proceeding as in A, *p*-bromoaniline (6·5 g.), and a mixture of picrates (from water instead of alcohol), amounting to 10·7 g., m. p. 155—180°, were collected. After a tedious process of crystallisation from water and alcohol, the latter gave a sparingly soluble picrate (0·4 g., m. p. >300° ; probably guanidine picrate), alacreatinine picrate (2·3 g. ; m. p. 210—211° ; yield 11%), and 2-*amino*-4(5)-*methylglyoxaline picrate* (XIV) (2·05 g., yield 10%). This salt crystallised from alcohol in brownish-yellow nodules, m. p. 186—187° (corr.) (Found : C, 37·2 ; H, 3·6. $C_4H_7N_3,C_6H_3O_7N_3$ requires C, 36·8 ; H, 3·1%). The hydrochloride, prepared from the picrate in the usual way, was not obtained crystalline, but its aqueous solution resembled that of 2-aminoglyoxaline hydrochloride in its behaviour towards nitrous acid in acid and alkaline solution.

C. *With cold stannous chloride.* Stannous chloride (12·0 g., hydrated) in concentrated hydrochloric acid (30 c.c.) was added to a solution of the azo-compound (6·6 g.) in 3% hydrochloric acid

(66 c.c.) at 0°. After keeping over-night at the laboratory temperature, the solution had become clear and colourless, and was worked up as before, when *p*-bromoaniline (3·5 g.) was obtained together with a mixture of picrates from which 3·2 g. (yield 38%) of pure alacreatinine picrate were isolated.



One of us (R. B.) is indebted to the Department of Scientific and Industrial Research for a grant which he desires gratefully to acknowledge.

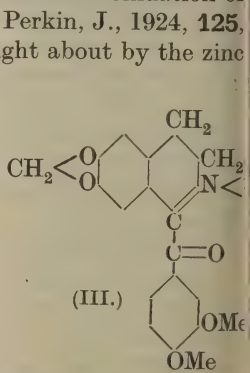
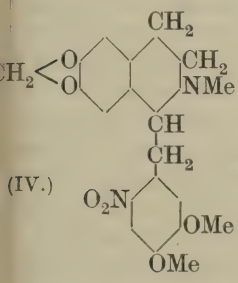
CCLXXIII.—*A Synthesis of* dl-*Dicentrine.*

By ROBERT DOWNS HAWORTH, WILLIAM HENRY PERKIN, jun., and JOHN RANKIN.

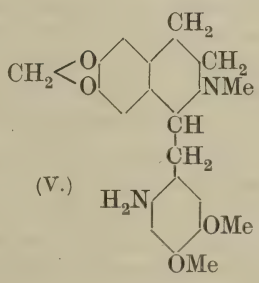


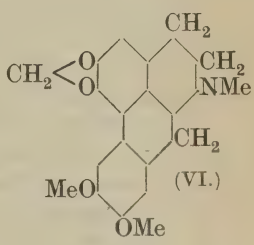
THE observation that 1-veratrylnorhydrohydrastinine is converted into 6′-nitroveratrylnorhydrohydrastinine by the action of nitric acid (Haworth and Perkin, this vol., p. 1450) has led to an examination of the action of nitric acid on 1-*veratrylhydrohydrastinine* (I). This base was obtained by converting homoveratroylhomopiperonylamine into 1-veratryl-6 : 7-methylenedioxydihydro*iso*quinoline (Haworth, Perkin, and Rankin, J., 1924, **125**, 1694), the *methiodide* (II) of which was made into the more soluble methochloride, and reduced to 1-veratrylhydrohydrastinine (I), first by zinc dust and sulphuric acid and then electrolytically. This procedure is advisable when the crude methiodide is employed, because this contains the *methiodide* of 6 : 7-*methylenedioxy*-3′ : 4′-*dimethoxy*-1-*benzoyl*-3 : 4-*dihydro*isoquinoline (III) arising from the spontaneous oxidation of the dihydro*iso*quinoline (Buck, Haworth, and Perkin, J., 1924, **125**, 2180), and complete reduction cannot be brought about by the zinc dust and sulphuric acid reduction alone.

(I.)



(II.)





(III.)

1-Veratrylhydrohydrastinine (I) is a syrup from which a crystalline *hydrochloride, hydriodide* and *picrate* have been obtained. When

the base (I) was nitrated in acetic acid solution, 6′-*nitroveratrylhydrohydrastinine* (IV) was obtained as a buff-coloured, crystalline mass, from which a crystalline *hydriodide* and *picrate* have been prepared. The nitro-base (IV) was readily reduced to 6′-*aminoveratrylhydrohydrastinine* (V) by stannous chloride and hydrochloric acid, and although this substance has not been obtained in the crystalline state, a well-defined *dihydrochloride* has been prepared. The solution of the dihydrochloride yields an intense blue coloration on the addition of ferric chloride, indicating that the positions occupied by the nitro- and amino-groups are those represented in (IV) and (V) respectively.

(IV.)

(V.)

(VI.)

6′-Aminoveratrylhydrohydrastinine (V) was diazotised and treated with copper powder under conditions similar to those which Gadamer employed for the conversion of aminolaudanosine into *dl*-glaucine (*Arch. Pharm.*, 1911, **249**, 680), and a crystalline base, $C_{20}H_{21}O_4N$, m. p. 178—179°, was isolated in a yield of about 15%. The method of synthesis outlined above seems to us to leave no doubt that the synthetical alkaloid is dl-*dicentrine*, and on resolution this should yield an optically active base, identical with naturally occurring dicentrine. We are now engaged in an attempt to prepare considerable quantities of the *dl*-base for the purposes of this resolution and to improve the yields in the various stages of the synthesis; a more complete description of the preparation and properties of these substances is reserved for a future communication. The *dl*-base (VI) yields crystalline salts, the *methiodide* being particularly characteristic, whilst the *hydrochloride* and *picrate* also have been obtained. It should be mentioned that the synthetic base exhibits all those colour reactions with concentrated sulphuric acid, Erdmann's, Fröhde's and Mandelin's reagents which are characteristic of naturally occurring dicentrine (Asahina, *Arch. Pharm.*, 1909, **247**, 202).

Experimental.

1-*Veratryl*-6 : 7-*methylenedioxydihydroisoquinoline Methiodide* (II).—Homoveratroylhomopiperonylamine (20 g.) was converted into 1-veratryl-6 : 7-methylenedioxydihydro*iso*quinoline as described by Haworth, Perkin, and Rankin (*loc. cit.*), the total basic material extracted with benzene, dried over potassium carbonate, concentrated, and boiled with methyl iodide (12 c.c.), when a reddish-brown oil separated which gradually hardened; after 4 hours, the mass of yellow crystals (25 g.) was collected. This crude material, m. p. 228°, was usually employed for reduction purposes.

The *methiodide* is sparingly soluble in water and alcohol, and crystallises from boiling alcohol in beautiful, lustrous, straw-yellow plates, m. p. 239—240° (Found : C, 51·6; H, 4·9. $C_{20}H_{22}O_4NI$ requires C, 51·4; H, 4·7%).

6 : 7-*Methylenedioxy*-3′ : 4′-*dimethoxy*-1-*benzoyl*-3 : 4-*dihydro*iso*quinoline Methiodide* (III).—As this substance probably occurs in the crude methiodide described above, a small quantity was prepared for comparison with the above methiodide by boiling a benzene solution of 6 : 7-methylenedioxy-3 : 4-dimethoxy-1-benzoyl-3 : 4-dihydro*iso*quinoline (Buck, Haworth, and Perkin, *loc. cit.*) with excess of methyl iodide for several hours, when crystals separated which recrystallised from alcohol in amber-coloured rhombs, m. p. 232—233° (decomp.), sparingly soluble in water and alcohol (Found : C, 50·0; H, 4·2. $C_{26}H_{20}O_5NI$ requires C, 49·9; H, 4·2%).

1-*Veratrylhydrohydrastinine* (I).—The crude methiodide (25 g.) obtained as described above was suspended in water (500 c.c.) and digested with freshly-precipitated silver chloride for 4 hours, filtered off, and reduced with excess of zinc dust and dilute sulphuric acid for ½ hour. After filtration, the pale yellow solution was concentrated to 200 c.c., acidified with dilute sulphuric acid (50 c.c.), and reduced in an electrolytic cell with 5 amperes for 12 hours, when the solution became colourless and a mass of crystals separated. These were dissolved by warming, filtered, the base liberated by the addition of ammonia, extracted with chloroform, dried with potassium carbonate and evaporated, when an oil (12 g.) remained which could not be induced to crystallise. The *hydrochloride* was prepared by dissolving the base in dilute hydrochloric acid, and concentrating, when the salt separated in colourless, rhombic plates, m. p. 215—216°, which are readily soluble in alcohol and water (Found : C, 63·5; H, 6·4. $C_{20}H_{24}O_4NCl$ requires C, 63·6; H, 6·4%). The *hydriodide* was precipitated, by addition of potassium iodide to a hot solution of the hydrochloride, as an oil, which slowly hardened; it crystallised from water containing a little methyl alcohol in colour-

less, elongated prisms, m. p. 180—182° (Found : C, 51·2; H, 5·2. $C_{20}H_{24}O_4NI$ requires C, 51·2; H, 5·1%). It is soluble in methyl or ethyl alcohol, but sparingly so in water. The *picrate* was prepared in alcoholic solution, in which it was sparingly soluble, and crystallised from alcohol–glacial acetic acid in orange-yellow prisms, m. p. 188—189° (decomp.).

6′-*Nitroveratrylhydrohydrastinine* (IV).—Veratrylhydrohydrastinine (5 g.) dissolved in glacial acetic acid (25 c.c.) was treated at 5—10° with concentrated nitric acid (10 c.c.) which had been previously warmed with carbamide. After ¼ hour the dark brown nitration mixture was poured into water, when a brown slime separated. The mixture was digested for ½ hour with excess of ammonia, the liquid decanted from the semi-solid mass, and the latter boiled with dilute hydrochloric acid and animal charcoal, filtered, made alkaline with ammonia, and the crude buff-coloured nitro-base (4 g.) collected. This material is sufficiently pure for reduction purposes, but in order to obtain a pure specimen of the nitro-base, the crude product was dissolved in methyl alcohol, mixed with ether, washed several times with water, the clear ethereal solution dried, concentrated, and diluted with petroleum (b. p. 40—60°) until a turbidity was produced. After some time the nitro-base separated in nodular masses of buff-coloured needles, m. p. 118° (Found : C, 61·8; H, 5·8. $C_{20}H_{22}O_6N_2$ requires C, 62·2; H, 5·7%). It is very soluble in the usual organic solvents with the exception of petroleum, and dissolves in dilute mineral acids to a pale yellow solution. When an acid solution of the base is reduced with zinc dust, the filtered solution gives an intense blue coloration with ferric chloride. The *hydriodide* is precipitated by the addition of potassium iodide to a solution of the base in dilute hydrochloric acid, and crystallises from much alcohol in pale yellow, elongated prisms, m. p. 213°. The *picrate* separates as an oil, which rapidly hardens, when an alcoholic solution of the base is treated with picric acid. It crystallises from glacial acetic acid in lemon-yellow needles, m. p. 192°.

6′-*Aminoveratrylhydrohydrastinine* (V).—6′-Nitroveratrylhydrohydrastinine (10 g.) was dissolved in glacial acetic acid (40 c.c.) and allowed to remain at 15° with hydrated stannous chloride (20 g.) and concentrated hydrochloric acid (40 c.c.) for 12 hours, when a crystalline tin double salt separated. The mixture was poured into water (500 c.c.), filtered, made strongly alkaline with potassium hydroxide, and extracted several times with chloroform; the extracts were dried over potassium carbonate and concentrated. The residual oil was very soluble in organic solvents with the exception of petroleum, and all attempts to induce crystallisation

have failed. The *dihydrochloride* was obtained by dissolving the base in ethyl alcohol and saturating with dry hydrogen chloride, when a mass of small, colourless prisms separated. These are sparingly soluble in methyl or ethyl alcohol, but readily soluble in water, the latter solution giving an intense blue coloration with ferric chloride. It recrystallises from aqueous alcohol in colourless prisms, m. p. 250° (decomp.) (Found : C, 56·1 ; H, 6·2. $C_{20}H_{26}O_4N_2Cl_2$ requires C, 55·9 ; H, 6·1%). The *base* was liberated from the hydrochloride by sodium hydroxide as a colourless, viscid oil.

dl-*Dicentrine* (VI).—The above dihydrochloride (2·5 g.) was dissolved in a little water, made alkaline with sodium hydroxide, and the base extracted with ether, dried, the solvent removed, and the residual oil dissolved in 10% sulphuric acid (10 c.c.). The solution was cooled by the addition of ice (20—30 g.) and 2*N*-sodium nitrite solution (3 c.c.) slowly added. The solution became emerald green and after ½ hour copper powder (1 g.) was added, when nitrogen was rapidly evolved and the solution developed a red coloration. After 3 hours the copper was removed by filtration, the filtrate reduced with zinc dust (1 g.) and concentrated hydrochloric acid (3 c.c.) and again filtered.

A second experiment was carried out on the same scale, and the slightly warm combined filtrates were extracted twice with chloroform. On cooling, *dl*-dicentrine hydrochloride (0·4 g.) separated from the chloroform whilst some non-basic resin remained dissolved. The acid liquors were made alkaline with ammonia and extracted six times with ether, the extracts dried with sodium sulphate, concentrated, and the residual oil was dissolved in boiling 15% hydrochloric acid (10 c.c.), filtered, and cooled, when a further crop of *dl*-dicentrine hydrochloride (0·5 g.) was obtained, the total yield being about 15% of that theoretically possible.

The other products of the reaction have not been closely investigated, but it might be mentioned that some phenolic base and probably also veratrylhydrohydrastinine are present in the dark-coloured hydrochloric acid liquors. Further a dark brown, amorphous substance is precipitated when the acid solution is rendered alkaline with ammonia, which is almost insoluble in ether and has not been further investigated.

dl-*Dicentrine* was obtained by dissolving the hydrochloride in boiling water, neutralising with sodium hydroxide, collecting the cream-coloured base, washing with water, and crystallising from methyl alcohol, when colourless prisms, m. p. 178—179°, were obtained (Found : C, 70·5 ; H, 6·2. $C_{20}H_{21}O_4N$ requires C, 70·8 ; H, 6·2%). It is readily soluble in chloroform, ethyl acetate, acetone, benzene, and hot alcohol, moderately soluble in ether and

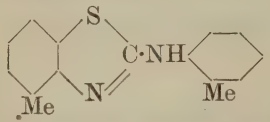
cold alcohol, and sparingly soluble in petroleum. It dissolves in concentrated sulphuric acid to a colourless solution which rapidly becomes reddish-violet. A colourless solution is obtained with Erdmann's reagent which rapidly becomes greenish-blue, whilst deep blue colorations are developed immediately with Fröhde's and Mandelin's reagents. The *hydrochloride*, obtained by dissolving the base in hot dilute hydrochloric acid, is very sparingly soluble in alcohol and cold water, but crystallises from boiling water in a gelatinous mass or very small, colourless needles which darken at 250° and melt with some decomp. at 263—265° (Found: C, 63·3; H, 5·8. $C_{20}H_{22}O_4NCl$ requires C, 63·6; H, 5·8%). The *methiodide* was obtained by heating the base with a large excess of methyl iodide in a sealed tube at 100° for 1 hour. The methyl iodide was removed by distillation, and the residue extracted with boiling alcohol, from which the methiodide separated on cooling in well-defined, colourless, four-sided plates, m. p. 228—229° (Found: C, 52·7; H, 5·1. $C_{21}H_{24}O_4NI$ requires C, 52·4; H, 5·0%). The *picrate* was prepared in alcoholic solution and crystallised from much alcohol in orange prisms, m. p. 188—189°.

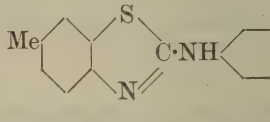
One of us (R. D. H.) is indebted to the Commissioners of the 1851 Exhibition for a studentship which has enabled him to take part in this research, and to the Research Fund Committee of the Chemical Society for a grant which has defrayed some of the expenses of the investigation.

THE DYSON PERRINS LABORATORY,
OXFORD. [*Received, July 7th*, 1925.]

CCLXXIV.—*Aminobenzthiazoles. Part I.* 1-*Anilinobenzthiazole and its Tolyl Homologues.*

By ROBERT FERGUS HUNTER.





THE objects of this series of investigations are: to synthesise benzthiazoles and allied heterocyclic ring systems from arylthiocarbamides, to study the chemistry of the bromo-addition compounds of the aminobenzthiazoles, and to examine the mobility of the triad system N:C·N[H] $\rightleftharpoons$ N[H]·C:N in amino- and substituted aminothiazoles. The synthesis of 1-anilinobenzthiazole (I) from *s*-diphenylthiocarbamide by way of the tetrabromide of the former (Hugershoff, *Ber.*, 1903, **36**, 3121) probably takes place by way of a labile dibromo-addition compound of the thiocarbamide (*loc. cit.*). The thiazole must always be isolated as the tetrabromide and in a sense the ten-

dency to close the thiazole ring is dependent on the tendency to form the bromo-addition compound.

(I.) $C_6H_4<^{S}_{N}>C\cdot NHPh$ $C_6H_4<^{SBr_2}_{NBr_2}>C\cdot NHPh$ (II.)

The physical and chemical properties of 1-anilinobenzthiazole tetrabromide leave little doubt that the compound has a perbromide structure, probably (II) : it is reduced by sulphurous acid in the usual way (this vol., p. 1318) ; on treatment with alkalis, hydroxylic solvents, etc., it passes into dibromoanilinobenzthiazole ; and on exposure to air it gradually loses part of its bromine, yielding a stable tribromide.

Hugershoff (*loc. cit.*) observed that di-*o*- and -*p*-tolylthiocarbamides on bromination formed red bromides, which on reduction yielded " tolylaminotoluthiazoles " : these must be 1-*o*-toluidino-3-methylbenzthiazole (III) and 1-*p*-toluidino-5-methylbenzthiazole (IV), respectively.

(III.)   (IV.)

He did not, however, investigate the bromides beyond noting that they lost bromine on exposure to air, yielding yellow, crystalline substances.

The first product of bromination of di-*o*-tolylthiocarbamide in chloroform is the red unstable hexabromide (V), whilst di-*p*-tolylthiocarbamide yields a tetrabromide (VI). These lose bromine on exposure to air, yielding stable tribromides ; on reduction they are converted into the thiazoles (III and IV, respectively), and on treatment with hydroxylic solvents and alkalis pass into dibromo-1-toluidinomethylbenzthiazoles, $C_6H_2MeBr<^{S}_{N}>C\cdot NH\cdot C_7H_6Br$.

$C_6H_3Me<^{SBr_4}_{NBr_2}>C\cdot NH\cdot C_7H_7$ (V.) $C_6H_3Me<^{SBr_2}_{NBr_2}>C\cdot NH\cdot C_7H_7$ (VI.)

The tribromides resemble the higher bromides in regard to their ease of reduction by sulphurous acid and their conversion into dibromo-substitution products by alkalis, but differ markedly from them in stability. They all crystallise from inert solvents in well-defined crystals of definite melting point and are relatively stable to air. They are, further, incapable of conversion into the higher bromides by bromination.

The conversion of the higher bromides into the tribromides is a mild oxidative change involving the direct elimination of bromine.

In view of the stability of the products it appears reasonable to suggest that they are the hexabromides of condensation products, 1-anilinobenzthiazole tribromide, for example, being

(VII.) $Br_2N\ll\overset{C(NHPh)}{\underset{C_6H_4}{—}}\gg SBr\cdot SBr\ll\overset{C(NHPh)}{\underset{C_6H_4}{—}}\gg NBr_2$;

unfortunately, concordant values for the molecular weights have not yet been obtained.

To complete the present study, the bromination of di-*m*-tolylthiocarbamide has been investigated. A red, crystalline hydrobromide was isolated containing seven bromine atoms,

(VIII.) $C_6H_3Me\ll\overset{SBr_4}{NBr_2}\gg C\cdot NH\cdot C_7H_7,HBr$.

The compound yielded a yellow bromide on exposure to air, and on reduction passed into the free base, which may be either 1-*m*-toluidino-4- or -6-methylbenzthiazole. In the absence of definite proof of its structure, it is proposed to term it 1-m-*toluidino*-m-*toluthiazole*.

Experimental.

s-Di-*o*-, -*m*-, and -*p*-tolylthiocarbamides were prepared as described in the literature and melted at 161°, 112°, and 176°, respectively.

1-*Anilinobenzthiazole* (I).—*s*-Diphenylthiocarbamide (50 g.) suspended in 260 c.c. of chloroform was brominated according to Hugershoff's directions (*loc. cit.*). The red needles of the tetrabromide were dried in a vacuum [m. p. 112° (decomp.). Found : Br, 56·8. Calc., Br, 58·6%], suspended in sulphurous acid, and reduced with sulphur dioxide until all solid matter was colourless on crushing. The product was digested with warm 2*N*-sodium hydroxide, the free base washed, dried at 110° (yield quantitative), and crystallised first from ethyl acetate, which is a much better solvent than the alcohol recommended by Hugershoff, and then twice from absolute alcohol; it was thus obtained in small crystals, m. p. 159°. The *acetyl* derivative had m. p. 158° after recrystallisation from ethyl acetate.

The tetrabromide (II) was prepared by heating 1 g. of thiocarbanilide and 1 c.c. of bromine in chloroform under reflux for 2 minutes; on cooling and scratching, fine, red needles separated, which were dried in a vacuum over potassium hydroxide (Found : Br, 58·8%). The substance commences to decompose at about 110°, and melts at 117°. Hugershoff's m. p. of 136° is possibly given erroneously, since even the tribromide melts more than 10° below this temperature.

1-*Anilinobenzthiazole Tribromide* (VII ?).—Bromine was gradually

evolved when 5 g. of the tetrabromide were exposed to the atmosphere for 2 or 3 days. The yellow, crystalline product, m. p. usually about 115°, was recrystallised from chloroform, the *tribromide* being obtained in small, yellow prisms which sintered at about 120° and melted to a clear red liquid at 125° (Found : Br, 51·5. $C_{13}H_{10}N_2Br_3S$ requires Br, 51·7%).

1-o-*Toluidino*-3-*methylbenzthiazole* (III).—Di-*o*-tolylthiocarbamide (10 g.) dissolved in 50 c.c. of chloroform was brominated with 8·5 c.c. of bromine, diluted with an equal volume of chloroform, as in the previous case. The solution, after being heated under reflux for 10 minutes, was either agitated with " dry " ether, when the tribromide of the thiazole separated, or evaporated in a vacuum at room temperature, when a red crystalline crust of a mixture of bromides was obtained; this became yellow at 187°, brown at 205°, red at 230°, viscous and dark at 260°, and melted with charring at 265°. The crude bromide obtained by either method was reduced as in the previous case, and the product was boiled with 2*N*-alkali for a short time. The free base melted below the liquid and hardened on cooling; after being washed and dried, it was crystallised from ethyl acetate, and then from alcohol, being thus obtained in short prisms, m. p. 135° (sintering).

The *acetyl* derivative was obtained in minute crystals sintering at 77°.

1-o-*Toluidino*-3-*methylbenzthiazole Hexabromide* (V).—Di-*o*-tolylthiocarbamide (1 g.) was brominated as in the previous case, and the solution, after being heated under reflux for 3 minutes, was cooled; the fine, red needles of the hexabromide which separated on scratching were dried in a vacuum over potassium hydroxide. They lost bromine at 60° and melted to a clear red liquid at 76—78° (Found : Br, 66·4. $C_{15}H_{14}N_2Br_6S$ requires Br, 65·5%).

The *tribromide* was obtained by exposing 5 g. of the red bromide to the air as in the previous case. After recrystallisation from chloroform it was obtained in small, yellow, glistening prisms, m. p. 250° (decomp.), becoming orange at 205° and red-brown at 240° [Found : Br, 48·7. $(C_{15}H_{14}N_2Br_3S)_2$ requires Br, 48·6%].

Dibromo-1-o-*toluidino*-3-*methylbenzthiazole*.—When boiled with alcohol, either bromide dissolved; thereafter colourless crystals of the *hydrobromide* of the dibromo-substitution product suddenly separated. These, recrystallised from glacial acetic acid and washed with ether, were obtained in lustrous prisms, m. p. 280° (decomp.) (Found : Br, 48·0. $C_{15}H_{12}N_2Br_2S,HBr$ requires Br, 48·7%). The hydrobromide was digested with warm 2*N*-sodium hydroxide, and the free base was recrystallised from glacial acetic acid and washed with ether; tufts of shining needles, m. p. 205°, were obtained, which

however, retained an appreciable quantity of acetic acid (Found : Br, 32·9%). They were digested with warm alcohol; the base was then obtained in small prisms having the same m. p. as before (Found : Br, 39·3. $C_{15}H_{12}N_2Br_2S$ requires Br, 38·9%).

1-p-*Toluidino*-5-*methylbenzthiazole* (IV).—Di-*p*-tolylthiocarbamide (10 g.) was brominated as in the previous case. The red needles of the tetrabromide were dried in a vacuum and reduced. The free base crystallised from ethyl acetate in hair-like crystals, m. p. 162°.

The *acetyl* derivative was obtained in spherical aggregates of needles, m. p. 158°. The *tetrabromide*, prepared as in the previous case, sintered at 130°, softened at 140°, and melted to a clear red liquid at 145° (Found : Br, 54·9. $C_{15}H_{14}N_2Br_4S$ requires Br, 55·6%). The *tribromide*, obtained by exposing the tetrabromide to the air for some days, crystallised from chloroform in slender, orange needles softening at 145°; m. p. 148° (decomp.) [Found : Br, 49·2. $(C_{15}H_{14}N_2Br_3S)_2$ requires Br, 48·6%].

Dibromo-1-p-*toluidino*-5-*methylbenzthiazole*.—The tribromide was dissolved in boiling alcohol, and the solution concentrated; on scratching and cooling, the *hydrobromide* separated. After recrystallisation from glacial acetic acid it was obtained in small crystals turning yellow at 220°, pale brown at 240°, and melting at 256—258° (Found : Br, 47·8. $C_{15}H_{13}N_2Br_3S$ requires Br, 48·7%). It was treated with warm dilute alkali, and the free base recrystallised from glacial acetic acid and washed with ether, when pale cream crystals were obtained, m. p. 159—160°. They retained an appreciable quantity of solvent as in the case of the *o*-compound (Found : Br, 36·6. $C_{15}H_{12}N_2Br_2S$ requires Br, 38·9%).

1-m-*Toluidino*-m-*toluthiazole*.—Di-*m*-tolylthiocarbamide (4 g.) was dissolved in 40 c.c. of chloroform and brominated with 6 c.c. of bromine diluted with an equal volume of chloroform; heat and hydrogen bromide were evolved and the red bromide was crystalline. The product was dried in a vacuum and reduced by sulphurous acid and sulphur dioxide in the usual way. The base crystallised from ethyl acetate in small, stout, colourless crystals, m. p. 184—186° (Found : S, 11·7. $C_{15}H_{14}N_2S$ requires S, 12·6%).

1-m-*Toluidino*-m-*toluthiazole Hexabromide Hydrobromide*.—Di-*m*-tolylthiocarbamide (1 g.) was dissolved in chloroform and brominated with 1 c.c. of bromine, the solution was refluxed for 3 minutes and allowed to cool slowly in a hot water-bath; the small, four-sided, red tablets which separated were dried in a vacuum over potassium hydroxide. They crumbled to a semi-crystalline, dark mass at 110°, became orange and crystalline at 187°, pale yellow at 197°, and were unmelted above 200° (Found : Br, 69·1. $C_{15}H_{15}N_2Br_7S$ requires Br, 68·9%).

1-m-*Toluidino*-m-*toluthiazole Tribromide Hydrobromide*.—The red bromide was exposed to the atmosphere for some days, and the orange-yellow crystalline residue refluxed with chloroform, in which it was very sparingly soluble. The product consisted of small, yellow crystals of the usual type which softened at 136° and sintered at 190° [Found: Br, 56·3. $(C_{15}H_{15}N_2Br_4S)_2$ requires Br, 55·6%].

The bromide was reduced in the usual way by sulphurous acid and showed the usual stability to air, etc.

In conclusion, the author desires to express his gratitude to Prof. J. F. Thorpe, F.R.S., for the kind interest he has taken in the progress of these experiments.

CCLXXV.—*The Amino-4-Pyridones.*

By WILLIAM HAUGHTON CROWE.

A COMPARISON of the reactions of the pyridones with those of the aromatic phenols is of considerable interest, and in connexion with the formation of nitro-derivatives and their subsequent reduction it has already been shown that 4 : 6-dimethyl-2-pyridone (Collie and Tickle, J., 1898, **73**, 229) and lutidone (Collie and Hall, J., 1898, **73**, 237) exhibit a formal resemblance to the corresponding xylenols. The simplest pyridones are not very readily accessible and this circumstance no doubt accounts for the fact that their substitution products have not been closely studied. A mononitro-4-pyridone, m. p. 279°, and a dinitro-4-pyridone have now been obtained and reduced; the former by tin and hydrochloric acid to an amino-4-pyridone, and the latter by ammonium sulphide to an aminonitro-4-pyridone. Whilst the work was in progress Koenigs and Freter (*Ber.*, 1924, **57**, 1187) published an account of the nitration of 4-pyridone, but it appears that they did not isolate the nitro-derivatives in a pure condition. Thus they state that the mononitro-derivative has m. p. 269—270° and that the yellow dinitro-compound crystallises with $1H_2O$.

EXPERIMENTAL.

3-*Nitro*-4-*pyridone*.—A mixture of 4-pyridone, fuming nitric acid, and concentrated sulphuric acid was heated on the water-bath for 2 days, poured into water, the acid nearly neutralised with solid sodium carbonate, the solution evaporated to dryness, and the residue extracted with alcohol. The product crystallised from hot

water in yellow needles, m. p. 279° (Found : C, 43·0; H, 3·9; N, 20·2. $C_5H_4O_3N_2$ requires C, 42·9; H, 2·9; N, 20·0%). A concentrated solution gave a lemon-yellow precipitate of the sodium salt on treatment with sodium hydroxide.

3-*Amino*-4-*pyridone*.—Reduction of the nitro-compound with tin and hydrochloric acid proceeded very violently. The solution was diluted with water, the tin removed as sulphide, and the filtrate evaporated on the water-bath; the crystals of the *hydrochloride* thus obtained were dried in a vacuum over sulphuric acid (Found : Cl, 22·0. $C_5H_6ON_2,HCl,H_2O$ requires Cl, 21·6%). The *chloroplatinate* was obtained by treating a concentrated solution of the hydrochloride with platinic chloride and crystallised from hot concentrated hydrochloric acid [Found : C, 18·3; H, 2·5; Pt, 30·1. $(C_5H_6ON_2)_2,H_2PtCl_6,H_2O$ requires C, 18·5; H, 2·5; Pt, 30·1%].

3 : 5-*Dinitro*-4-*pyridone*.—A mixture of 4-pyridone (2 g.), fuming nitric acid (7 c.c.), and concentrated sulphuric acid (13 c.c.) was heated at 140° for about 8 hours and poured into cold water, when 3 : 5-*dinitro*-4-*pyridone* was obtained as a faintly yellow, crystalline precipitate. It crystallised from 50% acetic acid in long, colourless needles (Found : N, 22·9. $C_5H_3O_5N_3$ requires N, 22·7%). A solution in alcohol and acetone gave with sodium ethoxide a brilliant yellow precipitate of the sodium salt.

3-*Nitro*-5-*amino*-4-*pyridone*.—The dinitropyridone was boiled under reflux with the calculated quantity of ammonium sulphide in alcohol, the solid filtered off, and extracted with hot strong hydrochloric acid. On cooling, the *hydrochloride* crystallised in needles, which were recrystallised from concentrated hydrochloric acid with the addition of animal charcoal (Found : C, 31·7; H, 3·5; N, 22·1; Cl, 18·3. $C_5H_5O_3N_3,HCl$ requires C, 31·4; H, 3·7; N, 21·9; Cl, 18·5%). The substance gave yellow solutions, and turned orange in the air, due to loss of hydrogen chloride and formation of the free base.

The author wishes to express his indebtedness to Professor J. N. Collie, F.R.S., for his valuable help and advice during the research, and also to the Department of Scientific and Industrial Research for a grant which made the work possible.

CCLXXVI.—*Researches on Residual Affinity and Co-ordination. Part XXV. A Quadridentate Group Contributing Four Associating Units to Metallic Complexes.*

By Gilbert T. Morgan and J. D. Main Smith.

Fundamental advances were made in the experimental verification of the co-ordination theory when Werner showed that certain compounds and compound radicals were capable of furnishing two associating units to the co-ordination complex surrounding a metallic atom, for by means of such complexes he was able to identify the three-dimensional structure of many co-ordination compounds. Of chemical substances contributing two associating units the following may be cited: ethylenediamine, αα-dipyridyl, dimethyldithiolethylene, and tetramminodihydroxycobaltic bromide, $(NH_3)_4Co(OH)_2Br$, the last of these being noteworthy owing to its completely inorganic character. There are also numerous complex radicals which function as two associating units: the carbonato-, malonato-, and oxalato-groups and the monoenolic radicals of acetylacetone and its homologues, R·CO·CH:C(OH)R′, R and R′ being alkyl or aryl groups. To these compounds and compound radicals capable of occupying two positions in the co-ordination complex the generic name of chelate groups has been given (J., 1920, **117**, 1457) because their tenacious grip of the implicated metallic atom leads to the formation of remarkably stable co-ordination complexes.

Werner also identified groups capable of treble attachment to metallic atoms, such tridentate residues containing three fused chelate groups. The tridentate groups recognised by Werner already contained, however, one metallic atom, so that on association of these tridentate groups with the co-ordinating nuclear atoms the complexes became binuclear, as, for instance, in the case of triamminocobaltic hydroxide, $(NH_3)_3Co(OH)_3$, identified in the complex cation of the salt in which the three hydroxyl groups

$$\left[\begin{matrix} & OH & \\ (NH_3)_3Co & OH & Co(NH_3)_3 \\ & OH & \end{matrix}\right] Br_3$$

contribute simultaneously three units to the co-ordination numbers of each of two cobalt atoms.

Recently Pope and Mann have proved that αβγ-triaminopropane, $NH_2·CH_2·CH(NH_2)·CH_2·NH_2$, is capable of treble attachment to metallic atoms. Two molecular proportions of this triacidic base

(*tp*) occupy six co-ordination positions round cobalt and rhodium atoms, forming the complex cations $[Co\ tp_2]'''$ and $[Rh\ tp_2]'''$. This demonstration constitutes the first example of a tridentate non-metallic group in complexes containing a single nuclear atom (*Compt. rend.*, 1924, **178**, 2085; *Proc. Roy. Soc.*, 1925, **107**, 80).

We have now succeeded in identifying a group capable of quadruple attachment to metallic atoms, this being the first known case of a quadridentate group in co-ordination complexes. This quadridentate group is furnished by the bivalent radical of *ethylenediaminobisacetylacetone*, $C_{12}H_{20}O_2N_2$, a compound first prepared by Combes (*Compt. rend.*, 1889, **108**, 1252) on condensing two molecules of acetylacetone with one molecule of ethylenediamine with elimination of two mols. of water. Combes showed that this product is a dienolic diketone,

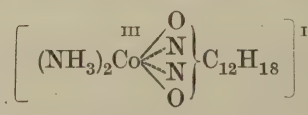
$CH_3{\cdot}C(OH){:}CH{\cdot}C(CH_3){:}N{\cdot}CH_2{\cdot}CH_2{\cdot}N{:}C(CH_3){\cdot}CH{:}C(OH){\cdot}CH_3$,

yielding a violet cupric salt containing one atomic proportion of copper to one molecular proportion of the dienolic radical.

In attempting to prepare an additive co-ordination compound of cupric acetylacetone and ethylenediamine we obtained accidentally the green monohydrate of Combes's violet salt, copper ethylenediaminobisacetylacetone, which separated from the indigo-blue solution of copper acetylacetone in ethylenediamine hydrate. This observation led to other experiments on Combes's ethylenediaminobisacetylacetone and particularly to the preparation of its *cobaltous* salt,* a non-ionised complex which proved to be dihydrated, and,

$$\left[(H_2O)_2\ Co^{II}\begin{matrix}O\\N\\N\\O\end{matrix}\right\}C_{12}H_{18}\right] \qquad \text{(I.)}$$

as the co-ordination number of bivalent cobalt is usually six, this composition suggested that the organic group might occupy four of the six co-ordination positions. Since, however, the co-ordination number of tervalent cobalt is invariably six, the oxidation of this cobaltous salt in the presence of ammonia should, on the foregoing supposition, lead to a cobaltammine containing two of ammonia and one molecular proportion of the supposed quadridentate group per cobaltic atom with a single univalent acidic ion outside the complex.



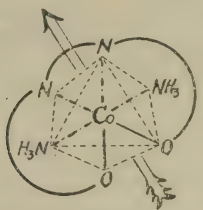
On reaction with ammonium chloride, excess of ammonia, and hydrogen peroxide, this supposition was verified, for the cobaltous salt yielded the anticipated cobaltammine readily and almost

* The co-ordination compounds of ethylenediaminobisacetylacetone with several other bivalent metals have been investigated and will be discussed subsequently.

quantitatively. The chloride radical present was wholly ionised, immediately precipitable with silver nitrate, and yielded the less soluble *bromide*, *iodide*, *chlorate*, *perchlorate*, *nitrite*, *nitrate*, and d-*camphorsulphonate* (Reychler) by double decomposition with the sodium or potassium salts of the corresponding acids.

Excepting the chloride and *d*-camphorsulphonate, all the salts prepared were anhydrous when crystallised from water, thus confirming the view that the cobaltic co-ordination number of six is made up solely of two ammonia molecules and the organic radical. Hence this organic radical, which contributes four to the cobaltic co-ordination number, is actually a quadridentate group.

The univalent complex cobaltammine ion is thus demonstrated to have the following chemical constitution :

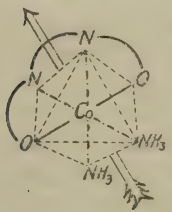


Five stereochemical arrangements of the groups present in this co-ordination complex are, however, possible, depending on the positions taken up on the octahedron by the ammonia molecules and by the bivalent quadridentate group, $C_{12}H_{18}N_2O_2$ or

$$-O\cdot C(CH_3){:}CH\cdot C(CH_3){:}N\cdot CH_2\cdot CH_2\cdot N{:}C(CH_3)\cdot CH{:}C(CH_3)\cdot O-.$$

If the two ammonia molecules are in the antipodal *trans*-positions (Diagram 1) the quadridentate group must be wrapped equatorially round the octahedron. This configuration contains two planes of symmetry and the compound is optically inactive and irresolvable. If the two ammonia molecules are in contiguous *cis*-positions, then three associating units of the quadridentate group must occupy the corners of one triangular face of the octahedron with the fourth associating unit overlapping on to an adjacent face, and this arrangement can be made in four different ways, giving rise to four stereoisomeric modifications. None of these four isomerides possesses a plane, a centre, or an alternating axis of symmetry and hence they are all optically active. Two of them are mirror images of the other two and the four isomerides comprise two enantiomorphous pairs.

Conclusive evidence has now been obtained that the product actually isolated contains two racemoid modifications which have been resolved into optically active forms by *d*-camphorsulphonic (Reychler) acid, and that all these active forms on keeping are spontaneously transformed into the single inactive and irresolvable form. The lack of optical activity in the last indicates that it is the *trans*-form (Diagram 1), in which the pair of ammonia molecules is in the *trans*-octahedral position. The active form with the low optical activity is in all probability the *cis-trans*-form (Diagram 2),

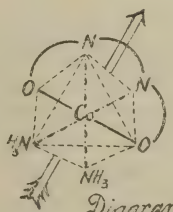


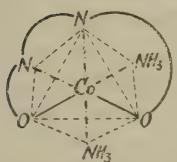
in which only the dyad axis of symmetry of the *trans*-form is retained, the pair of ammonia molecules here being in the *cis*-position while the pair of oxygen atoms is retained in the *trans*-position. The active form with the very high activity may thus be regarded as the *cis*-form (Diagram 3), in which none of the elements of symmetry is retained, the pair of oxygen atoms as well as the pair of ammonia molecules being in *cis*-positions.

Two Planes of Symmetry intersecting in One Dyad Axis of Symmetry.

Diagram 1.

Trans Inactive Isomeride





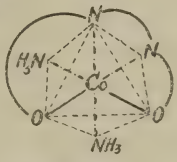


Diagram 2.

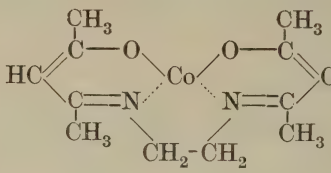
Cis-trans Enantiomorphous Pair each with One Dyad Axis of Symmetry and small optical activity.



Cis-cis Enantiomorphous Pair without elements of Symmetry and with high optical activity

Diagram 3.

It has not been possible, however, to confirm these structures by chemical means, for the compounds are not decomposed by hot concentrated hydrochloric or hydrobromic acid to yield either the *cis* (violeo)- or *trans* (praseo)-dichlorodiamminoethylenediamminocobaltic halides which could be identified by their respective violet and green colours.

Whatever be the exact chemical structure of the organic group in the complex, the evidence is conclusive that it is a quadridentate

group and moreover that it can be arranged spatially round the co-ordination sphere so as to yield the *cis*- and *trans*-configurations with respect to the ammonia molecules (Diagrams 1, 2 and 3). The tricyclic system of the three chelate components of the quadridentate group associated with the octahedral cobalt atom is shown in plan in Diagram 4; two of the rings are six-membered and one is five-membered.

(*Diagram* 4.)

Experimental.

$C_2H_4(N{:}C{\cdot}CH_3{\cdot}CH{\cdot}CO{\cdot}CH_3)_2$ = ec (ethylenediaminobisacetylacetone).

*Diaquocobaltous Ethylenediamino*bis*acetylacetone*, $[(H_2O)_2\,ec\,Co]$ (Formula I).—Hexa-aquocobaltous chloride (4·8 g. = 1 mol.) was dissolved in hot water (20 c.c.), and ethylenediaminobisacetylacetone (4·5 g. = 1 mol.) and 5*N*-sodium hydroxide (8 c.c. = 2 mols.) added, forming a green paste. On boiling, the mixture turned brownish-yellow and a reddish-orange, crystalline precipitate separated. After washing with water and air-drying, bright orange-red prisms were obtained in yield varying from 85 to 45%, the higher yields being obtained with exclusion of air during the reaction (Found: Co, 18·7. $C_{12}H_{22}O_4N_2Co$ requires Co, 18·6%). The compound was insoluble in water and readily dissolved in most organic solvents to orange solutions which darkened in air owing to oxidation. It readily dissolved in dilute mineral acids with complete decomposition into acetylacetone and cobaltous and ethylenediamine salts.

*Diamminoethylenediamino*bis*acetylacetonocobaltic Chloride Dihydrate*, $[(NH_3)_2Coec]Cl(H_2O)_2$.—This salt was readily obtained in 83% yield on oxidation of the foregoing cobaltous salt by the calculated amount of 6*N*-hydrogen peroxide in the presence of excess of 18*N*-ammonia and ammonium chloride. The salt separated from the cooled mixture in pale fawn needles which were recrystallised from hot water, washed with alcohol, and air dried [Found: Co, 15·2; N (as NH_3), 7·35; H_2O, 8·1. $C_{12}H_{28}O_4N_4ClCo$ requires Co, 15·3; N (as NH_3), 7·25; $2H_2O$, 9·3%).

This feebly coloured cobaltic salt was moderately soluble in water to a brownish-red, neutral solution, from which silver nitrate solution immediately precipitated silver chloride. Concentrated solutions of the appropriate sodium or potassium salts precipitated

the bromide, iodide, nitrite, nitrate, chlorate, perchlorate, and *d*-camphorsulphonate of the complex base from concentrated solutions of the chloride. The chloride dissolved in boiling concentrated hydrochloric or hydrobromic acid solutions, but was not decomposed. It dissolved in boiling caustic soda solution, evolving ammonia and forming a clear reddish-brown solution which appeared to contain the complex diaquo-base. The chloride was quite insoluble in all organic solvents.

The following salts were prepared in quantitative yield by precipitation from concentrated solutions of the chloride by concentrated solutions of the appropriate alkali salt. All except the *d*-camphorsulphonate (Reychler) were very sparingly soluble in water and were precipitated as fine, yellowish-brown needles, which were washed with water and alcohol and air-dried. The camphorsulphonate, which is moderately soluble in water and in moist alcohol, was recrystallised from water and washed with acetone and ether and air-dried.

Bromide, $[(NH_3)_2$ ec Co]Br. Found: Co, 14·7; H_2O at 100°, nil. $C_{12}H_{24}O_2N_4BrCo$ requires Co, 14·9%.

Iodide, $[(NH_3)_2$ ec Co]I. Found: Co, 13·4; N (as NH_3), 6·4; H_2O at 100°, nil. $C_{12}H_{24}O_2N_4ICo$ requires Co, 13·4; N (as NH_3), 6·3%.

Nitrite, $[(NH_3)_2$ ec Co]NO_2. Found: Co, 16·2; N (as NH_3), 7·8; N (as NO_2), 4·0; organic N, 7·6; C, 39·7; H, 6·6; H_2O at 100°, nil. $C_{12}H_{24}O_4N_5Co$ requires Co, 16·3; N (as NH_3), 7·8; N (as NO_2), 3·9; organic N, 7·8; C, 39·9; H, 6·65%.

Nitrate, $[(NH_3)_2$ ec Co]NO_3. Found: Co, 15·7; H_2O at 100°, nil. $C_{12}H_{24}O_5N_5Co$ requires Co, 15·7%).

Chlorate, $[(NH_3)_2$ ec Co]ClO_3. Found: Co, 14·8; H_2O at 100°, nil. $C_{12}H_{24}O_5N_4ClCo$ requires Co, 14·8%.

Perchlorate, $[(NH_3)_2$ ec Co]ClO_4. Found: Co, 14·2; H_2O at 100°, nil. $C_{12}H_{24}O_6N_4ClCo$ requires Co, 14·2%.

d-*Camphorsulphonate*, $[(NH_3)_2$ ec Co]$C_{10}H_{15}O_4S,H_2O$. Found: Co, 10·6; H_2O at 100°, 3·1. $C_{22}H_{41}O_7N_4SCo$ requires Co, 10·6; H_2O, 3·2%.

Resolution of the Racemoid Mixture.—Aqueous solutions of the salts were transparent only in the darker red of the spectrum, and the light of the lithium line 6708 Å. (10^{-8} cm.) was used throughout the polarimetric measurements. Owing to the intensity of colour, solutions stronger than about 1% of the camphorsulphonates and 0·5% of the bromides in 0·5-dcm. tubes could not be used.

cis-dextro-*Bromide*.—On mixing saturated solutions of the complex chloride and the sodium salt of *d*-camphorsulphonic (Reychler) acid, fine, pale fawn needles of the *d*-camphorsulphonate separated,

isolated in six crops, which were washed with acetone and ether and air-dried. The first crop was found to be strongly dextrorotatory. The second crop was redissolved in water and decomposed with a solution of potassium bromide, the complex bromide immediately separating in fine, fawn needles, which were washed with alcohol and ether and air-dried (Found : Co, 14·7%). This bromide was indistinguishable in appearance and general properties from the racemoid bromide, but was strongly dextrorotatory, $[\alpha]_{Li} = +452°$, $[M] = +1784°$. Owing to the evanescent nature of this optical activity it was very fortunate that the specimens were submitted to independent observers.*

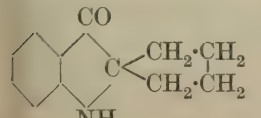
cis-trans-dextro-dextro-*Camphorsulphonate*.—The third crop from the above resolution had $[\alpha]_{Li} = +36°$, $[M] = +202·0°$, and deducting $+51·7°$ for the *d*-camphorsulphonate ion, $[M] = +150·3°$ for the cobaltic ion (Found : Co, 19·6%). Subsequent crops possessed successively diminishing activities. Recrystallisation of the crops failed to raise the activity for the cobaltic ion above $[M] = +150°$, and the most soluble crops invariably had a strong lævorotation. The highest lævorotation ever observed was $[M] = -108°$ for the cobaltic ion.

cis-trans-dextro-*Bromide*.—The corresponding *cis-trans-d-d*-camphorsulphonate was decomposed with potassium bromide solution, and the bromide isolated as in the case of the *cis*-bromide (Found : Co, 14·8%). $[\alpha]_{Li} = +40°$, $[M] = +158°$. This *cis-trans*-bromide alone was invariably obtained after the first preparation, and was indistinguishable, except for optical activity, from the racemoid bromide.

Inactive (*or* trans) *Bromide*.—The foregoing optically active salts, on keeping a few days, were found to be completely inactive, the camphorsulphonates having only the activity due to the camphorsulphonate ion, and being irresolvable. Once these inactive salts had been identified, it was found impossible to prepare active salts again. Numerous preparations were performed at ordinary and low temperatures, in sunlight and in darkness, and even in new apparatus in a different building, but optically active salts were never again obtainable. A specimen of the first preparation, which had originally yielded both the *cis*- and the *cis-trans*-bromides, was found to be quite irresolvable after 10 days. We

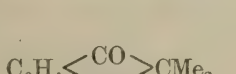
* A specimen of the racemoid bromide (S. 2) and of the *cis*-bromide (S. 1) was submitted to Mr. C. E. Wood for polarimetric examination without informing him which or if either of the specimens was optically active. His report is as follows : *S*. 1.—Weight, 0·0664 g., dissolved in 12·5 c.c. of water and examined in 0·5-dcm. tube with light of lithium line 6708 Å., $[\alpha]_{Li} = +531°$, $[M] = +2097·4°$. *S*. 2.—Weight, 0·0666 g., dissolved in 12·5 c.c. of water and examined in 0·5-dcm. tube—inactive.—C. E. W.

are unable to assign the precise cause of the inability to obtain active salts after the first ten or so preparations, but it is worthy of remark that active salts could not be obtained after the inactive salts had been brought into existence, pointing to the probability that the result is due to infection. This possibility is not wholly ruled out by preparation in new apparatus in a different building, because the inactive salt may have been a partial product only in later preparations and the active salts simultaneously formed thus infected at the moment of coming into existence. Found for the inactive *bromide* : Co, 14·8%. The inactive bromide was indistinguishable in appearance and general properties from the racemoid and active bromides.



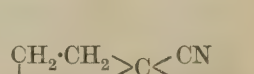
The authors desire to express their thanks to the Advisory Council of the Department of Scientific and Industrial Research for grants which have helped to defray the expense of this investigation.

UNIVERSITY OF BIRMINGHAM,
EDGBASTON. [*Received, July 15th,* 1925.]



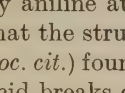
CCLXXVII.—*The Synthesis and Reactions of* 1-*Anilino*-cyclo*pentane*-1-*carboxylic Acid.*

By SYDNEY GLENN PRESTON PLANT and JOHN ERNEST FACER.

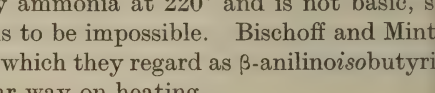


DURING the investigations of the derivatives of tetrahydrocarbazole (Perkin and Plant, J., 1921, **119**, 1825; 1923, **123**, 676) a substance (m. p. 113°) was isolated which appeared to be ψ-indoxyl*spirocyclo*pentane (I). Bucherer and Grolée (*Ber.*, 1906, **39**, 986) have prepared α-anilino*iso*butyric acid (see also Tiemann, *Ber.*, 1882, **15**, 2039; Bischoff and Mintz, *Ber.*, 1892, **25**, 2326) by the hydrolysis of the nitrile obtained from the condensation of aniline with acetone cyanohydrin, and found that it could be made to give very small quantities of 2 : 2-dimethyl-ψ-indoxyl (II) on fusion with a mixture of sodium ethoxide and potassium hydroxide. A similar series of reactions, starting from aniline and *cyclo*pentanone cyanohydrin, ought to yield ψ-indoxyl*spirocyclo*pentane and so establish definitely the constitution of this product, from which several derivatives have been obtained (see also Sidgwick and Plant, this vol., p. 209).

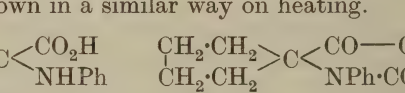
(I.)



(II.)



(III.)



We have now prepared 1-*anilino*-1-*cyano*cyclo*pentane* (III) in this way and converted it into the corresponding *amide*, which can then be hydrolysed to 1-*anilino*cyclo*pentane*-1-*carboxylic acid* (IV). This acid is comparatively unstable and when heated above its melting point loses aniline and water, a substance (m. p. 142°) being formed which appears to be the lactone of 1-1′-*hydroxy*cyclo*pentane*-1′-*carboxylylanilino*cyclo*pentane*-1-*carboxylic acid* (V). This compound is slowly dissolved by a cold solution of sodium hydroxide and is slowly reprecipitated by hydrochloric acid. It is unchanged by aniline at 170° or by dry ammonia at 220° and is not basic, so that the structure (VI) seems to be impossible. Bischoff and Mintz (*loc. cit.*) found that the acid which they regard as β-anilino*iso*butyric acid breaks down in a similar way on heating.

(IV.)

(V.)

(VI.)

Fusion of 1-anilino*cyclo*pentane-1-carboxylic acid with a mixture of sodium ethoxide and potassium hydroxide gave no ψ-indoxyl-*spirocyclo*pentane, but considerable quantities of carbazole were isolated. Many different methods have been investigated for the purpose of eliminating water from the acid at a lower temperature, but without success. The acetyl derivative of 1-anilino*cyclo*pentane-1-carboxylic acid has also been prepared, but this resisted all efforts made to convert it into 6-acetyl-ψ-indoxyl*spirocyclo*pentane.

Experimental.

1-*Anilino*-1-*cyano*cyclo*pentane*.—The bisulphite compound (104 g.) of *cyclo*pentanone was added to water (300 c.c.) and treated with potassium cyanide (38 g.). The *cyclo*pentanone cyanohydrin was extracted with benzene, the solution washed with water and dried over calcium chloride. After the addition of aniline (50 g.), the mixture was boiled for 12 hours and then extracted with half its volume of dilute hydrochloric acid, washed with water, and the solvent removed under diminished pressure. The residue was dissolved in hot petroleum (b. p. 60—80°) and crude 1-*anilino*-1-*cyano*cyclo*pentane* separated, on cooling, as an oil which soon solidified. It was recrystallised from a small quantity of alcohol and obtained in colourless prisms, m. p. 58° (Found: C, 77·5; H, 7·5; N, 15·0. $C_{12}H_{14}N_2$ requires C, 77·5; H, 7·5; N, 15·0%). It decomposes on distillation with the formation of some aniline.

A solution of 1-anilino-1-cyano*cyclo*pentane in cold sulphuric acid

was kept for 2 days and then poured on to ice. On making alkaline with ammonia, the *amide* of 1-*anilino*cyclo*pentane*-1-*carboxylic acid* was precipitated in a pure condition. It separates from alcohol in colourless plates, m. p. 161° (Found : N, 13·5. $C_{12}H_{16}ON_2$ requires N, 13·7%). The *nitrosoamine*, precipitated on addition of sodium nitrite to a solution of the amide in dilute sulphuric acid, separates from alcohol in practically colourless prisms, m. p. 122° (Found : N, 18·0. $C_{12}H_{15}O_2N_3$ requires N, 18·0%).

1-*Anilino*cyclo*pentane*-1-*carboxylic Acid.*—The amide of the acid was dissolved in cold, concentrated hydrochloric acid and almost immediately a precipitate of the hydrochloride separated. The mixture was carefully evaporated to dryness and the residue treated with sodium hydroxide solution till alkaline. After boiling for a short time, the whole was filtered while still hot, and the filtrate acidified with acetic acid, when 1-*anilino*cyclo*pentane*-1-*carboxylic acid* separated as a colourless solid. It crystallised from xylene in colourless prisms, m. p. 162° (Found : N, 6·9. $C_{12}H_{15}O_2N$ requires N, 6·8%).

1-Anilino*cyclo*pentane-1-carboxylic acid is soluble in both acids and alkalis and gives a *nitrosoamine* which can be recrystallised from dilute alcohol and obtained in colourless plates, m. p. 124° (decomp.) (Found : N, 12·2. $C_{12}H_{14}O_3N_2$ requires N, 12·0%).

1-Anilino*cyclo*pentane-1-carboxylic acid, on heating at 230° in a small distillation flask, decomposes and a mixture of aniline and water can be collected. The residue solidifies on cooling, and can be purified by warming first with dilute hydrochloric acid and then with dilute sodium carbonate solution. On recrystallisation from petroleum, the *lactone* of 1-1′-*hydroxy*cyclo*pentane*-1′-*carboxylyl*-*anilino*cyclo*pentane*-1-*carboxylic acid* separates in clusters of colourless prisms, m. p. 142° (Found : C, 72·3; H, 7·3; N, 4·7. $C_{18}H_{21}O_3N$ requires C, 72·2; H, 7·0; N, 4·7%).

An intimate mixture of 1-anilino*cyclo*pentane-1-carboxylic acid (16 g.), sodium ethoxide (48 g.), and potassium hydroxide (40 g.) was gradually heated from 270° to 320° and maintained there for 15 minutes. After cooling, the product was pulverised and added to much water. The undissolved solid was collected, dried, and distilled. The colourless distillate (3 g.), which solidified, crystallised from alcohol in colourless plates, m. p. 238°, of carbazole, identified by analysis (Found : N, 8·5. Calc., N, 8·4%), a mixed melting point determination, and preparation of the picrate, which separated from alcohol in bright red needles, m. p. 184° (compare Schmidt and Schall, *Ber.*, 1907, **40**, 3230).

A solution of 1-anilino*cyclo*pentane-1-carboxylic acid (4 g.) in dry benzene (60 c.c.) was boiled with acetic anhydride (5 c.c.) for

7 hours, the benzene removed under reduced pressure, and the residue treated with acetone–petroleum. 1-*Acetylanilino*cyclopentane-1-*carboxylic acid* crystallises from acetone in colourless prisms, m. p. 195° (Found: N, 5·7. $C_{14}H_{17}O_3N$ requires N, 5·7%).

One of us (S. G. P. P.) wishes gratefully to acknowledge the receipt of a grant from the Chemical Society Research Fund which has defrayed a part of the cost of this investigation.

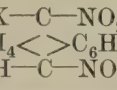
OXFORD. [*Received, June 30th,* 1925.]

CCLXXVIII.—*The Action of Nitrogen Dioxide on Anthracene Derivatives.*

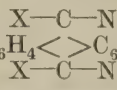
By EDWARD DE BARRY BARNETT.

MEISENHEIMER (*Annalen*, 1902, **323**, 205; 1904, **330**, 133) has shown that treatment of anthracene and of 9-nitroanthracene with nitrogen dioxide leads to the addition of nitro-groups to the "bridge" bond with production of dinitro- and trinitro-dihydroanthracene. The action of alkali on these compounds leads to loss of 1 mol. of nitrous acid with re-establishment of the "bridge," but for this purpose pyridine is much more satisfactory and leads to purer products owing to its having no tendency to rearrange the resulting nitro-compound into an oxime (compare Barnett, Cook, and Grainger, J., 1922, **121**, 2065). The facile addition of nitro-groups appears to be common to all anthracene derivatives in which the "bridge" is intact, and in this way the "bridge" exhibits very close analogy to an ethylenic bond (compare Wieland, *Annalen*, 1922, **421**, 2065). The resulting compounds should, in the majority of cases, be capable of existing in *cis*- and *trans*-forms, and as evidence has recently been obtained (Barnett and Matthews, *Rec. trav. chim.*, 1924, **43**, 534; Barnett, Cook, and Matthews, *ibid.*, 1925, **44**, 217, 728, 818) that the geometrical configuration and the stability of compounds formed by addition to the "bridge" are profoundly influenced by the presence of other substituents in the molecule, the action of nitrogen dioxide on several anthracene derivatives has been examined, with the following results.



(i) Neither *meso*- nor *Bz*.-substituents have any appreciable influence on the ease with which addition to the "bridge" takes place, 9 : 10-dibromoanthracene, for example, reacting with nitrogen dioxide almost as easily as anthracene itself.

(ii) *Bz*.-Substituents do not increase the stability of the compounds formed by the addition of nitro-groups to the "bridge,"



whereas in the case of the addition of halogen atoms, the presence of chlorine atoms in α-positions results in an enormous increase in stability (Barnett and co-workers, *loc. cit.*).

(iii) *Ms.*-Substituents appear to decrease the stability of the 9 : 10-dinitro-9 : 10-dihydroanthracenes.

(iv) Any compound of the general formula I will undergo re-establishment of the " bridge " with great ease on treatment with pyridine.

(I.)

(II.)

If X is a hydrogen atom, this re-establishment is brought about by loss of nitrous acid and formation of a derivative of 9-nitroanthracene. If X is a nitro-group, loss of nitrous acid and formation of a derivative of 9 : 10-dinitroanthracene take place. If X is a halogen atom, loss of halogen acid takes place. This last point is interesting, as Schaarschmidt (*Ber.*, 1924, **57**, 2065; 1925, **58**, 499) has shown that the action of nitrogen dioxide on halogen benzenes, with or without the addition of aluminium chloride, leads to the production of nitrohalogen benzenes, the *p*-isomeride predominating, often almost to the complete exclusion of the *o*-isomeride. In Schaarschmidt's experiments intermediate additive compounds were undoubtedly formed (and actually isolated in the impure state in combination with aluminium chloride). Since these lose nitrous acid rather than halogen acid, their structure must be different from that of those additive compounds formed by addition to an anthracene " bridge." This difference may be due to addition having taken place to a double bond (Kekulé formula). Alternatively, addition may have taken place to a " bridge " (Dewar formula), the different behaviour of the benzene and anthracene derivatives lying in their geometrical configuration, *cis-* in the case of anthracene derivatives, *trans-* in the case of benzene derivatives. Owing to the very unstable nature of the additive compounds it is extremely difficult to decide which of these alternatives is correct.

(v) Compounds of the general formula II, where X represents halogen, are extremely unstable and pass readily at the ordinary temperature into 9-nitro-9-halogen anthrone (when X is bromine) or into the corresponding anthraquinone (when X is chlorine).

(vi) When the molecule is unsymmetrical, loss of nitrous acid from a derivative formed by the addition of nitrogen dioxide may or may not lead to the same nitro-compound as is formed by loss of water from the compound (nitrodihydroanthranol) obtained by the addition of nitric acid to the " bridge."

Experimental.

Nitrogen dioxide generated by heating a mixture of lead nitrate and sand was passed into a solution or suspension of the anthracene derivative in chloroform, the whole being well cooled in a freezing mixture. The increase in weight gave the amount of nitrogen dioxide used; except where otherwise stated, it was found best to use excess. As a rule the reaction was complete in a few minutes, but in all cases the whole was kept in a freezing mixture for an hour before working up. The additive compounds were isolated by diluting and washing with light petroleum and recrystallising the solid, usually from luke-warm chloroform–light petroleum. Owing to the unstable nature of the additive compounds, recrystallisation is often very troublesome, and it was generally found best not to attempt to crystallise more than a gram at a time. The products can only be dried in a vacuum desiccator at the ordinary temperature, and they retain solvent very obstinately. They are all colourless, crystalline solids.

9-Nitroanthracene and 9 : 10-dinitroanthracene (m. p. 310°, not 294° as given in the literature) were prepared very easily by the action of cold pyridine and alcohol on the additive compounds obtained from anthracene and 9-nitroanthracene respectively.

1-Chloroanthracene gave an additive compound, which, owing to its slight power of crystallisation, could not be obtained pure. The crude substance on treatment with pyridine and alcohol in the cold gave 1-*chloro*-9 (*or* 10)-*nitroanthracene* (golden-yellow needles from alcohol or glacial acetic acid, m. p. 155°) which is different from the chloronitro-compound produced by the action of pyridine on the additive compound obtained from 1-chloroanthracene and nitric acid (Barnett and Matthews, *Rec. trav. chim.*, 1924, **43**, 538) (Found: N, 5·4. $C_{14}H_8O_2NCl$ requires N, 5·4%).

2-Chloroanthracene gave an additive compound which could only be obtained as a viscous oil. This with pyridine and alcohol gave a yellow solid which was obviously a mixture of isomeric chloronitro-compounds, but no simple method of separation was found.

1 : 5-*Dichloro*-9 : 10-*dinitro*-9 : 10-*dihydroanthracene* was obtained from 1 : 5-dichloroanthracene. It retains chloroform very obstinately; the sample analysed had been recrystallised, although with very heavy loss, from warm acetone (Found: N, 8·0. $C_{14}H_8O_4N_2Cl_2$ requires N, 8·3%). On heating, it turns yellow and then melts at 156° with violent evolution of gas. With cold pyridine and alcohol it passes very readily into 1 : 5-dichloro-9-nitroanthracene.

The additive compound from 1 : 8-dichloroanthracene could not

be obtained free from solvent, and a sample dried for 5 days in a vacuum desiccator gave a strong carbylamine reaction (Found: N, 5·7 after 1 day, 5·65 after 5 days. $C_{14}H_8O_4N_2Cl_2,1\frac{1}{2}CHCl_3$ requires N, 5·4%). It melts at 215° with violent evolution of gas, after turning yellow at a much lower temperature. On treatment with cold pyridine and alcohol it gave the same 1 : 8-dichloro-9 (or 10)-nitroanthracene as is obtained by the action of pyridine on the additive compound of nitric acid and 1 : 8-dichloroanthracene (Barnett and Matthews, *loc. cit.*).

9-*Bromo*-9 : 10-*dinitro*-9 : 10-*dihydroanthracene*.—The quantities used were 4 g. of nitrogen dioxide, 10 g. of 9-bromoanthracene, and 20 c.c. of chloroform. The solid collected after keeping for an hour and identified after recrystallisation as 9 : 10-dibromoanthracene was a by-product and was not present in the original 9-bromoanthracene. The main product, twice recrystallised, was colourless; on heating, it turned yellow and then sintered at about 115°, but had no definite melting point (Found: N, 8·0. $C_{14}H_9O_4N_2Br$ requires N, 8·0%). 9 : 10-Dinitroanthracene was the sole product obtained by the action of pyridine and alcohol.

9-*Bromo*-9-*nitroanthrone*.—The quantities were 5 g. of nitrogen dioxide, 10 g. of 9 : 10-dibromoanthracene, and 25 c.c. of chloroform; the period of keeping was about 2 hours. The product, recrystallised twice, formed colourless, silky needles which sintered at 116° and agreed in their general properties with the description of 9-bromo-9-nitroanthrone given by Meisenheimer (*Annalen*, 1904, **330**, 181) (Found: N, 4·45. Calc., N, 4·4%). This compound passes into anthraquinone very easily. The reaction is probably decomposition rather than hydrolysis, as it was completed in a few minutes when the compound was added to boiling benzene which had been dried for several weeks over metallic sodium.

9 : 10-*Dichloro*-9 : 10-*dinitro*-9 : 10-*dihydroanthracene*.—The solid obtained from 7 g. of nitrogen dioxide and 12·5 g. of 9 : 10-dichloroanthracene in 50 c.c. of chloroform was washed with cold chloroform–light petroleum and then twice recrystallised from chloroform. It is extremely unstable and decomposes almost at once into anthraquinone on boiling with chloroform, but by working with amounts of about 0·5 g., dissolving these in chloroform at 30°, and at once cooling the solution in a freezing mixture, snow-white crystals were obtained. Owing to the rapid decomposition which takes place at the ordinary temperature it was found necessary to analyse the product after drying it for an hour in a vacuum desiccator over concentrated sulphuric acid (Found: N, 8·0. $C_{14}H_8O_4N_2Cl_2$ requires N, 8·3%).

1 : 5 : 9-*Trichloro*-9 : 10-*dinitro*-9 : 10-*dihydroanthracene*.—The product from 3 g. of nitrogen dioxide and 7 g. of 1 : 5 : 9-trichloroanthracene in 15 c.c. of chloroform, after being twice crystallised, was a slightly yellow, crystalline powder which on heating decomposed with violent evolution of gas at 156° (Found in material dried for 3 hours : N, 7·4. $C_{14}H_9O_4N_2Cl_3$ requires N, 7·5%).

1 : 5-*Dichloro*-9 : 10-*dinitroanthracene* was obtained by the action of cold pyridine and alcohol on the above trichlorodinitrodihydroanthracene. After being twice recrystallised from pyridine, it formed pale yellow needles, m. p. 277° (Found : N, 8·3. $C_{14}H_6O_4N_2Cl_2$ requires N, 8·3%).

2 : 3 : 9-*Tribromo*-9-*nitroanthrone*.—Excess of nitrogen dioxide was passed into a well-cooled suspension of 10 g. of 2 : 3 : 9 : 10-tetrabromoanthracene in 50 c.c. of chloroform, and the whole kept for 3 hours in a freezing mixture. Unchanged tetrabromoanthracene was removed, the filtrate diluted with light petroleum, and the solid which separated washed with light petroleum and then twice recrystallised from warm chloroform–light petroleum (Found : N, 2·8. $C_{14}H_6O_3NBr_3$ requires N, 2·9%). When heated with toluene, this product evolves brown fumes and passes quantitatively into 2 : 3-dibromoanthraquinone.

The products obtained by the action of nitrogen dioxide on anthranyl methyl ether, 9-phenylanthracene or 9-phenylanthranyl methyl ether were, not additive compounds, but 9-nitroanthrone, 9-nitro-10-phenylanthracene and 9-phenyl-9-hydroxyanthrone respectively, all of which were identified by direct comparison with authentic samples.

SIR JOHN CASS TECHNICAL INSTITUTE,
LONDON, E.C. 3. [*Received, July 6th*, 1925.]

CCLXXIX.—*The Constitution of Indian Kamala. Part I.*

By SIKHIBHUSHAN DUTT.

KAMALA was first investigated by Anderson, who isolated from it a crystalline compound, rottlerin, $C_{11}H_{10}O_3$ (*Edin. New Phil. J.*, 1855, **1**, 300). This has been investigated by various chemists including A. and W. Perkin (*Ber.*, 1886, **19**, 3109), A. G. Perkin (J., 1893, **63**, 975), Jawein (*Ber.*, 1887, **20**, 182), Telle (*Arch. Pharm.*, 1906, **244**, 441), Bartolotti (*Gazzetta*, 1894, **24**, ii, 480). A. G. Perkin (J., 1895, **67**, 230) obtained from it *o*- and *p*-nitrocinnamic acids, *p*-nitrobenzaldehyde, and *p*-nitrobenzoic acid by the action

of fuming nitric acid, and acetic and benzoic acids and phloroglucinol by fusion with potassium hydroxide. The present investigation was undertaken with a view to elucidate further the constitution of the substance.

Benzene is the most suitable solvent for extracting the colouring matter from kamala, as it dissolves very little of the resin. The pure colouring matter is best crystallised from toluene. The m. p. (206—207°) of the rottlerin isolated by the author is 15° higher than that recorded by A. G. Perkin (Telle, *loc. cit.*, gives m. p. 203—204°); the two substances, however, appear to be almost identical in chemical properties.

On treatment with acetic anhydride rottlerin yields a colourless, crystalline *hepta-acetyl* derivative melting at 165°; Perkin isolated a hexa-acetyl derivative as a yellow, crystalline powder melting at 130—135°. Possibly rottlerin contains, in addition to six phenolic hydroxyl groups, an alcoholic hydroxyl group which can be acetylated only under suitable conditions. In support of this view is the fact that only *hexamethoxy* and *hexabenzoyl* derivatives are obtainable from rottlerin by the action of methyl sulphate and benzoyl chloride in presence of dilute sodium hydroxide solution —conditions under which an alcoholic hydroxyl group is scarcely attacked at all.

Acetylrottlerin and acetylmethoxyrottlerin form dibromo-additive compounds. This indication of the presence of a double bond in rottlerin is supported by the fact that the action of fuming nitric acid on the substance produces a large quantity of *p*-nitrocinnamic acid.

On fusion with potassium hydroxide rottlerin yields phloroglucinol as the only phenolic compound, and on oxidation with permanganate acetyl- and methoxy-rottlerin are converted into triacetyl- and trimethyl-phloroglucinoldicarboxylic acids, respectively. These facts indicate that rottlerin contains two phloroglucinol residues joined to the parent structure by either one or two side chains; if by one side chain, an alkyl substituent is present in the phloroglucinol nucleus. Moreover, as phthalic and terephthalic acids are almost always formed in the oxidation of rottlerin, there appear to be two more benzene nuclei in its molecule, containing side chains in ortho-positions in the one and in para-positions in the other. The two acids, however, may be produced by selective elimination of a side chain from the same benzene nucleus containing three side chains in the 1 : 2 : 4-positions. This alternative is the more probable, for the presence of five benzene nuclei would account for thirty out of the thirty-three carbon atoms in the molecule of rottlerin; there would remain

only three carbon atoms, two of which must be present in the side chain containing the double bond. In all probability, therefore, rottlerin contains four benzene nuclei, of which (1) two must be phloroglucinol residues, (2) one must be in the residue $C_6H_5 \cdot CH{:}CH \cdot C$, and (3) one must be a benzene nucleus containing at least three side chains.

Rottlerin is converted into a ketone, rottlerone, by the action of 2% sodium carbonate solution (Perkin, *loc. cit.*), and therefore appears to contain a secondary alcoholic hydroxyl group.

As Telle (*loc. cit.*) seems to have isolated the mono-, di-, and trimethyl ethers of phloroglucinol from the products of interaction of barium hydroxide solution, and of sodium hydroxide and zinc dust, and rottlerin, the phenolic hydroxyl groups in this would appear to be more or less methylated. The present author, however, obtained a negative result in the estimation of methoxyl by Zeisel's method. The phenolic portion of the rottlerin molecule is completely destroyed by the action of oxidising agents, but phenolic derivatives are obtained in large yields by oxidation of acetyl- and methoxy-rottlerin, in which the phenolic hydroxyl groups are protected from the action of the oxidising agent.

From the ease with which cinnamic acid and dihydrocinnamic acid are produced from rottlerin by the action of oxidising and reducing agents respectively, it seems that the molecule contains a group $C_6H_5 \cdot CH{:}CH \cdot CO\cdot$ or $C_6H_5 \cdot CH{:}CH \cdot C(OH)<$. The presence of this would account for the formation of benzaldehyde, benzoic acid, and their derivatives by the action of various reagents..

Experimental.

Preparation of Rottlerin.—Commercial kamala (150 g.) was passed through a 100-mesh sieve and heated under reflux with 1200 c.c. of benzene for 8 hours. The solution was filtered at once and again after 12 hours and concentrated to about 200 c.c. The colouring matter, which separated slowly in large, brownish-yellow plates, was washed with alcohol and twice recrystallised ftom toluene; rottlerin was thus obtained in large, glistening, brownish-yellow plates, m. p. 206—207° (yield about 9 g.) (Found: C, 69·2; H, 5·5; *M*, ebullioscopic in toluene, 585, 615, 598, by silver salt, 675. Calc. for $C_{33}H_{30}O_9$, C, 69·4; H, 5·2%; *M*, 570).

The substance is sparingly soluble in the usual organic solvents. In doiling toluene and amyl alcohol it dissolves to the extent of about 12%, but separates almost completely on cooling. It is very soluble in basic solvents like pyridine, quinoline, or aniline and also in alkali hydroxides and carbonates.

Acetylrottlerin, $C_{33}H_{23}O_9(C_2H_3O)_7$, prepared by boiling pure

rottlerin with acetic anhydride (5 parts) and a few drops of pyridine and crystallised from dilute acetone, acetic acid, and alcohol, was obtained in colourless needles, m. p. 165° [Found: C, 64·9; H, 5·2. $C_{33}H_{23}O_9(C_2H_3O)_7$ requires C, 65·3; H, 5·0%]. An estimation of acetyl by Perkin's method confirmed the presence of 7 such groups.

Dibromoacetylrottlerin, $C_{33}H_{23}O_9Br_2(C_2H_3O)_7$.—Acetylrottlerin and bromine (in slight excess of 1 mol.) were allowed to react in cold glacial acetic acid. The mixture, which was not completely decolorised on gentle warming, was poured into water; the precipitate crystallised from carbon disulphide in pale yellow, microscopic needles, m. p. 145° [Found: Br, 15·2. $C_{33}H_{23}O_9Br_2(C_2H_3O)_7$ requires Br, 15·6%].

Benzoylrottlerin, $C_{33}H_{24}O_9(C_6H_5{\cdot}CO)_6$, obtained by the Schotten-Baumann method, was a light yellow powder which could not be crystallised from any solvent. It was moderately soluble in most of the organic solvents, insoluble in alkali hydroxides, and did not melt below 300° (Found: C, 75·8; H, 4·5. $C_{75}H_{54}O_{15}$ requires C, 75·3; H, 4·5%).

Methoxyrottlerin, $C_{33}H_{24}O_3(OMe)_6$.—Rottlerin dissolved in 5% aqueous sodium hydroxide was shaken with excess of methyl sulphate, more alkali and methyl sulphate were added, and the process was repeated four or five times, the solution being kept alkaline. The mixture was then warmed on the water-bath for 1 hour and the yellow solid was collected after cooling and dissolved in ether. The ethereal solution was exhaustively extracted with dilute sodium hydroxide solution, and the ether evaporated; the residue crystallised from dilute acetic acid in pale yellow, microscopic needles, m. p. 135—137° [Found: C, 71·1; H, 6·9; OMe, 28·8. $C_{33}H_{24}O_3(OMe)_6$ requires C, 71·5; H, 6·4; OMe, 28·4%].

Acetylmethoxyrottlerin, $C_{33}H_{23}O_3(OMe)_6{\cdot}C_2H_3O$.—A mixture of 2 g. of methoxyrottlerin, 10 c.c. of acetic anhydride, and 1 drop of pyridine was boiled for ½ hour and poured into water. The colourless product crystallised from acetic acid in fine clusters of needles, m. p. 215—217° [Found: C, 70·2; H, 6·6. $C_{33}H_{23}O_3(OMe)_6{\cdot}C_2H_3O$ requires C, 70·7; H, 6·3%].

Dibromoacetylmethoxyrottlerin, $C_{33}H_{23}O_3Br_2(OMe)_6{\cdot}C_2H_3O$.—The procedure was that for preparing dibromoacetylrottlerin. The pale yellow product, which could not be crystallised, decomposed on heating and was moderately soluble in most of the organic solvents [Found: Br, 18·2. $C_{33}H_{23}O_3Br_2(OMe)_6{\cdot}C_2H_3O$ requires Br, 18·6%].

Action of Oxidising Agents on Rottlerin and its Derivatives.—(1) *Fuming nitric acid.* Rottlerin (10 g.) was gradually added to 50 c.c. of nitric acid (*d* 1·5), the temperature being always kept

below 0°. The colouring matter dissolved very easily and torrents of red fumes were evolved. After 1 hour, the mixture, which had become almost solid owing to separation of *p*-nitrocinnamic acid, was diluted somewhat with ice-cold nitric acid (*d* 1·4) and filtered; the crystals melted at 285° after crystallisation from alcohol. A further quantity of *p*-nitrocinnamic acid was obtained on pouring the nitric acid mother-liquor into ice-water. The filtrate on extraction with ether yielded a gum from which succinic acid was isolated. Acetic acid was detected in the mother-liquor. No *o*-nitrocinnamic acid, *p*-nitrobenzoic acid, or *p*-nitrobenzaldehyde could be isolated (compare Perkin, *loc. cit.*). *p*-Nitrobenzaldehyde and *p*-nitrobenzoic acid were formed in fairly good quantity if the mixture was allowed to warm during the reaction, but even so, no *o*-substituted derivative could be isolated.

(2) *Dilute nitric acid* (*d* 1·2). Rottlerin (10 g.) was heated on the water-bath for 72 hours with 200 c.c. of dilute nitric acid with occasional shaking; the brownish-yellow colour of the rottlerin had then disappeared and the liquid was thick with white crystals. The mixture was filtered; acetic acid was detected in the filtrate. The crystals gave benzoic acid on distillation in steam; the non-volatile portion, on repeated extraction with boiling water, yielded almost colourless needles of *p*-nitrobenzoic acid, m. p. 237°. A small quantity of phthalic acid was obtained by evaporating the aqueous filtrate to dryness and crystallising the residue from boiling water.

The residue left after extraction with boiling water was insoluble in almost all solvents. Heated under diminished pressure, it sublimed in long needles of terephthalic acid (the methyl ester melted at 139°, alone or mixed with methyl terephthalate) (Found: C, 57·5; H, 3·9; Ag in silver salt, 57·2. Calc., C, 57·8; H, 3·6; Ag, 56·8%).

(3) *Alkaline potassium permanganate.* Rottlerin (5 g.) dissolved in 250 c.c. of 3% sodium hydroxide solution was treated with 1% potassium permanganate until this was no longer decolorised. The solution was filtered, concentrated to small volume, and acidified. The white precipitate was distilled in steam, small quantities of benzoic and acetic acids passing over. The non-volatile residue on extraction with hot water, yielded a small quantity of phthalic acid, while the aqueous mother-liquor, on extraction with ether yielded an unidentified dibasic acid, $C_{18}H_{20}O_4$, which crystallised from glacial acetic acid in glistening prisms, m. p. 192°. The aqueous mother-liquor after extraction with ether contained oxalic acid (isolated as calcium salt). The insoluble residue left after all these operations was terephthalic acid.

(4) *Alkaline hydrogen peroxide.* The same substances are obtained by the prolonged action of hydrogen peroxide on a cold alkaline solution of rottlerin as by the action of potassium permanganate; some benzaldehyde also is produced and the yield of the unknown acid is greater.

(5) *Alkaline potassium ferricyanide.* The reaction, which was very slow in the cold, was completed in several hours in the warm. On acidifying the alkaline solution, a tarry mass was obtained, which on distillation in steam yielded small quantities of benzaldehyde and benzoic acid. From the dark brown, brittle residue, which was very soluble in alkali or ether, nothing definite could be isolated. On oxidation with alkaline permanganate, it yielded a mixture of phthalic and terephthalic acids and also a small quantity of another acid, m. p. 216°. The last appears to be a tribasic acid from the analysis of its silver salt, but it was not obtained in sufficient quantity for further examination.

(6) *Potassium persulphate.* Rottlerin (5 g.) dissolved in 150 c.c. of concentrated ice-cold sulphuric acid was gradually treated with 14 g. of finely powdered potassium persulphate with stirring, until carbon dioxide was no longed evolved. The solution, which became colourless after being stirred for 2 hours, was poured on to ice, and the precipitate collected; acetic acid was detected in the filtrate. The precipitate was separated by steam distillation into volatile benzaldehyde and benzoic acid and non-volatile phthalic and terephthalic acids with only traces of cinnamic acid. The unknown dibasic acid, which is an almost constant oxidation product of rottlerin, was not formed.

(7) *Fusion with potassium hydroxide.* Ten grams of rottlerin were gradually added to 100 g. of potassium hydroxide and 10 c.c. of water at 100°; the mixture was then heated at 180—200° for ½ hour. The cold melt was dissolved in water, acidified with concentrated hydrochloric acid, extracted with ether, and the ether evaporated. The dark brown, viscous mass thus obtained, which had a strong odour of acetic acid, gave, on steam distillation, acetic and benzoic acids. An ethereal extract of the residue, on decoloration with animal charcoal and concentration at the ordinary temperature, yielded large, transparent leaflets of phloroglucinol, m. p. 218°. The ethereal mother-liquor on complete evaporation left a brown gum from which nothing definite could be isolated.

Action of Reducing Agents.—(1) *Zinc dust and sodium hydroxide.* A mixture of 5 g. of rottlerin, dissolved in 150 c.c. of 5% sodium hydroxide, and 20 g. of zinc dust was heated on the water-bath for 1 hour, and the colourless solution was filtered and acidified with hydrochloric acid. The yellowish-white, viscous mass obtained,

on distillation in steam, gave an acid distillate from which small quantities of succinic and acetic acids were isolated. The non-volatile residue, on cooling, solidified to a brown, brittle mass, from which dihydrocinnamic acid was isolated by extracting the powdered substance with sodium bicarbonate solution. The final dark brown residue could not be crystallised, nor could anything definite be isolated from it. It gave a dark violet coloration with ferric chloride, dissolved in sodium hydroxide or carbonate solution with a dark brown colour, and on fusion with potassium hydroxide at 200°, yielded comparatively large quantities of phloroglucinol.

(2) *Tin and hydrochloric acid.* A mixture of 10 g. of rottlerin with 20 g. of tin dust was heated with 150 c.c. of fuming hydrochloric acid on the water-bath with frequent stirring until all the tin had dissolved. The mass was diluted with water and filtered hot. The filtrate on extraction with ether yielded small quantities of acetic and succinic acids. The tarry residue on extraction with sodium bicarbonate yielded 1·3 g. of dihydrocinnamic acid. The residue, which could not be crystallised, yielded phloroglucinol on fusion with potassium hydroxide.

(3) *Sodium hyposulphite.* Rottlerin in alkaline solution, on treatment with sodium hyposulphite, yielded a brown, tarry mass from which only dihydrocinnamic acid could be isolated.

(4) *Hydriodic acid and red phosphorus.* A mixture of 5 g. of rottlerin, 2 g. of red phosphorus, and 20 c.c. of hydriodic acid (*d* 1·75), when heated in a sealed tube at 230—250° for 6 hours developed great pressure, due to what was probably a gaseous aliphatic hydrocarbon, and separated into two layers. The upper dark brown, oily layer, isolated by means of ether, distilled between 135° and 260°; decomposition then set in. The largest fraction b. p. 145—160°, on redistillation gave, between 152° and 159°, a colourless liquid with an odour resembling that of mesitylene. It was probably *n*-propylbenzene (Found: C, 89·7; H, 10·2. Calc. C, 90·0; H, 10·0%), but only a small quantity was available for examination. When heated with fuming nitric acid, it yielded a very small quantity of a crystalline acid, m. p. 140°, which did not depress the m. p. of *m*-nitrobenzoic acid.

(5) *Pyrogenic reduction with zinc dust.* Ten grams of rottlerin were distilled with zinc dust in the usual way in a stream of hydrogen. Gaseous hydrocarbons were evolved. The distillate which was collected in a receiver cooled in a freezing mixture consisted of a mixture of a crystalline solid and a liquid. The latter was absorbed in porous plate; the solid, crystallised from alcohol gave colourless plates, m. p. 190°, of β-methylanthracene and yielded β-methylanthraquinone on oxidation with nitric acid

The liquid, extracted from the porous plate with ether, was colourless, had b. p. 230—240°, and could not be identified; it was not obtained in sufficient quantity for analysis or quantitative examination.

Oxidation of Acetylrottlerin with Permanganate.—Acetylrottlerin (20 g.) suspended in 500 c.c. of water was oxidised at 80° with 25 g. of potassium permanganate in 5% solution, kept neutral by the addition of 10 g. of copper sulphate. The excess of permanganate was destroyed by ferrous sulphate, and the solution filtered. The filtrate, on evaporation to a small volume and acidification, yielded a small quantity of benzoic acid; the mother-liquor contained oxalic and acetic acids.

The precipitated oxides of manganese, iron and copper were suspended in water and dissolved by passing a current of sulphur dioxide. The brown, crystalline residue was extracted with boiling water, and from the solution a small quantity of phthalic acid was obtained. The insoluble residue, on extraction with alcohol, left terephthalic acid. The alcoholic extract, after decoloration with animal charcoal and dilution with hot water, yielded triacetylphloroglucinoldicarboxylic acid in glistening prisms, m. p. 260—270° (decomp. and evolution of carbon dioxide) (Found : C, 49·2; H, 3·7; Ag in the silver salt, 39·4. Calc. for $C_{14}H_{12}O_{10}$, C, 49·4; H, 3·5%. Calc. for $C_{14}H_{10}O_{10}Ag_2$, Ag, 38·9%). The ethyl ester, prepared in the usual way, melted at 96° and was identical with that described by Moore (J., 1904, **85**, 167). On deacetylation with concentrated sulphuric acid in absolute alcohol, the acid yielded ethyl phloroglucinoldicarboxylate, m. p. 106° (Moore, *loc. cit.*).

On heating in a vacuum at 220°, the acid evolved carbon dioxide. The melt was dissolved in ether, washed with very dilute sodium hydroxide, decolorised with animal charcoal, and the solution evaporated; colourless prisms, m. p. 105°, of triacetylphloroglucinol were thus obtained. When this was hydrolysed by solution in strong sulphuric acid, phloroglucinol was produced in quantitative yield.

Oxidation of Methoxyrottlerin with Permanganate.—Methoxyrottlerin was oxidised by a boiling neutral solution of potassium permanganate and the reaction products were isolated in the ways described above. Benzoic, acetic, phthalic, and terephthalic acids were obtained together with trimethylphloroglucinoldicarboxylic acid, which crystallised from dilute alcohol in glistening, white needles, m. p. 248—255° (decomp. and evolution of carbon dioxide) (Found : C, 51·3; H, 4·8; Ag in the silver salt, 46·4. Calc. for $C_{11}H_{12}O_7$, C, 51·5; H, 4·6%. Calc. for $C_{11}H_{10}O_7Ag_2$, Ag, 45·95%). The acid was heated at 240° for ½ hour until the evolution of carbon

dioxide had ceased, and then distilled. A colourless liquid passed over at 250—255° and solidified in the receiver to a crystalline mass of glistening leaflets, m. p. 50—51°, of trimethylphloroglucinol. This gave a quantitative yield of phloroglucinol on hydrolysis with concentrated hydriodic acid.

The greater part of this work was done in the Laboratories of the Dacca College and the Dacca University during 1921–1923. My best thanks are due to Mr. Nirmal Kumar Sen for his help in the preparation of large quantities of rottlerin, and to Dr. E. R. Watson and Dr. P. C. Ghosh for their kind encouragement during the progress of the work.

IMPERIAL COLLEGE, LONDON, S.W.7. [*Received, June 30th,* 1925.]

CCLXXX.—*The Decomposition of Carbon Monoxide in the Corona due to Alternating Electric Fields. Part I.*

By MIGUEL CRESPI and ROBERT WINSTANLEY LUNT.

IN the course of experiments repeating the work of Moser and Isgarischeff (*Z. Elektrochem.*, 1910, **16**, 613) on the decomposition of carbon dioxide when submitted to the corona produced by alternating electric fields of commercial frequencies, one of the authors (R. W. L.) observed the formation of a solid substance the properties of which appeared to be similar to those of the solid obtained by Brodie when investigating the action of the electric discharge on carbon monoxide (*Annalen*, 1873, **169**, 270; *Proc. Roy. Soc.*, 1873, **21**, 245). The chief characteristics assigned to the solid by Brodie were a dark brown colour, high solubility in water and alcohol (the former solution giving a marked acid reaction), and a very low solubility in ether. Basing his arguments on the composition of the gas phase before and after exposure to the discharge, Brodie stated that there appeared to be two oxides, possibly two of a series, to which he assigned the formulæ C_4O_3 and C_5O_4. Four years later, Berthelot (*Ann. Chem. Phys.*, 1877, **10**, 72) repeated some of Brodie's work and assigned the formula C_4O_3 to the solid substance he prepared.

In view of the scanty information existing on this interesting compound of carbon and oxygen experiments have been carried out with the aim of describing in some detail the properties of this material and the conditions under which it is produced. The difficulties encountered in producing appreciable quantities of the

solid substance have occasioned some delay in completing a survey of its properties and this communication will therefore be confined to an account of the behaviour of carbon monoxide when subjected to alternating electric fields of frequency 250 over the pressure range 760 to 80 mm. Hg.

Experimental.

Description of Apparatus.—Source and Measurement of Electric Power. Single-phase alternating current of frequency 250 was supplied from a motor alternator set and transformed up to the required voltage over the range 2000 to 10,000 volts. The voltage applied to the reaction vessel was measured by a Kelvin-White instrument and the current flowing through it was indicated approximately by a dynamometer type milliameter reading 0—50 milliamperes.

Reaction Vessel. A glass vessel fashioned in the usual manner of a Siemen's ozoniser, that is to say, constructed of concentric cylinders, served to contain the gas during exposure to the discharge. One end of the inner tube was closed and the other was ground to fit into the outer tube; it could therefore be removed from the outer tube when necessary. Surrounding the outer tube was a glass jacketing tube which was filled with mercury and served as the high-tension electrode. The inner tube was filled with mercury and constituted the other electrode, which was earthed. It was cooled by a stream of water at room temperature flowing through a thin-walled glass tube immersed in the mercury. The temperatures of each electrode were recorded by alcohol thermometers, it having been observed that mercury thermometers rapidly fouled under the experimental conditions obtaining.

The reaction vessel was so arranged that carbon monoxide could be fed in from a reservoir or the vessel connected to a Töpler pump; it was also connected to a mercury manometer. The volume of gas in the connecting capillary tubes which was out of contact with the discharge was reduced to a minimum. The diameters of the outer wall of the vessel were 22·4 mm. (external) and 21 mm. (internal), and of the inner wall 16 mm. (external) and 14·8 mm. (internal). The length of electrodes was approx. 300 mm.

Preparation of Carbon Monoxide.—The gas produced by dropping recrystallised formic acid into an evacuated flask containing warm sulphuric acid was passed over solid potash and dried by flowing through some 6 feet of tubing packed with phosphorus pentoxide. It was analysed by exposure to alkaline pyrogallol and by absorption in ammoniacal cuprous chloride solution, in which the gas was completely soluble. The gas so prepared was free from oxygen.

Measurements and Results.—Two sets of observations were carried out, one at 4500 volts and the other at 9000 volts. In every case the heat generated in the reaction vessel was sufficient to raise the mean temperature of the vessel several degrees above the room temperature despite the cooling of the inner electrode.

In order to follow the pressure change during exposure to the discharge it became necessary to know the value of the mean temperature of the vessel, T_m, corresponding to any two given values of the temperature of the outer and inner electrodes, T and T_1, respectively. The following empirical relationship was observed to hold

$$\log T_m = k \log T_1 + (1 - k) \log T$$

with an accuracy of about 1%. The value of k was determined in several cases by observing the pressure of the gas, p_1, corresponding to electrode temperatures, T and T_1, and the pressure, p_2, of the same gas when the whole system was allowed to reach a uniform temperature, T_2. We then have

$$(T_m + 273)/(T_2 + 273) = p_1/p_2.$$

Substituting the values so obtained for T_m in the above equation, the mean value of k was found to be 0·737.

Preliminary experiments established that the sole products of the reaction were the brown solid, which is deposited on the walls of the reaction vessel, and a residual gas mixture of carbon monoxide and dioxide, containing not more than traces of oxygen.

The experimental procedure was to introduce carbon monoxide into the evacuated reaction vessel and to record the pressure of the gas in the reaction vessel and the temperature of the two electrodes every quarter of an hour from the commencement of the discharge until sensible equilibrium was reached, as indicated by the cessation of pressure change.

After discontinuing the discharge, the residual gas was pumped off and analysed by absorbing the carbon dioxide present with solid potash. Knowing the composition of this residual gas and the values of the gas pressure before and after exposure to the discharge, the composition of the solid substance produced can readily be calculated.

The brown solid deposited on the walls of the vessel has no appreciable vapour pressure.

The results are given in Tables I and II: p_0 and p_∞ are the initial and the equilibrium pressure (mm. of Hg at 0°) of the gas in the reaction vessel; t is the time (mins.) required to reach sensible equilibrium; a is the ratio C/O in the solid; and b is the ratio CO/CO_2 in the equilibrium gas mixture.

TABLE I.

Voltage applied to reaction vessel = 4500 volts r.m.s.
Current flowing through reaction vessel = 1·0 milliamperes (approx.).

p_0.	p_∞.	a.	b.	t.	$(p_0 - p_\infty)/t$.

317·6	219·1	1·228	11·00	150	0·66
201·4	145·4	1·256	11·76	75	0·74
141·6	110·1	1·335	12·93	60	0·86
105·3	83·2	1·348	13·59	35	0·63
78·7	61·5	1·409	11·22	25	0·69
			mean 12·07		mean 0·71

TABLE II.

Voltage applied to reaction vessel = 9000 volts r.m.s.
Current flowing through reaction vessel = 2·5 milliamperes (approx.).

p_0.	p_∞.	a.	b.	t.	$(p_0 - p_\infty)/t$.
501·0	327·5	1·186	11·27	225	0·77
304·7	213·4	1·267	10·11	135	0·68
193·3	140·8	1·274	11·04	90	0·61
130·8	100·2	1·308	12·63	35	0·87
94·4	73·7	1·398	11·49	25	0·82
			mean 11·82		mean 0·77

The curves representing the velocity of reaction can be derived from the following expression :—

$$-dp_t/dt = (k + tk')(p_t - p_\infty),$$

where p_t denotes the pressure at any time t, and k and k' are constants which appear to be functions of the initial pressure and of the electrical conditions, although the time required to reach sensible equilibrium seems to be practically independent of the latter. The form of these functions remains to be determined. The observed values of p_t and those calculated from the above equation are set forth in Tables III and IV; the agreement obtaining is satisfactory and not uninteresting. The values of the mean rate of decrease of pressure, which are cited in the sixth column of Tables I and II show a remarkable constancy.

The wide range of electrical and pressure conditions obtaining being borne in mind, one of the most interesting results is the constancy observed in the composition of the residual gas when equilibrium is reached. This approximates closely to a mixture of one volume of carbon dioxide with twelve volumes of carbon monoxide.

The composition of the solid substance appears to be independent of the electrical conditions over the range examined, and solely dependent on the gas pressure, the ratio of carbon to oxygen in the solid substance increasing continuously with decreasing gas pressure.

This observation is in agreement with the work of the Genera Electric Company's Research Staff on the disappearance of carbo monoxide in discharge tubes when operated at pressures less tha 1 mm. of mercury (*Phil. Mag.*, 1920, **40**, 585). They were of th opinion that at such pressures the monoxide decomposed to carbo and the dioxide, although no chemical tests were made to establis the formation of carbon.

In addition to possessing the properties recorded by Brodie and Berthelot the solid substance is very hygroscopic. In view of the small quantities of material available up to the present time the systematic examination of its chemical properties is reserved for a later communication.

Summary.

(1) A description has been given of the behaviour of carbon monoxide in the corona due to alternating electric fields of frequency 250. It decomposes giving a solid substance, containing carbon and oxygen, and a mixture of carbon dioxide and monoxide of approximately constant composition.

(2) The composition of the solid substance appears to be independent of the electrical conditions and varies solely with the gas pressure.

(3) In so far as the properties of the solid substance have been examined they are similar to those recorded by earlier investigators. In addition the substance has been found to be highly hygroscopic.

(4) Experiments are in progress to determine more completely the nature of the solid substance.

The authors wish to tender their thanks to the Ramsay Memorial Fellowship Trust for a Fellowship (M. C.) and to the Commissioners for the Exhibition of 1851 for a Senior Studentship (R. W. L.) which have enabled them to carry out this research, and particularly to Professor F. G. Donnan, F.R.S., for his deep interest and advice during the progress of the research.

CCLXXXI.—*Anode Phenomena in the Electrolysis of Potassium Ethyl Malonate.*

By John Braithwaite Robertson.

R. E. Gibson (this vol., p. 475) has shown that the synthesis of trichloromethyl trichloroacetate by electrolysis of trichloroacetic acid takes place only when the anode potential exceeds 2·34—2·37 volts on the hydrogen standard and concluded that the anode process is one of direct oxidation. However, as he points out, this is not a carbon to carbon synthesis, and it appeared desirable to determine whether similar results would be obtained in a true Kolbe synthesis.

As in the apparatus devised for measuring anode potentials, only small currents could be employed, and therefore only small quantities of synthetic product obtained, potassium ethyl malonate proved to be a very suitable material because, whereas this salt is very soluble in water, the diethyl succinate formed on synthesis is an oil and sparingly soluble in the solution employed. On production of this oil a change in the appearance of the gas bubbles leaving the anode was easily observable, as Gibson found to be the case with trichloroacetate. When no synthesis occurred, these were small in size and left the anode freely, but as soon as the oil was formed they became much larger and appeared to cling to the anode, a phenomenon attributable to their being coated with a thin film of the synthetic oil.

Preliminary experiments showed that a change occurred at a potential of about $\epsilon_H = 2{\cdot}3$, where ϵ_H is potential referred to the normal hydrogen electrode as standard. Below this potential the gas evolved at the anode was chiefly oxygen, whereas above this potential scarcely any oxygen was produced, the gas being almost pure carbon dioxide.

A series of determinations was carried out to fix this point more exactly. Measurements were made at different values of the applied *E.M.F.* between the electrodes of (1) the anode potential, (2) the current, and (3) the volume and composition of the gases evolved in unit time. Similar measurements were also made when electrodes of (1) platinised platinum, (2) grey platinum, and (3) gold were used. The apparatus employed is practically identical with that described by Gibson, except that here it was not necessary to have the anode and the cathode in separate compartments.

The potential difference between the anode and a calomel electrode was measured by the compensation method, with use of an Ostwald decade rheostat, a battery of accumulators, a sensitive galvanometer, and a standard cadmium cell. The current passing through the electrolyte was measured on a milliamperemeter, and the *E.M.F.* between the electrodes on a shunted voltmeter.

After all necessary connexions had been made, the current was switched on and the voltage adjusted to give the desired *E.M.F.* between the electrodes. Readings of the anode potential were made at intervals. The potential took a considerable time to become constant, in general about an hour, but in some cases several hours; with gold electrodes within a certain range no steady reading was obtained even after a constant *E.M.F.* had been applied for 12 hours. When equilibrium was reached, the evolved gases were collected for a measured length of time varying from $\frac{1}{2}$ hour to 3 hours (depending on the current passing) until

at least 20 c.c. were obtained. During this time frequent regular readings of anode potential and current were made, and the means of these were taken as representing the potential and current during the period. If these readings varied by more than a few hundredths of a volt or a few milliamperes, as the case might be, the experiment was abandoned. The amount of hydrogen found on analysis served as a check on the amperemeter readings. It was necessary to determine only the carbon dioxide and oxygen in the gas sample, the residue being hydrogen. Several tests with fuming sulphuric acid showed that no unsaturated hydrocarbon gases were produced.

The results are detailed on p. 2060 : c is the current in milliamperes, ϵ_H the anode potential, and CO_2 and O_2 are the volumes (c.c at *N.T.P.*) evolved per hour.

The solution used in each case was N-potassium ethyl malonate. The values for carbon dioxide do not represent the total carbon dioxide produced, as a considerable proportion of this remains in the solution, being fixed as carbonate or bicarbonate by the alkali formed round the cathode, but they are useful for purposes of comparison.

The diagrams show curves for oxygen evolved per hour and current carried plotted from the above data, the numbers of the diagrams corresponding with those of the tables on p. 2060.

With smooth platinum electrodes (Ib) there is, between anode potentials of 2·30 and 2·37, a sudden drop in oxygen evolved. A similar drop, although not so sharp, occurs with grey platinum electrodes (Ig) at a potential of about 2·4. The characteristic change in the nature of the bubbles leaving the anodes was also apparent about these points. This value of 2·3—2·4 therefore corresponds to the potential at which the synthesis of diethyl succinate occurs. A large-scale experiment with grey platinum electrodes and a current of 1 ampere showed that above this potential synthesis took place as with smooth platinum, a film of oil appearing on the surface of the electrolyte after about 15 minutes. This value of the anode potential is the same as that found by Gibson (*loc. cit.*) in the formation of trichloromethyl trichloroacetate. The shape of the current curve, however, differs from his. Whereas he found a drop in the curves on formation of the ester, here a fairly sharp rise takes place. In order to determine whether the difference was due to the different natures of the reactions or simply to differences in apparatus and working conditions, Gibson's experiment was repeated using the apparatus already described but replacing the platinum foil anode by one of platinum wire. With N-trichloroacetic acid, a similar curve to Gibson's was obtained.

* The gold electrodes even under low potentials soon became coated with a brown covering of dispersed gold. The current and potential readings, however, were quite as constant as in the case of platinum, so it may be assumed that in spite of this "spattering" the surface area remained practically constant throughout.

This type of curve was also given when potassium trichloroacetate was used as electrolyte. With potassium ethyl malonate, however, a curve similar in all respects to that of Fig. 1 was obtained. The difference is therefore connected with the nature of the reactions at the anode and may be conditioned by the presence or

absence of halogen. Gibson assumes that the anode changes from "platinum α," which is stable at low potentials and which does not favour synthesis, to "platinum β," stable above 2·2 volts and favouring synthesis. The following facts would seem to lend support to this view. After a solution of potassium ethyl malonate had been electrolysed for a time at an anode potential above the synthetic value the applied *E.M.F.* was reduced so as to bring the anode potential below this value; the resulting current always approximated after a short interval to that obtained when ascending the curve. This was not the case when potassium trichloro-

FIG. 1.

Curve IB: *Bright platinum.* *Curve* IG: *Grey platinum.*

Vertical axis: on left, current in milliamperes ⊙; *on right, oxygen per hour in c.c.* ×.

acetate was the electrolyte. For instance, a solution of the latter was electrolysed for 20 hours at a high potential. The anode potential was then 2·8 volts and the current 0·3 m.a. The applied *E.M.F.* was then reduced, the anode potential becoming 2·2 volts and the current 0·07 m.a. On the ascending curves the current corresponding to this potential was 0·65 m.a., nearly ten times as large. The anode was still covered with the large bubbles typical of synthesis, although the potential was now well below the synthetic potential. On removing these bubbles by rubbing with a piece of wire (without interruption of the current), although there was a momentary rise of current, it subsequently returned

rapidly to 0·07 m.a. as large bubbles reformed on the anode. Repeated rubbings effected no permanent change. The electrolysis was then allowed to proceed undisturbed for 5 days with the same constant applied *E.M.F.* At the end of this time, anode potential was still 2·2 volts, but the current had increased to 0·7 m.a., a value agreeing well with the 0·65 m.a. obtained in the ascending series. On Gibson's hypothesis, these results are simply explained by assuming that " platinum β " was formed on the surface of the anode during its period of high potential, that this " platinum β " continued to function as a synthetic agent on reduction of the potential below the normal synthetic value, but after the lapse of sufficient time it, being metastable at low potentials, had gradually reverted to " platinum α " with resulting cessation of synthesis and rise of current.

Interpretation of the Results.—When potassium ethyl malonate is electrolysed, the anion $CO_2Et{\cdot}CH_2{\cdot}CO{\cdot}O'$ is discharged at the anode. On discharge, this may react with the water, or with another similar anion, or the oxygen liberated from the water may oxidise ethyl hydrogen malonate. These possibilities are shown in the equations, where R stands for $CH_2{\cdot}CO_2Et$.

$$\text{Ia. } 2R{\cdot}CO{\cdot}O + H_2O = 2R{\cdot}CO_2H + O.$$
$$\text{Ib. } 2R{\cdot}CO_2H + O = R{\cdot}R + 2CO_2 + H_2O.$$
$$\text{II. } 2R{\cdot}CO{\cdot}O = R{\cdot}R + 2CO_2.$$
$$\text{III. } R{\cdot}CO_2H + 10\ O = 5CO_2 + 4H_2O.$$

Other subsidiary reactions may occur, but in the case of the malonates these are very limited in degree. Equation Ia represents the reaction of the anion with water with liberation of atomic oxygen. If this atomic oxygen unites with another atom, molecular oxygen is produced and escapes as gas at the anode. An equivalent quantity of hydrogen will be produced at the cathode by the reaction of the potassium ions, and the whole therefore amounts to the simple electrolysis of water. Equation Ib represents the formation of diethyl succinate as a result of the oxidation of the ethyl hydrogen malonate formed at the anode by the atomic oxygen simultaneously liberated. Equation II represents two discharged anions as uniting to form the same product, a molecule of carbon dioxide splitting off from each of them. Equation III represents complete oxidation of hydrogen ethyl malonate to carbon dioxide and water. It remains to determine which reactions prevail with the different electrodes and with different potentials. In general, equation Ia represents the prevailing reaction at low potentials. It would appear justifiable to look on this reaction as being maintained during rise of potential and to consider reaction Ib, II,

or III as being superimposed on it (compare Gibson, *loc. cit.*, p. 482).

FIG. 2.

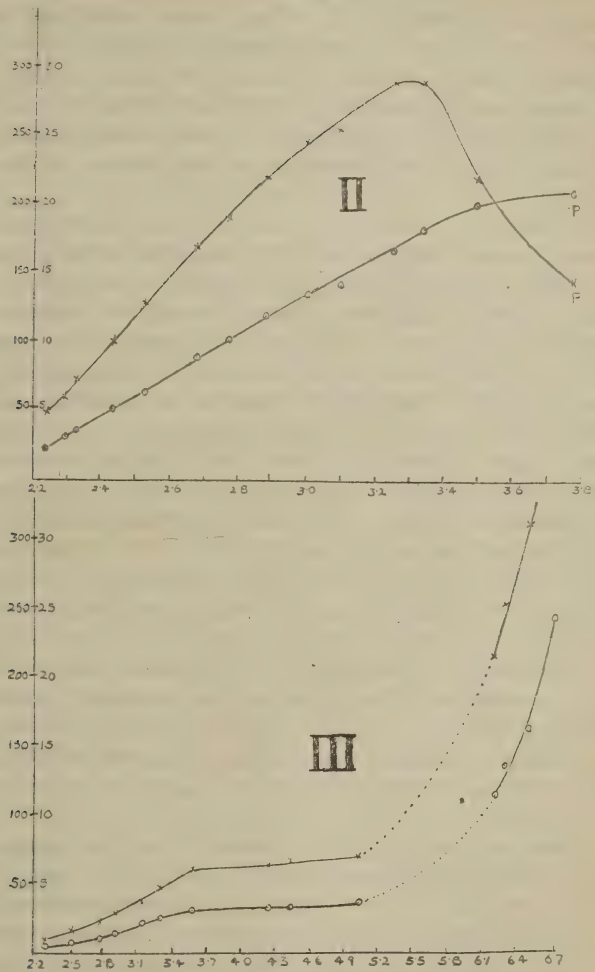

FIG. 3.

Curve II: *Platinised platinum.* *Curve* III: *Gold.*

Horizontal axis: anode potential, ϵ_H, *in volts.*
Vertical axis: on left, current in milliamperes ⊙; *on right, oxygen per hour in c.c.* ×.

There are then three possible forms of oxygen curve. (1) If reaction Ia alone holds throughout the whole range, the amount of oxygen evolved per unit time would be directly proportional to

the current, and would rise steadily with increasing potential, giving a continuously ascending curve. (2) If reaction II were superimposed at any stage, since no oxygen is either used up or produced by it, presumably the oxygen curve would here reach a maximum and then remain approximately at that value. (3) If either reaction Ib or III was superimposed, some of the oxygen formed in reaction Ia would be used for oxidation work and a fall in the value of oxygen evolved per unit time would thereby result.

We will now apply this reasoning in turn to each of the cases studied.

Bright Platinum (Curve Ib).—The oxygen curve rises with increase of potential and current to a maximum at a potential of 2·3 and then rapidly falls until at potential = 2·45 practically no oxygen is evolved. Synthesis of diethyl succinate therefore takes place at anode potential = 2·3, and this synthesis is performed with the help of the atomic oxygen liberated at the anode or according to equation Ib. This point is therefore an oxidation potential, not a discharging or decomposition potential, as it would be if equation II held. It will be noted also that the current curve begins to rise steeply about this point, although no break has been shown in the curve. This can be readily explained as being due to depolarisation of the anode resulting from the oxygen removal. At low potentials, the oxygen is never equal to half the hydrogen, as it would be if reaction Ia occurred alone, an appreciable quantity of carbon dioxide being always produced. This may result from either reaction Ib or III taking place, *i.e.*, either synthesis occurring below the apparently limiting potential or complete oxidation of part of the electrolyte. It is probable, as will be shown later, that the oxygen deficiency represents a complete oxidation of a small portion of the electrolyte to carbon dioxide and water (compare Murray, *loc. cit.*).

Grey Platinum (Curve Ig).—The curves for grey platinum resemble those for smooth platinum, the maximum in the oxygen curve being, however, less sharp. It is also noteworthy that before this point is reached the carbon dioxide evolved became relatively high as with smooth platinum. The reactions taking place are therefore probably the same in both cases. Although there is no direct experimental evidence to support the hypothesis, it seems probable that the comparative differences may be due to differences in surface current density.

Platinised Platinum (Curve II).—The oxygen and current curves rise steadily until an anode potential of about 3·3 is reached. The oxygen curve then falls while the current curve still ascends, although somewhat less steeply. If any synthesis takes place,

it is exceedingly small in amount, as is proved by the fact that on electrolysing 100 c.c. of solution between platinised platinum electrodes for 2 hours with a current of 2·5 amperes and extracting the resulting solution with ether, there remained on removal of the ether only a trace of an oily film which had not the characteristic odour of diethyl succinate. It would appear, therefore, that above an anode potential of 3·3 complete oxidation of the electrolyte (equation III) takes place in amount sufficient to produce a fall in the oxygen evolved. This is also shown by the larger increase in carbon dioxide. Below this value, only small quantities of carbon dioxide are produced, and relatively these are very much smaller compared with the oxygen evolved than is the case with smooth platinum. In order to test conclusively whether carbon dioxide is evolved at very low potentials, the following experiment was carried out. A modified apparatus was used which allowed a current of air free from carbon dioxide to be passed through the electrolyte. This was fitted with platinised electrodes and half filled with malonate solution to which a few drops of dilute sulphuric acid had been added. With no current passing, a slow stream of air was aspirated through the solution and then bubbled through a single drop of lime water contained in a small bubbling apparatus. After 2 hours there was no sign of milkiness in the lime water. This proved the malonate solution to be free from carbonate. A current of 10 milliamperes was then passed with an anode potential of 1·83, the same air current being continued. After $\frac{1}{4}$ hour there was evidence of carbon dioxide and after 1 hour the milkiness was very definite. Oxidation was therefore taking place even at this very low potential. Since there is little doubt that the only oxidation occurring with platinised platinum is the complete oxidation of equation III, this would support the conclusion that in the case of smooth platinum the carbon dioxide produced at low potentials is due to this reaction.

Gold (Curve III).—With gold electrodes at low potentials there is a very small yield of carbon dioxide, but its presence was proved by an experiment similar to that described in the case of platinised platinum. It probably represents a small amount of complete oxidation. The oxygen evolved rises steadily till a potential of 3·6 is reached, then remains practically constant till potential = 5·0. Thereafter occurs a region of oscillating potentials. With an applied *E.M.F.* between the electrodes of 7·3 volts, the current varied during 12 hours between the limits of 40 and 8 milliamps., with corresponding anode potential variation of 5·0—6·0. Both rise and fall were very slow, each occupying from 1 to 2 hours, and they showed no diminution in magnitude with time. Above

potential = 6·2, rapidly ascending smooth curves are obtained. The carbon dioxide evolved remains very small throughout and even at the highest potential reached the oxygen deficiency is only about 10%. It would thus appear that with gold there is very little oxidation of any kind, the main reaction throughout being that of equation Ia. The peculiar nature of the curves between anode potentials of 3·6 and 6·2 is doubtless due to some form of electrode effect, most probably the formation of an oxide of gold. On this assumption one can imagine that at potential 3·6 the atomic oxygen liberated at the anode, instead of combining to form molecular oxygen, begins to combine with the gold. This tendency continues until potential = 5·0, the gradual reduction in conductivity of the electrode due to the formation of the film of oxide rendering this portion of the curve flat. Above this potential, *i.e.*, throughout the dotted portion of the curve where readings were not obtainable, the oxide film is alternately formed and destroyed as the potential varies between about 5·0 and 6·0, the lower potential favouring the formation of oxide and the higher one causing it to decompose with oxidation of the electrolyte. The variation in the conductivity of the electrode during these changes accounts for the changes in current, which throughout shows oscillations in an inverse direction to those of the potential. The final sharp rise in the curves represents a range where the oxide is either not formed or is destroyed as soon as formed and no polarising effect occurs.

Summary.

(1) The formation of diethyl succinate on electrolysis of potassium ethyl malonate is shown to be an oxidation reaction and to take place only when the anode is of a suitable material and when its potential exceeds 2·3—2·4 volts referred to the normal hydrogen electrode as standard. The results are in general agreement with the views expressed by Gibson.

(2) Grey platinum resembles smooth platinum in its behaviour as electrode material.

(3) With platinised platinum and with gold anodes no synthesis occurs; but whereas the former at a potential of 3·3 causes a large oxidation of the electrolyte to carbon dioxide and water, with the latter little oxidation occurs even at potentials over 6.

(4) What appears to be complete oxidation of a portion of the electrolyte occurs with all the anode materials used, even at very low potentials. The extent of this oxidation is small with platinised platinum and gold, more considerable with smooth platinum and grey platinum.

(5) With gold a peculiar instability is observed, and an explanation of this is suggested.

My thanks are due to Professor Sir James Walker, F.R.S., for suggesting the lines of this research, and for helpful criticism during its performance.

CHEMICAL DEPARTMENT,
UNIVERSITY OF EDINBURGH. [*Received, June 6th*, 1925.]

CCLXXXII.—*The Reaction of Bromine with Aliphatic Acids. Catalytic Effect of Acyl Halides.*

By HERBERT BEN WATSON.

THE investigation of the mechanism of the α-bromination of aliphatic acids originated in the isolation by Steiner (*Ber.*, 1874, **7**, 184) of a red additive compound of acetic acid, bromine, and hydrogen bromide, which decomposed in absence of water to give hydrogen bromide and monobromoacetic acid, and the accelerating effect of hydrogen bromide was interpreted by Hell and Mühlhäuser (*Ber.*, 1879, **12**, 727) on the hypothesis that bromination was preceded by the formation of a compound of this type. Hell and Urech (*Ber.*, 1880, **13**, 531) showed that, although the velocity of bromination is dependent on the concentration of bromine, the reaction is not of the simple bimolecular type, an initial period of very low velocity being followed by a comparatively rapid disappearance of the halogen; and they regarded this observation as confirmation of Hell and Mühlhäuser's hypothesis.

The rapid bromination of aliphatic acids in presence of phosphorus or sulphur (Hell, *Ber.*, 1881, **14**, 891; Volhard, *Annalen*, 1888, **242**, 141; Zelinsky, *Ber.*, 1887, **20**, 2026) was regarded originally as involving complete conversion of the acid into acid bromide, followed by bromination of the latter, but this interpretation is not applicable to cases where a very marked acceleration results from the presence of quantities of phosphorus or sulphur which are insufficient for any large conversion (*e.g.*, Gorodetzky and Hell, *Ber.*, 1888, **21**, 1729; Ward, J., 1922, **121**, 1161).

A new view of the reaction was put forward by Lapworth (J., 1904, **85**, 41). He observed that hydrogen chloride, as well as hydrogen bromide, has a catalytic effect, and he regarded this action as being of the same nature as the influence of acids on keto-enol changes; accordingly, he suggested that the bromination of carboxylic acids, like that of acetone, involves a relatively slow catalysed change to the enolic form, followed by instantaneous addition of

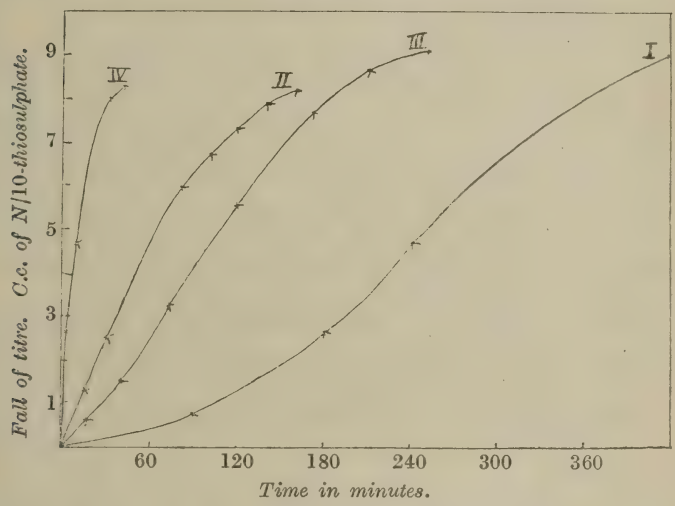
bromine at the point of unsaturation, and finally by loss of hydrogen bromide.

$$R{\cdot}CH_2{\cdot}CO_2H \xrightarrow{\text{catalyst}} R{\cdot}CH{:}C\begin{matrix}OH\\OH\end{matrix} \xrightarrow{Br_2} R{\cdot}CHBr{\cdot}C\begin{matrix}Br\\OH\\OH\end{matrix} \longrightarrow$$

$$R{\cdot}CHBr{\cdot}CO_2H + HBr.$$

He attributed the catalytic influence of *small* quantities of phosphorus to the formation of hydrogen bromide by the action of the phosphorus bromides on traces of water present or on the acid itself. This " enolic form theory " was adopted by Aschan (*Ber.*, 1912, **45**, 1913) to explain the production of brominated acid bromide and brominated acid chloride when bromine reacts with an acid chloride : but Meyer (*Ber.*, 1912, **45**, 2868) pointed out that such an interpretation is unnecessary, since the observation is explained equally well by assuming substitution followed by a reaction of hydrogen bromide with the brominated acid chloride (compare Staudinger and Anthes, *Ber.*, 1913, **46**, 1417). The results of an investigation of the bromination of acids in presence of small quantities of phosphorus were interpreted by Ward (*loc. cit.*) on the basis of Lapworth's suggestion, but he points out (J., 1923, **123**, 2212) that the theory demands the existence of carboxylic acids in a form which is neither observed nor indicated in other reactions : in the case of ketones, aldehydes, and compounds containing the $-CO{\cdot}CH_2{\cdot}CO-$ grouping where the theory has been applied successfully (Lapworth, J., 1904, **85**, 30; Dawson and Leslie, J., 1909, **95**, 1880; Dawson, Burton, and Ark, J., 1914, **105**, 1275; Meyer, *Annalen*, 1911, **380**, 235; *Ber.*, 1912, **45**, 2867; West, J., 1924, **125**, 1277), the existence of an enolide is indicated in other reactions.

The very powerful accelerating effect of a small quantity of acetic anhydride on the chlorination of acetic acid was observed by Hentschel (*Ber.*, 1884, **17**, 1286), and is now utilised in the industrial preparation of monochloroacetic acid. Hentschel postulated a pair of alternating reactions of the following type,



$$(CH_3{\cdot}CO)_2O + Cl_2 = CH_2Cl{\cdot}CO_2H + CH_3{\cdot}COCl \quad . \quad . \quad . \quad . \quad (1)$$

$$CH_3{\cdot}COCl + CH_3{\cdot}CO_2H = (CH_3{\cdot}CO)_2O + HCl \quad . \quad . \quad . \quad . \quad (2)$$

The individual reactions (1) and (2) had been observed by Gal (*Ann. Chim. Phys.*, 1869, **66**, 187) and Anschütz (*Annalen*, 1884, **226**, 1). Shaw (J., 1923, **123**, 2233) found that acetic anhydride similarly accelerates the bromination of acetic and homologous acids, and suggested that bromination may take place either (*a*) through the preliminary enolisation of the acid, or (*b*) through a series of changes involving acetic anhydride, similar to those postulated by Hentschel, the latter course being by far the more rapid.

A re-examination of the action of bromine on acetic, propionic, and *n*-butyric acids at 100° has been undertaken by the author, and the results are summarised in the following.

(a) *Catalytic Effect on Halogen Acids.*—When no catalyst is present initially, the course of the reaction indicates autocatalysis by the hydrogen bromide formed (see curve I): a "period of acceleration" is followed by the attainment of a maximum velocity, and the reaction then becomes steadily slower: variation in the initial concentration of bromine has a marked effect (compare Hell and Urech, *loc. cit.*). If hydrogen bromide is present initially, the

Acetic acid and bromine. Initial $[Br_2] = 0{\cdot}24\,M$.

I. *No added catalyst.* II. HBr *introduced* (0·268 *M*).
III. HCl *introduced* (0·317 *M*). IV. AcBr *introduced* (0·047 *M*).

reaction proceeds more quickly: a very small quantity of the halogen acid reduces the period of acceleration to a marked extent, and in presence of a moderate initial concentration of hydrogen bromide (0·2*M*) this period disappears (see curve II). The velocity is thus dependent on the concentration of bromine and that of hydrogen bromide: no simple mathematical relationship has been found for acetic and *n*-butyric acids, but in the case of propionic acid, when the acid is present in large excess, the velocity is represented with a tolerable degree of accuracy by the expression $v = k[Br_2][HBr]^{\frac{1}{2}}$. This expression holds over a wide range of concentration of hydrogen bromide extending from zero to molar (see Table II): when, however, the concentration of the halogen acid is very great (2*M*), a retarding influence comes into play.

This is undoubtedly due to perbromide formation, as indicated by the pale colour of the reaction mixture (compare Joseph and Jinendradasa, J., 1911, **99**, 274), a similar retardation having been observed in other reactions (Bugarsky, *Z. physikal. Chem.*, 1901, **38**, 561; 1904, **48**, 63; Bognar, *ibid.*, 1910, **71**, 529; Orton and Jones, *Rep. Brit. Assoc.*, 1910, 99). Hydrogen chloride also exerts a catalytic effect (compare Lapworth, Shaw), but is somewhat less effective than hydrogen bromide, and when it is present even at saturation the initial period of acceleration does not disappear completely (see curve III). The velocity does not remain constant as stated by Shaw (*loc. cit.*), who apparently took an insufficient number of points on the curve.

In order to determine whether this catalytic action is common to all acids, the effect of small quantities of trichloroacetic and sulphuric acids was examined. The effect of trichloroacetic acid is scarcely perceptible (see Table 1, *a* and *b*) : sulphuric acid also has but little effect, but the bromination is here complicated by side reactions. The marked catalytic effect of halogen acids is clearly specific, and not common to acids in general, and this fact together with the dependence of the velocity on the concentration of bromine is evidence against the validity of the " enolic form theory."

(b) *Catalytic Effect of Acetyl Bromide.*—The very powerful acceleration produced by the presence of a small quantity of acetic anhydride was observed by Shaw (*loc. cit.*), and a fuller investigation of this reaction at 100° has established the following facts (the acetic acid used contained 0·1% of water, and in all cases was present in very great excess) :

(1) If the anhydride is not in excess of the water present in the acid, no catalytic effect is observed.

(2) When the anhydride is in excess of the water, a short period of acceleration (which escaped Shaw's notice) is followed by a rapid reaction : after the initial period, the velocity is proportional to the concentration of bromine, and varies directly and almost proportionately with that of the anhydride (see Tables IV and V). The effect of acetic anhydride, as compared with that of halogen acids, is seen from the following :

Catalyst added.	No catalyst.	HBr = 0·053*M*.	HCl = 0·063*M*.	Ac_2O = 0·05*M*.
Initial titre (N/10-$Na_2S_2O_3$) ...	9·48	9·58	10·02	9·25
Fall of titre in 45 mins.	0·25	1·55	0·78	9·05

(3) If hydrogen bromide, in excess of the anhydride, is also introduced, the initial period of acceleration disappears, and the velocity is proportional to the concentration of bromine from the commencement. The actual value of k_1 is somewhat smaller than in (2), and

becomes very considerably smaller when the concentration of hydrogen bromide is high (see Table VI). This may be attributed to perbromide formation, which is indicated by the colour of the reaction mixture : such combination becomes more extensive as the water content of acetic acid diminishes (Jones, J., 1911, **99**, 402). A slight falling off in the value of k_1 towards the end of the reaction, which was observed in some of the experiments, is probably due to the same cause.

(4) The presence of hydrogen chloride in excess of the anhydride does not destroy the catalytic effect of the latter, as stated by Shaw (*loc. cit.*), but exerts a comparatively small retarding influence. Here again, after the initial period, the velocity is proportional to the concentration of bromine (see Table VII).

It is suggested that these results are best interpreted as follows : when a mixture of acetic acid, bromine, and acetic anhydride is heated at 100°, the anhydride not being in excess of the water present in the acid, complete and relatively instantaneous hydrolysis of the anhydride takes place, and no acceleration is observed. If the anhydride be in excess of the water, the first reaction consists in an immediate removal of water by hydrolysis of the equivalent quantity of anhydride. The remainder then reacts with bromine, $(CH_3{\cdot}CO)_2O + Br_2 = CH_2Br{\cdot}CO_2H + CH_3{\cdot}COBr$ (Gal, *loc. cit.*) : with the quantities of anhydride employed in the investigation, the percentage of the total bromine required for this reaction is small, being equivalent to about 0·5 c.c. of N/10-thiosulphate. The conclusion is thus reached that the observed acceleration is due to the presence of acetyl bromide. If this be the case, the velocity will reach its maximum value only when the bromination of the anhydride is complete, and thus the period of acceleration is accounted for. In presence of the more powerful catalyst the influence of the hydrogen bromide formed is inappreciable (or perhaps is balanced by perbromide formation), and there is no apparent autocatalysis : the reaction therefore follows the first order. If hydrogen bromide is present initially in excess of the anhydride, it reacts with great speed according to the equation $(CH_3{\cdot}CO)_2O + HBr = CH_3{\cdot}CO_2H + CH_3{\cdot}COBr$ (compare Gal, *loc. cit.*, on the reaction of hydrogen chloride with acetic anhydride). The acid bromide is then present from the commencement at its maximum concentration, and there is no period of acceleration.

In order to obtain direct evidence of the accelerating influence of acetyl bromide, the bromination of acetic acid in presence of varying small quantities of the acid bromide (introduced as such) was studied ; the results confirmed the hypothesis outlined above (see Tables VIII and IX). When the acetyl bromide is not in

excess of the water present in the acid, the reaction follows, as would be expected, the same course as when hydrogen bromide alone is introduced, while the acid bromide, present in excess of the water, is an exceedingly powerful catalyst * (see curve IV). Its effect is similar to that of the anhydride at equivalent concentration save that (*a*) the velocity is now proportional to the concentration of bromine from the commencement, and (*b*) the values of k_1 are somewhat lower (perbromide formation), and in agreement with the values obtained in presence of acetic anhydride and hydrogen bromide in conjunction. Measurements employing varying initial quantities of the catalyst showed that the velocity is proportional to the concentration of acetyl bromide (see Table X).

Acetyl bromide exerts a similar influence on the bromination of other aliphatic acids. The effect of acetic anhydride on the bromination of the homologues of acetic acid was observed by Shaw (*loc. cit.*), and the author has shown that acetic anhydride and acetyl bromide accelerate the bromination of propionic and *n*-butyric acids in a manner exactly similar to that described for acetic acid.

Examination of the effect of acetyl chloride has shown that if the acid chloride is not in excess of the water present it produces the same effect as does hydrogen chloride, while if it is in excess of the water the bromination is initially much faster than in presence of halogen acids, but less rapid than in presence of acetyl bromide : when sufficient hydrogen bromide has been produced to bring about complete conversion of the acid chloride to acid bromide ($CH_3 \cdot COCl + HBr \rightleftharpoons CH_3 \cdot COBr + HCl$, Staudinger and Anthes, *loc. cit.*) a rapid first-order reaction takes place : the actual value of k_1 is the same as when acetic anhydride is initially present and somewhat greater than when acetyl bromide is introduced initially (less " fixing " of bromine as perbromide). Acetyl chloride is thus a less powerful catalyst than acetyl bromide. The retarding in-

* An anomalous result obtained by Ward (J., 1922, **121**, 1164) receives a simple interpretation in the light of this fact. He found that acetic acid, previously saturated with hydrogen bromide, did not react completely with a molecular proportion of bromine after heating at 100° for *three* hours, and this observation is in harmony with the results of Lapworth (*loc. cit.*) and of the author. On the other hand, when he introduced acetyl bromide for the purpose of dehydrating the acid and at the same time providing halogen acid, he carried out the bromination in *one* hour. The amount of acetyl bromide added (3 g. to 50 g. of acetic acid) was equivalent to the water content of an acid having 0·878% of water (m. p. rather above 15°). Ward's acid had been purified by freezing, and it is unlikely that it contained such a high percentage of water. The indications are that the acetyl bromide was in excess of the water, and that its presence was responsible for the rapid bromination.

fluence of an excess of hydrogen chloride on the bromination in presence of acetic anhydride may then be attributed to the formation of acid chloride from the anhydride $(CH_3{\cdot}CO)_2O + HCl = CH_3{\cdot}CO_2H + CH_3{\cdot}COCl$ (Gal, *loc. cit.*); complete conversion of acid chloride into acid bromide during the reaction is here prevented by the excess of hydrogen chloride, and hence the comparatively small value of k_1.

(c) *Catalytic Effect of Acid Bromides in General.*—Investigation of the bromination of acetic and propionic acids in presence of bromoacetyl, propionyl, and benzoyl bromides has revealed the fact that the introduction of any one of these acid bromides brings about an acceleration identical with that which is produced by acetyl bromide at equivalent concentration. The velocity is proportional to the concentration of bromine and of acid bromide, and the values of k_1 are the same in each case (see Tables X and XI).

The introduction of benzoyl chloride into a reaction mixture of bromine and acetic acid produces an effect which is similar to that of acetyl chloride at equivalent concentration, except that the velocity is slightly less (see Table XII).

Discussion of Results.

1. The peculiar catalytic influence of *acid bromides* on the bromination of aliphatic acids may possibly involve the following steps. The acid bromide is first brominated,

$$R{\cdot}CH_2{\cdot}COBr + Br_2 = R{\cdot}CHBr{\cdot}COBr + HBr \quad . \quad . \quad . \quad (1)$$

The aliphatic acid (present in very great excess) then reacts with the brominated acid bromide,

$$R{\cdot}CHBr{\cdot}COBr + R{\cdot}CH_2{\cdot}CO_2H = R{\cdot}CH_2{\cdot}COBr + R{\cdot}CHBr{\cdot}CO_2H \quad (2)$$

the final product being the brominated acid, and the acyl bromide going through the same series of changes again.

The results of Urech (*Ber.*, 1880, **13**, 1688) indicate that the bromination of acetyl bromide is a reaction of the second order; in the scheme outlined above, the concentrations of acid bromide and brominated acid bromide remain constant during the reaction, while that of the acid is very large; for a given initial concentration of acid bromide, therefore, the velocity will vary only as the concentration of bromine, but will be proportional to the initial concentration of acid bromide. This is in complete agreement with the observed facts.

If the bromide of a different carboxylic acid be present initially, an exactly similar acceleration is observed, and a similar mechanism is thus indicated. This is interpreted most simply by supposing that reactions (1) and (2) above are preceded by

$$R'{\cdot}COBr + R{\cdot}CH_2{\cdot}CO_2H = R{\cdot}CH_2{\cdot}COBr + R'{\cdot}CO_2H,$$

which is exactly similar in character to reaction (2). This idea is in harmony with the observation of Polzenius (*Chem. Ztg.*, 1896, **20**, 46) that benzoyl chloride and acetic acid when heated together yield benzoic acid and acetyl chloride, whilst a similar reaction was suggested by Orton (J., 1901, **79**, 1351) as providing a possible explanation of the formation of acid amides by the reaction of benzoyl chloride with carboxylic acids in presence of ammonia.

The catalytic action of acid bromides cannot be interpreted by postulating the intermediate formation of the acid anhydride (compare Shaw, *loc. cit.*) or of a mixed anhydride, for an initial period of low velocity is observed when the anhydride is introduced, but not when the acid bromide is present initially.

2. *Acid chlorides* are less powerful catalysts than acid bromides, but their effect may be interpreted in a similar manner by postulating the reactions

$$R'\cdot COCl + R\cdot CH_2\cdot CO_2H = R\cdot CH_2\cdot COCl + R'\cdot CO_2H,$$
$$R\cdot CH_2\cdot COCl + Br_2 = R\cdot CHBr\cdot COCl + HBr,$$
$$R\cdot CHBr\cdot COCl + R\cdot CH_2\cdot CO_2H = R\cdot CH_2\cdot COCl + R\cdot CHBr\cdot CO_2H.$$

It must be assumed that one or more of these reactions proceed less rapidly than the corresponding reactions involving the acid bromide. The hydrogen bromide formed in the reaction, however, now reacts with the acid chloride (or brominated acid chloride), and the above reactions are gradually replaced by those in which the acid bromide takes part (compare Staudinger and Anthes, *loc. cit.*). The velocity ultimately attained will depend on the proportion of acid bromide or brominated acid bromide present in the equilibrium $R\cdot CH_2\cdot COCl + HBr \rightleftharpoons R\cdot CH_2\cdot COBr + HCl$ or the equilibrium $R\cdot CHBr\cdot COCl + HBr \rightleftharpoons R\cdot CHBr\cdot COBr + HCl$, and is not likely to be identical for all acid chlorides. This is in harmony with experimental results.

3. The accelerating effect of a small amount of *phosphorus* (Hell-Volhard-Zelinsky reaction) is now interpreted simply. The bromination of acetic acid at 100° in presence of a halogen acid is a slow process requiring at least *six* hours for completion (Lapworth, Ward; compare the author's results, Tables I to III), whilst in presence of a very small amount of phosphorus the reaction is complete in *one* hour (Ward, J., 1922, **121**, 1163). The catalytic effect of phosphorus is thus much more powerful than that of halogen acids, but is of the same order of magnitude as the effect of acid bromides. Moreover, the bromination in presence of phosphorus always results in the formation of a small quantity at least of acid bromide or brominated acid bromide (Ward), and it seems obvious that the acceleration is to be attributed to this small quantity of acid bromide.

4. *Halogen acids.* It may be further suggested that the effect of halogen acids is due to traces of the acid halides present in equilibrium with the aliphatic acid, $R{\cdot}CO_2H + HX \rightleftharpoons R{\cdot}COX + H_2O$. The very different effects of halogen acids and acyl halides indicate that the quantity of acyl halide necessary to produce the observed velocity would be too small for detection, and the existence of such an equilibrium has never been demonstrated. It is not impossible, however, in view of the reversible nature of the hydrolysis of many inorganic chlorides, while it is suggested by reactions of the type $R{\cdot}CN + R'{\cdot}CO_2H + 2HCl = R{\cdot}CO{\cdot}NH_2,HCl + R'{\cdot}COCl$ (Colson, *Compt. rend.*, 1895, **121**, 1155). An interpretation of this type is supported by the following facts : (*a*) the influence of halogen acids is specific, and not common to acids in general; (*b*) Lapworth (J., 1904, **85**, 41) observed that a small quantity of water (which would displace the above equilibrium towards the left-hand side, thus reducing the concentration of acyl halide) reduced very considerably the speed of bromination, and this result has been confirmed by the author; (*c*) when varying amounts of the acid bromide (producing the above equilibrium) are added, there is a continuous increase in velocity as the amount of acid bromide becomes greater, and not a sudden increase at the point where the bromide is just in excess of the water (see Table VIII), whilst, on the other hand, addition of anhydride causes a sudden increase at this point (see Table IV); in the former case, therefore, a gradual increase in the amount rather than a sudden change in the nature of the catalyst is indicated.

The above suggestion, by postulating a similar mechanism in every case, brings into harmony all previous observations of the catalysed bromination of aliphatic acids.

In ascribing the rapid bromination to an initial interaction of bromine with the acyl bromide, no hypothesis is at present put forward as to the stages of this reaction, but it is possible that the acyl bromide " enolises " or passes into an " active " state more readily and rapidly than the acid. In that case, the reaction would be the result of a *rapid* enolisation followed by a *slow* reaction with bromine,

$$R{\cdot}CH_2{\cdot}COBr \xrightarrow{\text{rapid}} R{\cdot}CH{:}C\begin{matrix}OH\\Br\end{matrix} \xrightarrow[Br_2]{\text{slow}} R{\cdot}CHBr{\cdot}C\begin{matrix}Br\\Br\\OH\end{matrix} \xrightarrow{\text{rapid}} R{\cdot}CHBr{\cdot}COBr + HBr$$

compare West, J., 1924, **125**, 1282). In such a suggestion α-bromination finds an easy explanation.

Experimental.

The acetic acid used throughout the investigation, except where otherwise indicated, melted at 16·4° (H_2O = 0·1%). All specimens of Kahlbaum's " 100% acetic acid " examined were completely free from impurities which react with bromine at the ordinary temperature : in some cases, this acid melted at 16·4°, and was used without fractionation, while from specimens of lower melting point (16 — 16·2°) good yields of acid melting at 16·4° were obtained by fractional distillation through an eight-pear still-head. Post-war acetic acids of British manufacture which were not stable to bromine at the ordinary temperature were purified by distillation from chromic anhydride (Orton and Bradfield, J., 1924, **125**, 960) followed by fractionation. The propionic and *n*-butyric acids were prepared by distillation of " Kahlbaum " acid, the fractions used boiling respectively at 140·8—141°/764 mm. and 162·2—162·3°/766 mm. Solutions of bromine in these acids showed no appreciable fall of thiosulphate titre after several days at 25°. The bromine was shaken three times with an equal volume of water, dried under concentrated sulphuric acid, and finally separated and distilled from a little barium carbonate in an all-glass apparatus.

The method employed in the velocity measurements was similar to that of Hell and Urech (*loc. cit.*) and of Shaw (*loc. cit.*). A reaction mixture was made up containing the aliphatic acid, bromine, and the catalyst in the desired proportions, the aliphatic acid always being in large excess. The thiosulphate titre of 2 c.c. was determined, and portions of 2 c.c. were then introduced into small tubes : the tubes were sealed immediately, and immersed in a bath of boiling water. At given intervals tubes were withdrawn, broken under aqueous potassium iodide, and the iodine was titrated against standard thiosulphate. The figures in the tables which follow refer to c.c. of N/10-thiosulphate : time is stated throughout in minutes.

Catalytic Effect of Halogen Acids.

Solutions of hydrogen bromide in the aliphatic acids were prepared by dropping aqueous hydrobromic acid (*d* 1·7) on to phosphorus pentoxide, and passing the evolved gas over moist red phosphorus then over phosphorus pentoxide, and finally into the aliphatic acid. The solutions of hydrogen chloride were obtained by dropping pure concentrated hydrochloric acid into pure concentrated sulphuric acid, and passing the gas liberated over calcium chloride and then into the aliphatic acid. The concentrations of the solutions were determined by precipitation as silver bromide or chloride, and the required volumes were introduced into different reaction mixtures

Effect of Acetyl Bromide.

The acetyl bromide was purified from dissolved halogen acid by bubbling dried air through the liquid under reduced pressure, and then fractionally distilled. Reaction mixtures of acetic acid, bromine, and varying small quantities of the acid bromide were made up and treated as before. The results are indicated in Tables VIII and IX.

Comparison of Effects of Different Acid Bromides.

Pure acetyl bromide was obtained as already described. Propionyl, benzoyl, and bromoacetyl bromides were prepared by treatment of propionic, benzoic, and acetic acids respectively with the required quantities of red phosphorus and bromine. The product was distilled from the phosphorus compounds under reduced pressure, and finally fractionated at ordinary pressure (compare Claisen, *Ber.*, 1881, **14**, 2473; Auwers and Bernhardt, *Ber.*, 1891, **24**, 2219). Reaction mixtures containing acetic or propionic acid (in large excess), bromine, and equivalent quantities of the different acid bromides were made up, and the reaction at 100° followed as before.

CCLXXXIII.—*Homologues of 2 : 2′-Diquinolyl.*

By Edward John Venn Conolly.

2 : 2′-Diquinolyl was prepared by Weidel (*Monatsh.*, 1881, **2**, 491; 1886, **7**, 327) by the action of sodium on quinoline, and its constitution proved by Weidel and Strache (*ibid.*, 1886, **7**, 306) from a study of its oxidation products. The preparation of homologues from 6-, 7-, and 8-methylquinolines is described below. During this work several instances of steric hindrance were observed. Thus, under the conditions stated below, good yields of the corresponding diquinolyls (I) and (II) were obtained from 6- and 7-methylquinolines, but the yield from 8-methylquinoline was very small; the substitution of potassium for sodium did not materially alter the results. The proximity of the methyl group to the nitrogen atom in the pyridine ring therefore seems to hinder the union of the two quinolyl nuclei. Also an ethiodide of 8 : 8′-dimethyl-2 : 2′-diquinolyl (III) could not be obtained even at 180°, possibly because the tertiary nitrogen atoms are practically "di-ortho-substituted."

While attempting to prove the constitution of the diquinolyls by a Fittig-Wurtz synthesis, the method of Tschitschibabin (*Ber.*, 1923, **56**, 1879) was used for the preparation of 6-methylcarbostyril.

Experimental.

6 : 6′-Dimethyl-2 : 2′-diquinolyl (I).—6-Methylquinoline (70 g.) and sodium (7 g.) in small pieces were heated together at about 100° during 2 hours and then at 150—160° during 7 to 8 hours. The dark brown, extremely viscous product, which solidified when cooled, was triturated with dry ether; sodium was removed by means of a fine sieve, and the ethereal solution filtered. The light brown residue of crude dimethyldiquinolyl (yield 37 g.) was extracted once with alcohol (100 c.c.), which removed most of the dark coloured impurities, and the light yellow residue was then repeatedly crystallised from benzene, until constant in melting point.

The ethereal filtrate obtained above was evaporated and the oily product distilled up to 160°/20 mm.; the dark red residue, which gradually solidified, when recrystallised from benzene gave a further small yield of the dimethyldiquinolyl.

6 : 6′-*Dimethyl*-2 : 2′-*diquinolyl* crystallises from benzene in small, colourless needles, m. p. 202·5—203° (Found: C, 84·6; H, 5·8; *M*, in camphor by Rast's method, 279. $C_{20}H_{16}N_2$ requires C, 84·5; H, 5·6%; *M*, 284). It is moderately soluble in acetone, alcohol, or light petroleum and very soluble in chloroform. It is readily soluble in hot benzene or toluene, less soluble in the cold.

The *hydrochloride* crystallises from hot water in very minute needles. The *picrate*, obtained from the base and picric acid in alcoholic solution, is practically insoluble in acetone, benzene, or chloroform, but fairly soluble in glacial acetic acid, from which it crystallises in small, yellow needles, m. p. 282—283° (decomp.). The *ethiodide*, $C_{20}H_{16}N_2,C_2H_5I$, prepared by heating the base with excess of ethyl iodide in a sealed tube at 150° for 1½ hours, crystallised from much alcohol in sparkling needles, m. p. 277—278° (decomp.; darkening at 275°) (Found: I, 28·2. $C_{20}H_{16}N_2,C_2H_5I$ requires I, 28·9%).

7 : 7′-*Dimethyl*-2 : 2′-*diquinolyl* (II).—7-Methylquinoline (38 g.) and sodium (4 g.) were heated together, and the product was treated with ether, as described above. The brown residue was recrystallised several times from aqueous acetone to remove tarry impurities and finally from carbon tetrachloride. 7 : 7′-*Dimethyl*-2 : 2′-*diquinolyl* was thus obtained in tufts of colourless needles, m. p. 208—209° (Found: C, 84·0; H, 5·8%). It is soluble in alcohol, acetone, chloroform, ethyl acetate, or carbon tetrachloride, but crystallises best from the last-named.

The *picrate* crystallises from alcohol in slender, yellow needles, m. p. 285—286° (decomp.; darkening at 284°). The *ethiodide*, obtained by heating the base with ethyl iodide at 130° in a sealed tube for 1 hour, crystallises from alcohol in clusters of golden-yellow needles, m. p. 274—275° (decomp.).

8 : 8′-*Dimethyl*-2 : 2′-*diquinolyl* (III).—8-Methylquinoline (50 g.) and sodium (4 g.) were heated together under the conditions previously described, but little, if any, diquinolyl was formed; the heating was therefore continued at 150—160° during a further 24 hours. The very viscous, dark brown mass was treated as in the previous cases, the ether evaporated, and the oily product distilled up to 160°/20 mm. The residue, which set to a hard, resinous mass when cold, was dissolved in acetone, and water added until a turbidity ensued; in the course of 3 or 4 days, crystals embedded in resinous matter separated. These were freed from resin

by washing them with acetone, crystallised again from acetone, and fractionally crystallised from carbon tetrachloride (yield very poor).

8 : 8′-*Dimethyl*-2 : 2′-*diquinolyl* forms tufts of colourless needles, m. p. 147—147·5° (Found : C, 84·0; H, 5·6%; *M*, in camphor, 290). It is soluble in benzene, chloroform, alcohol, or ethyl acetate, and crystallises readily from ethyl bromide or ethyl iodide.

The *picrate*, precipitated on mixing alcoholic solutions of the base and picric acid, crystallises from ethyl acetate in yellow needles, m. p. 264—265° after darkening at 258°.

2-*Hydroxy*-6-*methylquinoline*.—When an intimate mixture of finely powdered, freshly fused potassium hydroxide (40 g.) and 6-methylquinoline (44 g.) was heated at 250°, hydrogen was evolved in the theoretical quantity. The cooled reaction mixture was dissolved in water, the solution filtered if necessary, and the crude methylcarbostyril precipitated by the addition of dilute hydrochloric acid. Recrystallised from hot water, it formed long, yellow needles, m. p. 225—230°, and therefore was still impure. On heating at 12 mm., it began to sublime at 50° and passed over at 240—241°; the colourless distillate crystallised from alcohol in monoclinic prisms, m. p. 232—233° (Einhorn and Lauch, *Annalen*, 1888, **243**, 359, give m. p. 228°) (Found : C, 75·6; H, 5·7. Calc., C, 75·5; H, 5·7%).

2-*Bromo*-6-*methylquinoline*.—6-Methylcarbostyril (14 g.) and phosphorus tribromide (30 c.c.) were heated together on the water-bath during 3 hours and the solution was then gently boiled during a further ½ hour. The liquid was poured into water and the 2-bromo-6-methylquinoline distilled in steam; it separated from the distillate in long, colourless needles (yield 5·3 g.) and from alcohol in long, faintly yellow needles, m. p. 117—118° (Fischer and Guthmann, *J. pr. Chem.*, 1916, **93**, 378, give m. p. 126°) (Found : Br, 36·2. Calc., Br, 36·0%).

The *picrate*, obtained from boiling alcoholic solution, crystallised from alcohol in glistening, golden needles, m. p. 140·5°. The *ethiodide*, $C_{10}H_8NBr,C_2H_5I$, prepared by heating the base with excess of ethyl iodide in a sealed tube at 130° during 1 hour, crystallised from ethyl acetate in yellow prisms, m. p. 110—111°.

Attempts to synthesise 6 : 6′-dimethyl-2 : 2′-diquinolyl from 2-bromo-6-methylquinoline by the Fittig-Wurtz reaction and by the use of Grignard reagents were unsuccessful.

The author is indebted to Professor F. S. Kipping, F.R.S., for his interest in this work, and to the Department of Scientific and Industrial Research for a maintenance grant.

UNIVERSITY COLLEGE, NOTTINGHAM. [*Received, June 24th*, 1925.]

CCLXXXIV.—*The Thermal Decomposition of Ozone.*

By Robert Owen Griffith and Andrew McKeown.

In an investigation of the reaction between ozone and hydrogen at 100°, the results of which will shortly be published, it was necessary to compare the intrinsic rate of the reaction $2O_3 \longrightarrow 3O_2$, which occurs simultaneously with the reaction $H_2 + O_3 \longrightarrow H_2O + O_2$, with the velocity of deozonisation in the absence of hydrogen. Several determinations of the rate of thermal decomposition of ozone have already been published, the most important being those of Warburg (*Ann. Physik*, 1902, **9**, 1286), Clement (*ibid.*, 1904, **14**, 342), Jahn (*Z. anorg. Chem.*, 1906, **48**, 260), Perman and Greaves (*Proc. Roy. Soc.*, 1908, *A*, **80**, 353), Chapman and Clarke (J., 1908, **93**, 1638), and Chapman and Jones (J., 1910, **97**, 2463). There is general agreement between these authors that the decomposition of ozone, allowed to proceed in clean glass vessels at temperatures up to 150°, is apparently of the second order, a much better bimolecular than unimolecular constant being obtained, and there is also agreement as regards the order of magnitude of the bimolecular velocity coefficient at a common temperature, *e.g.*, 100°. There is conflict of opinion, however, regarding (*a*) the nature of the reaction, whether it is essentially homogeneous or heterogeneous, (*b*) the effect of pressure on the reaction velocity, and (*c*) the effect of addition of inert gases such as nitrogen. Chapman and Clarke believe that the reaction is practically a homogeneous one, while Perman and Greaves consider that their results indicate the surface of the containing vessel to be the main seat of the change. The present work was not undertaken for the purpose of deciding this point experimentally; our attention has been mainly confined to the effect of addition of other gases and variation of the partial pressure of oxygen on the velocity.

Jahn (*loc. cit.*) found that the velocity of deozonisation in mixtures of ozone and oxygen is inversely proportional to the partial pressure of the latter gas, while Perman and Greaves also found an increased velocity on diminishing the pressure of oxygen, although the effect was less than that obtained by Jahn. On the other hand, Chapman and Jones state that variation in the partial pressure of oxygen in ozonised oxygen is unattended by appreciable change in the velocity of deozonisation. The latter investigators were also unable to detect any effect due to admixture with nitrogen, although this was found by Jahn and by Perman and Greaves to increase the rate of decomposition of ozone.

In view of these discrepancies and also as the results would be of interest for comparison with corresponding velocity data for this reaction in the presence of hydrogen, experiments on the rate of deozonisation at 100° in ozonised oxygen at various pressures and in mixtures of ozonised oxygen with helium, with argon, with nitrogen, and with carbon dioxide have been carried out.

Experimental.

The velocity of deozonisation was measured by the static method, the difference in pressure between the reaction tube and a compensator tube, containing air and maintained at the same temperature, being registered by a manometer containing concentrated sulphuric acid.

The apparatus and experimental methods employed were those of Griffith and Shutt and of Griffith and MacWillie (J., 1923, **123**, 2752, 2767) suitably modified; the materials used in this work are also described in the same papers.

All the experiments were carried out at approximately 100°.

The reaction was followed for 2 to 3 hours, after which the reaction and compensator tubes were quickly cooled to room temperature * and the residual ozone was determined analytically. From the amount of ozone thus found, one could calculate the pressure increase which has to be added to the last pressure difference obtained at 100° to give the value of p_∞, the pressure reading which would have been observed had the reaction gone to completion.

If θ_1 = room temperature,* θ_2 = temperature of the steam, p = pressure increase required (expressed in mm. H_2SO_4), v = common volume of reaction and compensator tubes in c.c., z = number of gram-molecules of residual ozone in reaction tube, π_{θ_1} = total pressure at the temperature θ_1 in the reaction tube expressed in mm. H_2SO_4, and γ = volume of the manometer tubing in c.c. per mm., then it may be shown that

$$p = z \times 380 \times 13{\cdot}59 \times 22412 \times (273 + \theta_1) \times R/(1{\cdot}84 \times 273 \times v \times \alpha).$$

Here $\alpha = (1 + \gamma\pi_{\theta_1})/v$ (compare Griffith and Shutt, *loc. cit.*, p. 2756) and R is a factor the value of which would have been equal to the ratio of the absolute temperatures $273 + \theta_2$ and $273 + \theta_1$, had there been no "dead" space at the higher temperature θ_2, and had there been no alteration in the effective volumes of the reaction and compensator tubes owing to the motion of the manometric liquid. The value of R was determined experimentally;

* In reality, the temperature of the town water supply. The value of ϑ_1 for each experiment is not given in the tables. The mean value for the experiments given in Tables III and IV was 8°.

it depends on the ratio of " dead " space to volume of reaction tube and also on the total pressure; the values found are given in the tables.

Values of the bimolecular velocity coefficients ($k_{obs.}$) were calculated from

$$k_{obs.} = \frac{1}{t_2 - t_1}\left\{\frac{1}{p_\infty - p_2} - \frac{1}{p_\infty - p_1}\right\},$$

p_1 and p_2 being the observed manometric differences at the temperature θ_2 at times t_1 and t_2, respectively (time in minutes).

The coefficients were calculated in all cases between successive time readings, this method being the one best suited to show the magnitude of any " trend " in the constants.

From the values of $k_{obs.}$, the absolute values (k_a) of the coefficients in the units litres/moles-minutes were calculated from the equation

$$k_a = k_{obs.} \times \frac{R}{\alpha} \times (273 + \theta_1) \times 380 \times \frac{13{\cdot}59}{1{\cdot}84} \times 0{\cdot}08207.$$

Four reaction tubes were employed.*

Tube A : of German glass, 42 cm. long and approximately 2 cm. in diameter; volume = 126·5 c.c.; containing 2·0 c.c. of concentrated sulphuric acid spread along its entire length.

Tube B : of German glass, 41 cm. long, 2 cm. in diameter; volume = 125·0 c.c.; containing 3·0 c.c. of concentrated sulphuric acid spread along its entire length.

Tube C : of glass of unknown origin, 31 cm. long, approximately 2·6 cm. in diameter; volume = 153·8 c.c.

Tube D : of English glass, length = 39 cm., diameter = 2·2 cm.; volume = 156·6 c.c.

Most of the experiments were carried out with tube D. Only a few experiments could be carried out with tube A before it cracked, while tube C, though apparently its inner surface was as carefully cleaned as that of the others, gave far higher velocity coefficients and probably contained a trace of some catalytic material. The results of the three experiments performed with this tube are included in the table of results for comparison.

The velocity of deozonisation was determined at 100° with ozonised oxygen under pressures of approximately 330, 540, 760 and 1000 mm. of mercury. Experiments were also carried out at the same temperature, employing mixtures in various proportions of ozonised oxygen with helium, with argon, with nitrogen

* A few preliminary experiments were carried out in a fifth tube. The results (not here presented) agreed well with those obtained with Tubes A, B, and D.

and with carbon dioxide. The total pressure in these cases was either 760 or 1000 mm.

The reaction does not follow a strictly bimolecular course, there being a tendency for the second-order coefficients to increase with time, *i.e.*, with diminishing concentration of ozone. This increase, however, is small in ozonised oxygen mixtures under the highest pressures employed, but becomes rather more marked when the total pressure is reduced. In the presence of excess of any one of the four diluent gases investigated and when the total pressure was 1000 mm. of mercury, no sensible rise in the coefficient with time was observed.

Tables I, II, III, and IV summarise the results. Tables I and II relate to preliminary experiments carried out employing tubes A, B, and C, Tables III and IV to the final series, all the experiments in which were obtained with the same reaction tube D. In these tables, P_{θ_2} = total initial pressure of reaction mixture in mm. of mercury at the temperature θ_2; $p^{0_2}_{\theta_2}$ = sum of initial partial pressures of oxygen and ozone, which may be taken as the mean partial pressure of oxygen during the experiment; and $p^{z}_{\theta_2}$ = partial pressure of the added gas. The values given under $k_{\text{obs.}}$ are the highest and lowest values obtained for this bimolecular coefficient; $k'''_{\text{obs.}}$ is the weighted mean value of $k_{\text{obs.}}$, k'''_a is the absolute value corresponding to $k'''_{\text{obs.}}$, and k'''_a (corr.) is this absolute value corrected to a uniform temperature of 100°, using the figure 2·5 obtained by Warburg (*loc. cit.*) for the temperature coefficient of the reaction. The assumption here made, that this temperature coefficient is independent of the total pressure and composition of the gas mixture, can lead to no serious error, since in no case does the temperature of observation deviate from 100° by more than 1·2°.

The velocity of deozonisation in ozonised oxygen obtained with tube C (Table I, experiments 21—23) is much higher than that found employing any of the other tubes with the reaction mixture

at the same total pressure of 760 mm.; also the relative increase in the coefficient as the reaction proceeds is greater. Experiments 21—23 were carried out in the order given and it is of interest to note that the catalytic material of unknown nature present on the surface of the tube was gradually being rendered less active, as evidenced by the progressive fall in the velocity coefficients; possibly, had work with this tube been continued, the constant $k_{obs.}$ would eventually have fallen to the value obtaining in the other tubes. In connexion with this change of catalytic activity of the surface of the reaction vessel, a somewhat analogous effect was observed with tube D. After the experiments given in Tables III and IV had been completed, a fresh series carried out in the same tube (D) gave uniformly smaller coefficients than those recorded in Tables III and IV. Table V summarises a few of these experiments. The constants are now of the order of 10% less than those previously obtained under analogous conditions.

The coefficients obtained with tubes A and B containing sulphuric acid (Tables I and II) are only slightly lower than those obtained under identical conditions of pressure and composition of gas mixture in tube D, which contained no sulphuric acid (Tables III and IV). Since the catalytic effect of the glass surfaces of tubes A and B might have differed from that of D, a few experiments were carried out with tube D to test the effect of addition of sulphuric acid. The velocity coefficient was first determined for ozonised oxygen at a pressure of 755 mm., 3·9 c.c. of concentrated sulphuric acid were introduced into the tube so that it spread over its whole length (approximately one-eighth of the inner surface was covered by the acid), and the velocity coefficient was redetermined with the following results :—

Expts. 59 and 62 : No H_2SO_4 present; k^m_a (corr.) $= \left.\begin{matrix}9\cdot71\\9\cdot87\end{matrix}\right\}9\cdot79.$

Expts. 63 and 64 : In presence of H_2SO_4; k^m_a (corr.) $= \left.\begin{matrix}9\cdot31\\9\cdot45\end{matrix}\right\}9\cdot38.$

A slight diminution in the value of the velocity coefficient is therefore caused when part of the glass surface is replaced by one of sulphuric acid.

Discussion of Results.

Tables III and IV contain the main results of this work and summarise a number of determinations of the velocity of deozonisation at 100° under various conditions. These data were obtained with the same reaction tube D, and with (it is believed) its surface in a constant condition as regards possible catalytic action.

The tables show that :—

(*a*) The velocity of deozonisation in mixtures containing only ozone and oxygen is a function of the oxygen pressure, as already found by Jahn and by Perman and Greaves, but later contradicted by Chapman and Jones. We find that the velocity coefficient increases with decreasing total pressure, but the two quantities are not inversely proportional as stated by Jahn, rather their product diminishes as the pressure decreases. Actually it is found that the variation of k_a^m with pressure in tube D is very closely reproduced by the empirical relation $k_a^m = 11{,}500/(360 + P_{\theta_2})$.

The absolute values of the bimolecular velocity coefficient found by us are in fair agreement with those obtained by Warburg and by Perman and Greaves at the same temperature and under corresponding conditions of pressure. Thus, for ozonised oxygen at 100° and a pressure of 1000 mm. of mercury, we find $k_a^m = 7{\cdot}77$ for tube B and 8·35 for tube D, while Warburg gives a mean value, $k_a^m = 7{\cdot}54$. At 100° and 758 mm. pressure, our value of k_a^m (tube D) = 10·3 agrees fairly closely with that calculated from the results given by Perman and Greaves (Globe II), *viz.*, 9·72.

(*b*) The addition of any one of the gases nitrogen, argon, helium, and carbon dioxide causes an increase in the velocity of deozonisation, if the reaction velocity in the presence of one of these gases is compared with that found in ozonised oxygen alone with the same partial pressure of oxygen. In virtue of (*a*), this increase is still more pronounced if the coefficient found in the presence of one of these gases is compared with that observed in ozonised oxygen under the same *total* pressure. This increase in velocity is very marked when the partial pressure of the added gas is large. Thus the velocity coefficient k_a^m for ozonised oxygen at a pressure of 335 mm. is about 16·5 (mean of the results of experiments 41 and 47), whilst, in a mixture containing oxygen at the same partial pressure, but with a partial pressure of argon of 660 mm., the constant is now 28·5 (experiments 42, 43, and 48).

The increased velocity of deozonisation caused by addition of nitrogen is in qualitative agreement with the results of Jahn at

the higher temperature 127°, and of Perman and Greaves at 100°. Quantitatively, however, the relative increase in the coefficient observed by the latter investigators is somewhat greater than that obtained in the present work with the same gas mixture. On the other hand, Chapman and Jones could not detect any increase in the rate of reaction resulting from displacement of part of the oxygen in ozonised oxygen by nitrogen.

(*c*) The positive catalytic effects of the four gases investigated are in the order argon greatest, followed by nitrogen and carbon dioxide with approximately equal effects, and helium least. This order bears no relation to the catalytic effects found for these gases by Griffith and MacWillie on the rate of photochemical decomposition of ozone by visible light.

A necessary preliminary to any attempt at an explanation of the results presented in this paper appears to involve an answer to the question as to whether the decomposition of ozone under the conditions here investigated occurs mainly in the homogeneous gaseous phase or at the glass surface of the containing vessel. We are unable from the results of the present work or from the results of previous workers to arrive at a definite conclusion on this point. All that may safely be inferred is that some part at least of the measured rate is due to a heterogeneous change. This is shown by the slight variation in the velocity coefficient from tube to tube and by the retarding effect produced by covering a portion of the glass surface by sulphuric acid. We believe that our results may best be interpreted in the following way. The main reaction is a homogeneous change and is accompanied by a heterogeneous reaction whose velocity involves a lower power of the ozone concentration. This would explain the increase in the value of the bimolecular coefficient in each experiment with time, and in particular the relatively greater increase of this function with time the lower the pressure, *i.e.*, the lower the initial concentration of ozone. The few experiments carried out with tube C (21—23, Table I) support this view. Here apparently we are dealing with a case where the catalytic activity of the surface, and therefore the rate of the heterogeneous reaction, is of far greater significance than in the experiments with the other tubes. It will be observed that in these three cases, the greater the velocity of deozonisation, the greater also is the relative increase in the calculated bimolecular coefficient with time. This result is consistent with the conception of a constant intrinsic rate for the homogeneous process, together with a gradually decreasing catalytic activity of the surface which governs the intrinsic rate of the heterogeneous process.

If the observed reaction is a mixture of homogeneous and heterogeneous changes, which of these is it that the inert gases catalyse? Presumably, it is not the rate of heterogeneous change which is affected, and this for two reasons: (1) the velocity coefficient varies less with time in the presence of an inert gas than in its absence, indicating that the homogeneous change is accelerated relative to the heterogeneous change of lower order; (2) not only is the power of adsorption of such gases as argon and helium by glass surfaces small, but it is difficult to see how such adsorption could produce any other than a retarding effect on a heterogeneous change. We must therefore conclude that the catalytic effect of the inert gases investigated takes place in the gaseous phase.

We have thus to explain the retardation of the velocity of the homogeneous reaction by increase of the pressure of oxygen, and its acceleration by introduction of an inert gas. The effect of oxygen has been interpreted by Jahn (*loc. cit.*) in terms of the reaction scheme: $O_3 \rightleftharpoons O_2 + O$; $O + O_3 \longrightarrow 2O_2$, leading to $k_{obs.} \propto [O_3]^2/[O_2]$. This relation, however, is not in agreement with our experimental results; further, it appears improbable that the energy relations of the process of deozonisation are consistent with the formation of oxygen atoms at a temperature of 100°. If this mechanism be discarded, there remain such possibilities as:

(1) $O_3 \rightleftharpoons O_3^*$; $O_3^* + O_3 \longrightarrow 3O_2$,

where O_3^* represents an activated ozone molecule; or

(2) $O_3 \rightleftharpoons O_3^*$; $O_3^* + O_3 \rightleftharpoons$ complex; complex $\longrightarrow 3O_2$.

A qualitative agreement with the results of the present work may be obtained on the basis of this second possibility, if we make the following assumptions:

(*a*) The complex may either revert spontaneously into ozone molecules or decompose into oxygen molecules.

(*b*) Either of these changes may also be brought about by collision of the complex with an indifferent molecule.

Depending upon the type of the colliding molecule, one of these "decomposition by collision" processes will be favoured at the expense of the other. In this sense our results indicate that collisions with oxygen molecules favour the reversal: complex $\longrightarrow 2O_2$, whereas it is the process: complex $\longrightarrow 3O_2$ which is assisted by collision with inert gas molecules in the order argon, nitrogen, carbon dioxide, helium.

In connexion with the above assumptions, some theoretical considerations regarding the mechanism of chemical reactions which have recently been advanced by Christiansen (*Z. physikal. Chem.*, 1924, **113**, 35) and by Born and Franck (*Z. Physik*, 1925, **31**, 411) are of interest. Christiansen considers the first stage in

a bimolecular reaction to be the formation by collision of an active complex. This complex can subsequently decompose spontaneously into resultants, or can suffer deactivation by collision with a third molecule. Accordingly the probability that reaction should take place is determined by a factor of the form $\rho/(\rho + \Sigma\eta C)$, where ρ denotes the probability of spontaneous reaction, C is the concentration of any molecular species present, and the η's are specific coefficients such that $\Sigma\eta C$ gives the probability of deactivation of the complex by collision. Born and Franck have also dealt with deactivation processes occurring in chemical reactions, but from a somewhat different point of view. They conclude that, in order that additive processes of the type $A + B \longrightarrow AB$ may occur, it is necessary that the activated complex (or quasi-molecule) AB* first formed should, during its life period, suffer collision with a third molecule, whose function is to remove the difference in energy between AB* and AB. [On the other hand, they consider that, for substitution processes as $A + B \rightarrow C + D$ to occur, such ternary collisions are unnecessary.] Accordingly, the reaction velocity coefficient of Born and Franck should contain a function of the type $\Sigma\eta_1 C/(\rho_1 + \Sigma\eta_1 C)$, a function which is in a sense complementary to that of Christiansen; ρ_1, however, now defines the intrinsic probability of the reversal $AB^* \longrightarrow A + B$, and the η_1's refer to the change $AB^* \longrightarrow AB$.

The suggestions made by us in the reaction mechanism for the process of deozonisation include all four of the possibilities of change on the part of the complex entertained by Christiansen and Born and Franck. As a result, our final expression for the bimolecular velocity coefficient would contain a complex probability term of the form $(\rho + \Sigma\eta C)/(\rho + \rho_1 + \Sigma\eta C + \Sigma\eta_1 C)$ in which ρ and η refer to the change : complex $\longrightarrow 3O_2$ and ρ_1 and η_1 to the change : complex $\longrightarrow 2O_3$. As already stated, these possibilities afford a qualitative explanation of our results.

While it is not suggested that the mechanism postulated is necessarily the correct one, we believe that an explanation of the "negative" catalytic effect of oxygen and the "positive" effect of the other gases must involve considerations of the nature indicated above.

Summary.

The velocity of the thermal reaction $2O_3 \longrightarrow 3O_2$ has been determined at 100° in glass tubes in the presence and absence of sulphuric acid. The reaction follows approximately a bimolecular course, the velocity coefficients increasing slightly, however, with time. For ozonised oxygen mixtures, at pressures between 300 mm. and 1000 mm., the bimolecular coefficient k (expressed in the

units litres/moles-minutes) is given by $k = 11{,}500/(360 + P)$, where P = the pressure in mm. of gas mixture.

For mixtures of ozonised oxygen with any one of the gases argon, nitrogen, carbon dioxide, and helium, the velocity of deozonisation is greater than that found for ozonised oxygen with the same partial pressure of oxygen. This positive "catalytic" effect, which is greatest for argon and least for helium, increases with increasing partial pressure of added gas.

A short discussion of these results and of a possible mechanism of the reaction process is given.

The authors' thanks are due to Professor W. C. McC. Lewis for the facilities kindly provided for this work.

CCLXXXV.—*The Dissociation Pressures of Hydrated Double Selenates.*

By JOHN FERGUSON.

IN two former papers (J., 1922, **121**, 1407; 1924, **125**, 1307) the author in conjunction with R. M. Caven communicated an account of the dissociation pressures of hydrated double sulphates of the type $M''SO_4,M'_2SO_4,6H_2O$. The present paper contains the results of measurements of the dissociation pressures of hydrated double selenates of the same type.

The apparatus and methods employed have already been described (*loc. cit.*).

Each double selenate was prepared by crystallisation from a solution containing the two simple selenates in equivalent proportions. Selenium was the starting point in the preparation of the simple selenates. It was converted into copper selenate by Dennis and Koller's method (*J. Amer. Chem. Soc.*, 1919, **41**, 949), and this salt was electrolysed in warm saturated solution (Metzner, *Compt. rend.*, 1898, **127**, 54), yielding selenic acid, from which the simple selenates were obtained by neutralisation with the corresponding carbonates or hydroxides. The double selenates were analysed to test their purity.

The double selenates examined yielded dihydrates as the first stage in their dehydration. Induction lag phenomena were hardly so marked as in the case of the sulphates (J., 1924, **125**, 1308).

The pressures observed are equilibrium pressures in systems of the type $M''SeO_4,M'_2SeO_4,6H_2O \rightleftharpoons M''SeO_4,M'_2SeO_4,2H_2O+4H_2O$.

Nickel Ammonium Chromate.

This salt was prepared by Brigg's method (J., 1903, **83**, 392). It effloresces slowly in air, forming a brown substance which has the composition of the anhydrous salt. The dissociation pressures of a mixture of the hexahydrated salt and this substance were measured.

Clark and Buckner (*J. Amer. Chem. Soc.*, 1922, **44**, 242) and Clark (*Amer. J. Sci.*, 1924, **7**, 1) have carried out a long series of measurements of the stabilities of ammines of inorganic salts, as indicated by the temperatures at which the dissociation pressures of the ammines rise to a definite value (100 or 760 mm.). They have found that the stability *increases* with *diminishing* atomic volume of the positive part of the molecule, *e.g.*, in the series Cs, Rb, K, Na; Cd, Zn, Mn, Cu, Fe, and *increases* with *increasing* volume of the negative part, *e.g.*, in the series Cl, Br, I; MoO_4, CrO_4, SO_4, SeO_4. These results agree also with the work of Ephraim on the metallic ammines (*Ber.*, 1912, **45**, 1322).

In the following table are given the molecular volumes (determined by Tutton) of both double sulphates and selenates, and also the absolute temperatures at which their dissociation pressures attain a definite value (50 mm.).

Univalent metal or group.	Bivalent metal.	Sulphates.		Selenates.	
		T_{50}.	M.V.	T_{50}.	M.V.
Potassium	Copper	320·8°	197·8	316·6°	211·3

	Nickel	345·0	217·4	322·8	229·2
Ammonium	Cadmium	317·3	217·5	—	—
	Manganese	317·2	215·5	—	—
	Copper	332·0	207·7	333·7	222·2
	Cobalt	336·8	208·0	337·2	218·1
	Zinc	341·4	206·4	345·0	217·7
	Nickel	354·0	205·5	358·0	216·5

In the case of double salts formed by the same univalent metal or group with different bivalent metals, the temperature at which a pressure of 50 mm. is attained increases with decreasing molecular volume. The constitution of these double salts is probably of the type $M'_2[M''(SeO_4)_2]$, since it is known that in solutions of some of them at least, the bivalent metal migrates partially to the anode during electrolysis. Hence it may be said that stability in the sulphate or selenate groups, taken separately, is favoured by diminishing molecular volume of the anion or negative part of the molecule.

However, it must be pointed out that, although the double selenates have always a much greater molecular volume than the corresponding sulphates, the rubidium and ammonium double selenates are more stable than the rubidium and ammonium double sulphates. The potassium and cæsium double selenates are less stable than the corresponding sulphates.

Nickel ammonium chromate cannot be strictly compared with the sulphate and selenate double salts, as it does not form a dihydrate, like the other two. It is, however, the least stable of the three nickel ammonium salts, and has probably a much greater molecular volume (Tutton, *Min. Mag.*, 1912, **16**, 169).

As regards the positive part of the molecule, it is found that, the bivalent metal being the same, the stability increases with increasing molecular volume of the salt, in the order K, Rb, NH_4. The cæsium salts are anomalous, because, although they have as a class the greatest molecular volume, they are intermediate in stability between the potassium and rubidium salts. This rule, however, does not apply to the cæsium double sulphates of copper, cadmium and manganese, which are more stable than the corresponding potassium and rubidium salts. In the case of the two double selenate groups examined (copper and nickel) the cæsium and potassium dissociation pressure–temperature curves intersect, the cæsium salts being the less stable at lower temperatures.

If the cæsium salts are excluded from consideration, it follows that stability in the series of hydrated double sulphates and selenates is favoured by increasing atomic or molecular volume of the kation or positive part of the molecule.

To sum up, while it is obvious that the specific influence of the various atoms and groups enters as a complicating factor, the results tend to show that the stabilities of the hydrated salts are closely connected with the atomic or molecular volumes of the atoms and groups composing their molecules. The stabilities appear to *increase* with *decreasing* molecular volume of the anion, but increase with *increasing* atomic or molecular volume of the kation.

This relation is opposite to that which obtains with the metallic ammines (Clark and Buckner, *loc. cit.*).

Summary.

1. The dissociation pressures of certain double selenates of the type $M'_2SeO_4,M''SeO_4,6H_2O$ in contact with the corresponding dihydrates have been measured over a range of temperature.

2. The stabilities of these salts, and also of the double sulphates, as measured by the absolute temperatures at which their dissociation pressures attain the value of 50 mm., are greatly influenced by the molecular and atomic volumes of the groups and atoms in the molecule.

3. The specific action of the different atoms and groups introduces irregularities, especially noticeable in the case of cæsium double salts, but in general the stabilities of the hydrates increase with increasing volume of the kation and decrease with increasing volume of the anion.

4. These two relationships are the inverse of those obtaining with the metallic ammines.

The author wishes to thank Prof. R. M. Caven of the Royal Technical College for having suggested this research and for his continued interest in it. He also desires to thank the Carnegie Trust for the provision of a scholarship, which enabled the research to be undertaken.

THE ROYAL TECHNICAL COLLEGE,
GLASGOW.

[*Received, July 10th*, 1925.]

CCLXXXVI.—*Researches on Chromammines. Part II. Hydroxopentamminochromic Salts and Electrical Conductivities of Chromammines.*

By HERBERT JOSEPH SEYMOUR KING.

A. *Hydroxopentammino-chromic(-cobaltic) Hydroxide.*

IT was shown in Part I (King, J., 1924, **125**, 1329) that the alkaline solutions obtained by treating chloropentamminochromic or aquopentamminochromic chloride with moist silver oxide, which had until then been regarded as solutions of aquopentamminochromic hydroxide, gave hydroxopentamminochromic picrate with excess of picric acid. (That this is not due to instability of the aquopentamminochromic salt has now been shown by preparing the latter from the nitrate.) Hence the solutions were considered

to contain not aquo– but hydroxo–pentamminochromic hydroxide, a view supported by their intense reddish-violet colour, which is characteristic of " purpureo " rather than " roseo " solutions.

Further investigation showed that the aquopentamminochromic salt was obtained with oxalic acid, which thus behaved similarly to mineral acids (Christensen, *J. pr. Chem.*, 1881, **23**, 26).

$2[Cr(NH_3)_5OH](OH)_2+3H_2C_2O_4=[Cr(NH_3)_5H_2O]_2(C_2O_4)_3+4H_2O$.

2 : 4-Dinitrophenol, a much weaker acid than picric acid, gave the aquo-salt with both the chrommamine and the cobaltammine alkaline solutions. Also picric acid gave the aquo-salt with the cobaltammine solution, though 2 : 4-dinitro-α-naphthol-7-sulphonic acid, a much stronger acid, gave the hydroxo-salt (Part I). In view of these anomalous results, the nature of the alkaline solutions has been investigated from the point of view of electrical conductivity. From measurements of the conductivities of their salts, the conductivities of the aquopentamminochromic and hydroxopentamminochromic ions at zero concentration were found to be 174·3 and 73·3 mhos at 0°, giving 489·3 and 283·3 mhos for the limiting conductivities of the hydroxides. The value obtained by extrapolation of the conductivity data for the chromammine alkaline solution was 283·9, completely confirming the view that it contained only hydroxopentamminochromic hydroxide. The data of Lamb and Yngve (*J. Amer. Chem. Soc.*, 1921, **43**, 2352) for the conductivity of " aquopentamminocobaltic hydroxide " at 0° (ignoring the figure for $c = 0{\cdot}0002683$) give on extrapolation ($n = 1{\cdot}30$) the value 296 at infinite dilution, in fair agreement with the value 287 required for hydroxopentamminocobaltic hydroxide.

Aquopentamminochromic picrate was precipitated, on mixing solutions of aquopentamminochromic nitrate and 200% excess of sodium picrate, as aggregates of golden-yellow needles (Found : Cr, 6·0; NH_3, 9·9; N, 22·9; H_2O, 3·3.

$$[Cr(NH_3)_5H_2O]\{C_6H_2O_7N_3\}_3,\tfrac{1}{2}H_2O$$

requires Cr, 6·1; NH_3, 10·0; N, 23·1; H_2O, 3·2%). The salt lost all its water and also 43% of its ammonia on heating at 100° for 3 hours, so this is not a suitable method for introducing the picrato-group into the complex.

Aquopentamminochromic oxalate was obtained on mixing solutions of hydroxopentamminochromic hydroxide (Christensen, *loc. cit.*) and oxalic acid (3 mols.), precipitation occurring on shaking and cooling. It was washed with a little water, and with alcohol until free from oxalic acid. The air-dried product consisted of irregular, orange plates (Found : Cr, 16·3; NH_3, 26·4; H_2O of crystallisation, 10·9. $Cr(NH_3)_5H_2O]_2(C_2O_4)_3,4H_2O$ requires Cr, 16·1; NH_3, 26·4; H_2O of crystallisation, 11·2%). After a week in a vacuum over phosphoric

oxide, the water of crystallisation was completely removed, together with 4% of the ammonia. The salt lost 47% of its ammonia on heating at 100° for 3 hours, but still retained more than half of the co-ordinated water. Thus it was not possible to prepare an oxalato-salt from it by heating.

Aquopentammino-chromic (*-cobaltic*) 2 : 4-*Dinitrophenoxide*.—Finely powdered 2 : 4-dinitrophenol (2 mols.) was shaken mechanically for an hour with a solution of hydroxopentammino-chromic (-cobaltic) hydroxide, when the pure aquopentammino-salt was obtained, the excess of hydroxide remaining uncombined. The sparingly soluble product was washed with water, then triturated and washed with methyl alcohol, leaving a bright yellow powder. Ammonia was estimated as for picrates (Morgan and King, J., 1922, **121**, 1723). A. (Found: Cr, 7·4; NH_3, 11·7; N, 21·3; H_2O, 5·2.

$$[Cr(NH_3)_5H_2O]\{C_6H_3O_5N_2\}_3,H_2O$$

requires Cr, 7·2; NH_3, 11·8; N, 21·2; H_2O, 5·0%). 66% of the ammonia was removed in 3 hours at 85°, together with all the water. B. (Found: Co, 7·7; NH_3, 11·0; N, 20·1; H_2O, 9·2. $[Co(NH_3)_5H_2O]\{C_6H_3O_5N_2\}_3,3H_2O$ requires Co, 7·7; NH_3, 11·1; N, 20·1; H_2O, 9·4%). The compound charred at 100°.

Interaction of Hydroxopentamminocobaltic Hydroxide and Picric Acid Solutions.—Using three mols. of picric acid, the pure aquopentamminocobaltic salt was precipitated (Morgan and King, *loc. cit.*) (Found: Co, 7·1; NH_3, 10·1. Calc., Co, 7·0; NH_3, 10·1%). Two mols. of picric acid gave a mixture of the aquo- and hydroxo-salts.

B. *Hydroxopentamminochromic Salts.*

The only salts of this series hitherto described are the dithionate (Jörgensen, *J. pr. Chem.*, 1882, **25**, 419; Dubsky, *ibid.*, 1914, **90**, 99), picrate and dipicrylamide (Part I). The sulphate, nitrate, chloride, bromide, iodide, chromate and oxalate have now been obtained. They are rose-red salts, much more soluble in water than the corresponding cobaltammines (Werner, *Ber.*, 1907, **40**, 4098). They give solutions only very slightly alkaline to litmus and do not liberate ammonia from ammonium salts in the cold. Thus the tendency to form aquo-salts is less pronounced than in the case of hydroxopentamminocobaltic salts. The co-ordinated hydroxyl group cannot be acetylated or carbonated. Unlike the hydroxopentamminocobaltic salts, they smell of ammonia and are unstable even in the dark. They can, however, be kept indefinitely in an ammoniacal atmosphere. The salts most readily obtained pure and in quantity are the sulphate and nitrate.

That these are not basic aquo- but hydroxo-salts is demonstrated as follows.

(*a*) The sulphate and chromate were obtained anhydrous, whilst the nitrate, bromide, and iodide contained less water than is required for an aquo-salt.

(*b*) Hydroxopentamminochromic picrate was obtained from the sulphate by double decomposition.

(*c*) The electrical conductivities at 25° and a dilution of 1024 litres were of the order required (234 to 268 mhos) for salts with two univalent ions outside the complex, by Werner's empirical rule (Werner and Miolati, *Z. physikal. Chem.*, 1894, **14**, 506). The values obtained for the sulphate, nitrate, chloride, and oxalate were 234·0, 260·8, 274·6 and 235·5. (The value 266·2 obtained for hydroxopentamminocobaltic nitrate also agrees with the rule.)

Hydroxopentamminochromic sulphate was obtained by adding the hydroxopentamminochromic hydroxide solution (100 c.c.) from 4 g. of chloropentamminochromic chloride to 2·17 g. of ammonium sulphate in 3 c.c. of water and 16 c.c. of concentrated ammonia solution. When 50 c.c. of ice-cold alcohol had been added drop by drop to the cooled solution, rosettes of large, rose-red needles began to form. On addition of 20 c.c. more alcohol most of the sulphate crystallised (3·5 g.). It was collected, washed with ammoniacal alcohol and ether, and kept in a vacuum in presence of soda-lime and ammonium carbonate (Found : Cr, 21·2; NH_3, 33·8; S, 13·0. $[Cr(NH_3)_5OH]SO_4$ requires Cr, 20·8; NH_3, 34·0; S, 12·8%).

A sample was triturated with acetic anhydride for 20 minutes. The product was dissolved in water and treated with a solution of sodium picrate. Hydroxopentamminochromic picrate (Part I) was precipitated, showing that no acetylation had occurred (Found : Cr, 8·3; NH_3, 12·8; N, 23·3. Calc., Cr, 7·9; NH_3, 13·0; N, 23·5%).

When carbon dioxide was passed into a cooled concentrated solution of the sulphate, 3 to 4 mols. of ammonia were displaced, an insoluble bluish-violet carbonate of variable composition being formed.

Hydroxopentamminochromic nitrate was not readily obtained by adding the hydroxide to ammonium nitrate solution, as a large excess of alcohol and ether was needed for precipitation and the salt then separated as an oil. Five g. of aquopentamminochromic nitrate (Werner and Surber, *Annalen*, 1914, **405**, 220) were dissolved in 30 c.c. of concentrated ammonia, and cooled alcohol (60 c.c.) was added drop by drop to the ice-cold solution until a permanent crystalline precipitate formed (small, irregular, red plates). This was collected immediately and washed with ammoniacal alcohol and ether (Found: Cr, 18·2; NH_3, 29·6; N, 34·3.

$$[Cr(NH_3)_5OH](NO_3)_2,\tfrac{1}{2}H_2O$$

requires Cr, 18·1; NH_3, 29·7; N, 34·1%). Although the salt had

an ammoniacal odour, it lost only 2½% of its ammonia when kept during 10 weeks over phosphoric oxide in a vacuum.

Action of Pyridine on Aquopentamminochromic Nitrate.—A strong solution of the aquo-salt was treated with excess of ice-cold pyridine, the colour changing from orange to dark red. Addition of alcohol gave an orange precipitate, the ammonia content of which (26·1%) indicated that 25% of the aquo- had been hydrolysed to the hydroxo-nitrate.

Aquopentamminochromic halides, prepared by Christensen (*loc. cit.*) from hydroxopentamminochromic hydroxide, were more conveniently obtained in pure condition as follows.

Chloride.—A solution of 7·5 g. of aquopentamminochromic nitrate in 60 c.c. of water was filtered into 160 c.c. of ice-cold strong hydrochloric acid, when partial precipitation of the crystalline salt occurred. Ice-cold alcohol (100 c.c.) was added and the salt was at once collected (3·7 g.) (Found : NH_3, 32·7. Calc., NH_3, 32·6%). The chlorine was completely and immediately precipitated in the cold by silver nitrate, showing that no chloropentamminochromic salt was present.

Bromide.—A solution of 5 g. of aquopentamminochromic nitrate was added to 60 c.c. of ice-cold strong hydrobromic acid, an immediate precipitate of 5 g. of the bromide being formed. This was freed from a trace of purpureo-salt by dissolving in water (50 c.c.) and filtering into 50 c.c. of ice-cold hydrobromic acid. The *iodide* was prepared similarly to the bromide.

Hydroxopentamminochromic chloride was obtained as aggregates of small, very soluble, rose needles (2 g.) on dissolving aquopentamminochromic chloride (3 g.) in 15 c.c. of concentrated ammonia and slowly adding ice-cold alcohol (60 c.c.) until precipitation was complete. The salt lost 18·6% of its ammonia in 3 hours at 100° (Found : Cr, 21·4; NH_3, 35·0; Cl, 28·9. $[Cr(NH_3)_5OH]Cl_2,H_2O$ requires Cr, 21·4; NH_3, 35·0; Cl, 29·2%).

Hydroxopentamminochromic bromide separated as a solid mass of pink needles when aquopentamminochromic bromide was dissolved in ammonia, and a little ice-cold alcohol added (Found : Cr, 16·3; NH_3, 26·1; Br, 49·5; H_2O, 3·0. $[Cr(NH_3)_5OH]Br_2,\frac{1}{2}H_2O$ requires Cr, 16·1; NH_3, 26·4; Br, 49·5; H_2O, 2·8%).

Hydroxopentamminochromic iodide was obtained as bunches of minute, pink needles by dissolving 5 g. of aquopentamminochromic iodide in 30 c.c. of concentrated ammonia and adding slowly 100 c.c. of ice-cold alcohol. It was somewhat less soluble than the other salts (Found : Cr, 12·7; NH_3, 20·6; I, 60·9. $[Cr(NH_3)_5OH]I_2,\frac{1}{2}H_2O$ requires Cr, 12·5; NH_3, 20·4; I, 60·9%). When solid potassium iodide was added to a solution of aquopentamminochromic nitrate

in concentrated ammonia, an addition compound of the hydroxo-iodide with potassium iodide was obtained (pink needles).

Hydroxopentamminochromic chromate was obtained by adding the hydroxide solution (55 c.c.) from 4 g. of chloropentamminochromic chloride to 2·5 g. of ammonium chromate dissolved in ammonia. The intense reddish-brown solution was treated with alcohol until a permanent crystalline precipitate just formed (aggregates of thin, brown plates). This was collected and washed with ammoniacal alcohol and ether (Found : Cr, 38·7; NH_3, 31·3. $[Cr(NH_3)_5OH]CrO_4$ requires Cr, 38·5; NH_3, 31·5%).

No reduction in weight occurred when the salt was kept for a fortnight over phosphoric oxide.

Hydroxopentamminochromic Oxalate.—The hydroxide solution from 5 g. of chloropentamminochromic chloride (100 c.c.) was added to 2·92 g. of ammonium oxalate in 100 c.c. of water, when ammonia was immediately evolved. Ammonia solution (10 c.c.) was added, and a considerable excess of alcohol and ether; the precipitate of large, pink needles was readily soluble in water (Found : Cr, 18·6; NH_3, 30·4. $[Cr(NH_3)_5OH]C_2O_4,2H_2O$ requires Cr, 18·7; NH_3, 30·6%).

Hydroxopentamminocobaltic Nitrate.—The following is a more convenient method than that given by Werner (*loc. cit.*) for preparing the pure monohydrated salt. To a filtered solution of 20 g. of aquopentamminocobaltic nitrate in 100 c.c. of concentrated ammonia, 240 c.c. of boiling alcohol are added and the mixture is cooled quickly to prevent separation of an oil. The precipitate is dissolved in ammonia, and to the ice-cold filtered solution cooled alcohol is added drop by drop until crystallisation begins (yield 7 g.) (Found : Co, 19·4; NH_3, 28·1. Calc., Co, 19·5; NH_3, 28·1%).

C. *Electrical Conductivities of Chromammines and Cobaltammines.*

The λ–$C^{1/3}$ *Graph* (see Porter, *Trans. Faraday Soc.*, 1919, **15**, 122).—The electrical conductivities of a large number of salts of bivalent chromammine and cobaltammine kations give, for the concentration range $v = 32$ to $v = 1024$, a rectilinear λ–$C^{1/3}$ graph. This has been found to be the case for hydroxopentamminochromic nitrate, chloride and hydroxide, hydroxopentamminocobaltic nitrate, chloropentamminochromic chloride and bromide, chloropentamminocobaltic sulphate, bromide, chloride and nitrate, nitropentamminochromic chloride (xantho), nitropentamminocobaltic nitrite and chloride (xantho), dinitrotetramminocobaltic nitrate (flavo) and chloride (croceo). It has therefore been concluded that in normal cases the λ–$C^{1/3}$ graph for such salts over this range should be rectilinear and that deviations are due to such

phenomena as polymerisation in concentrated solution, hydration and hydrolysis. This view was supported by the fact that in several cases where deviation was found at 25° the graph was rectilinear at 0° (*e.g.*, chloropentamminochromic bromide, Table III). Further, in cases where this graph is rectilinear, extrapolation to zero concentration by means of the $1/\lambda$–$(C\lambda)^{n-1}$ graph gives concordant values for the mobility of the complex ion, whilst extrapolation of data for the same ion which give a curved λ–$C^{1/3}$ graph leads to a quite different mobility value. Thus for the bivalent hydroxopentamminochromic ion, extrapolation of the conductivity data for the nitrate and chloride gives mobility values 131·6 and 131·9 at 25°, whilst the oxalate and sulphate data, which deviate from the straight-line rule (probably owing to polymerisation in concentrated solution), lead to mobility values 380·9 and 195·0.

The rectilinear λ–$C^{1/3}$ graph does not appear to be suitable for extrapolation of conductivity data to infinite dilution, since accurate data for concentrations less than $\frac{1}{1000}$ (*e.g.*, for potassium chloride) are lower than those required by the graph. For ammines of chromium and cobalt it leads usually to results 6% higher at 25° than those obtained by the $1/\lambda$–$(C\lambda)^{n-1}$ graph.

In many cases at $v = 2000$, and sometimes at higher concentrations, the conductivities of ammines are *higher* than those required by the rectilinear λ–$C^{1/3}$ graph. Such data have been considered to be influenced by decomposition of the complex ion, and have been ignored in calculating λ_∞. They are bracketed in the tables.

The rule does not appear to apply to salts of tervalent complex kations. The λ–$C^{1/3}$ graphs for hexammino-chromic (-cobaltic) and aquopentammino-chromic (-cobaltic) salts are curved. Nevertheless, extrapolation leads to concordant results from different salts of the same ion.

Conductivity Data.—The usual Kohlrausch method was employed, resistances being measured by a standardised Post Office box. An open cylindrical cell of constant 0·1197 was used for the salts. The conductivity water was obtained by a single distillation of distilled water with a little potassium bisulphate, and its specific conductivity varied between $0{\cdot}66 \times 10^{-6}$ and $1{\cdot}1 \times 10^{-6}$ mho, at 0°. Except in the case of hexammino-salts, the method of successive dilutions was not employed. A fresh solution was prepared for each measurement, and its conductivity was determined forthwith. This was particularly necessary in the case of hydroxo-salts, since their conductivity increased rapidly when they were kept in contact with the electrodes.

Table I.

Hydroxopentammino-chromic and -cobaltic Salts.

v is the reciprocal of the concentration in mols. per litre, and λ the molecular conductivity in mhos.

Bracketed data have been ignored in calculating λ_∞.

α	83·8	86·5	88·1	89·5	96·4	—

The hydroxide solution was prepared by triturating chloropentamminochromic chloride with moist silver oxide (Christensen, *loc. cit.*), filtering, and washing the oxide with a little ice-cold conductivity water. Air was excluded as much as possible during the preparation, and the conductivity was measured in a stoppered flask-shaped cell. The concentration was determined by an ammonia estimation. The hydroxide prepared from aquopentamminochromic chloride gave similar results. A positive water correction was applied (Lamb and Yngve, *loc. cit.*). The water used was practically "equilibrium water," its specific conductivity being $0·66 \times 10^{-6}$ mho at 0°.

The conductivities for hexamminochromic nitrate at 25° are considerably higher than those recorded by Werner and Miolati (*loc. cit.*).

Ionic Mobilities.—The conductivity at infinite dilution has been obtained in every case from the $1/\lambda$–$(C\lambda)^{n-1}$ graph (Noyes and Coolidge, *Carnegie Inst. Pub.*, **63**, 50).

Hydroxopentamminochromic ion. The data for the chloride and nitrate (Table I) give mobility 73·0 and 73·5 (n = 1·56 and 1·52) at 0° and 131·9 and 131·6 (n = 1·60) at 25°. The means of these closely concordant values are adopted in Table VI. The data for hydroxopentamminochromic hydroxide give mobility 73·9 at 0°, in excellent agreement with the figure derived from the salts.

Hydroxopentamminocobaltic ion. The data for the nitrate (Table I) give mobility 76·6 at 0° (n = 1·50) and 131·0 at 25° (n = 1·60).

Chloropentamminochromic ion. The data in Table III give the ionic mobility as 75·2 and 76·8 (chloride and bromide) at 0° (n = 1·50) and as 139·7 (chloride) at 25° (n = 1·50). The data of Werner and Miolati (*loc. cit.*) for the chloride at 25° give a slightly lower value (138·4). The lower figure 75·2 at 0° has been adopted, since the bromide results are probably affected by hydration.

Chloropentamminocobaltic ion. The data of Werner and Miolati (*loc. cit.*; *Z. physikal. Chem.*, 1896, **21**, 235) for chloropentamminocobaltic salts at 25° give an ionic mobility 3·5% higher than that of the corresponding chromammine ion, but extrapolation of the more recent results obtained by Harkins, Hall, and Roberts (*J. Amer. Chem. Soc.*, 1916, **38**, 2643) for the chloride gives values 74·8 at 0° and 140·8 at 25° (n = 1·60 and 1·82). These are the values adopted in Table VI.

Aquopentammino-chromic and *-cobaltic ions* at 0°. The data of Table IV give mobilities 174·3 ($n = 1·40$) and 161·7 ($n = 1·44$). The latter agrees well with the estimated value of 160 given by Lamb and Yngve (*loc. cit.*).

Hexamminochromic ion. The data of Table V give mobility 180·0 at 0° ($n = 1·46$) and 369·6 and 370·8 (nitrate and bromide) at 25° ($n = 1·42$ and 1·40).

The diminution in mobility of the complex ion at 0° on replacing one ammonia molecule of the hexammine by water is 5·7 in the chromammine, 5·3 in the cobaltammine series (see Table VI).

The values employed for the mobilities of the anions at 0° and 25° were Cl′, 41·1 and 75·5; Br′, 43·1 and 77·8; NO_3', 40·4 and 70·6; OH′, 105·0 (0°); $\frac{1}{2}SO_4''$, 78·0 (25°); $\frac{1}{2}C_2O_4''$, 72·7 (25°).

The ionic mobilities of the complex kations are collected in Table VI. Those indicated by an asterisk are taken from the table given by Lamb and Yngve (*loc. cit.*). Q = valency of kation.

TABLE VI.

Kation.	$\Lambda_{0°}$.	$\Lambda_{0°}/Q^2$.	$\Lambda_{25°}$.	$\Lambda_{25°}/Q^2$.
1 : 2-$[Co(NH_3)_4(NO_2)_2]^{\cdot}$	18·1*	18·1	36·3*	36·3
1 : 6-$[Co(NH_3)_4(NO_2)_2]^{\cdot}$	17·9*	17·9	36·1*	36·1
$[Cr(NH_3)_5OH]^{\cdot\cdot}$	73·3	18·3	131·8	33·0
$[Co(NH_3)_5OH]^{\cdot\cdot}$	76·6	19·2	131·0	32·8
$[Cr(NH_3)_5Cl]^{\cdot\cdot}$	75·2	18·8	139·7	34·9
$[Co(NH_3)_5Cl]^{\cdot\cdot}$	74·8	18·7	140·8	35·2
$[Cr(NH_3)_6]^{\cdot\cdot\cdot}$	180·0	20·0	370·2	41·1
$[Co(NH_3)_6]^{\cdot\cdot\cdot}$	167·0*	18·6	327·0*	36·3
$[Cr(NH_3)_5H_2O]^{\cdot\cdot\cdot}$	174·3	19·4	—	—
$[Co(NH_3)_5H_2O]^{\cdot\cdot\cdot}$	161·7	18·0	314·0*	34·9

The mobilities of corresponding chromammine and cobaltammine bivalent ions are practically identical.

The marked increase in mobility of the complex ions with increase of valency has no parallel among ordinary metallic kations. If the mobility is divided by the square of the valency, an approximate constant is obtained throughout the table, showing that the mobility is proportional to the square of the ionic charge. The mean values of Λ/Q^2 for univalent, bivalent and tervalent ions are 18·0, 18·8 and 19·0 at 0° and 36·2, 34·0 and 37·4 at 25°. For metallic kations, Λ/Q is approximately constant.

The author is indebted to the Chemical Society for a grant which has partly defrayed the cost of this investigation.

CCLXXXVII.—*Electrometric Studies of the Precipitation of Hydroxides. Part I. Precipitation of Magnesium, Manganous, Ferrous, Cobalt, Nickel, and Thorium Hydroxides by Use of the Hydrogen Electrode.*

By Hubert Thomas Stanley Britton.

No satisfactory system of classifying the metals according to the strengths of their hydroxides has yet been evolved, although it is this property which underlies the general chemical character of the elements and also many analytical separation processes. Measurements of the basic strength by determinations of electromotive force, of heats of formation of oxides and salts, of dissociation pressures of sulphates at different temperatures, and of the hydrolysis of various salts in solution have led to different arrangements. The arrangement in the order of the dissociation constants of the hydroxides as calculated from hydrolysis data is not altogether satisfactory, for in the majority of cases sufficiently accurate measurements cannot be made.

Curiously enough, the order of the precipitation of the hydroxides by the gradual addition of alkali has received no serious attention, except with regard to the separation of the rare-earths. Hildebrand's work (*J. Amer. Chem. Soc.*, 1913, **35**, 847) in this connexion has been repeated and extended by the present author. A definite hydrogen-ion concentration, within narrow limits, has to be attained before the precipitation of any particular hydroxide can take place. This would be expected from a consideration of the "solubility product." An insoluble hydroxide, MOH, attains equilibrium with undissociated molecules and ions in solution, thus :

$$\text{MOH (solid)} \rightleftharpoons \text{MOH (undissociated)} \rightleftharpoons \text{M}^{\cdot} + \text{OH}'.$$

The "solubility product" $= [\text{M}^{\cdot}][\text{OH}'] = [\text{M}^{\cdot}]K_w/[\text{H}^{\cdot}]$, where $K_w = [\text{H}^{\cdot}][\text{OH}']$. The precipitation of the hydroxide thus depends on the concentration of both the metal- and the hydrogen-ions. In ordinary analytical operations, the concentrations of the metal ions do not vary to any considerable extent and consequently precipitation depends largely on the hydrion concentration. The hydrion concentrations necessary for the precipitation of a large number of hydroxides, which have now been determined, constitute a suitable basis for the classification of the hydroxides. The order is "parallel" to the increasing magnitude of the solubility products, but whether it is that of the basic strengths cannot be stated with certainty; this can be so only if the concentration of undissociated

molecules is the same for each hydroxide—a point about which nothing is known.

The Hydrogen Electrode.

For titrations involving the separation of precipitates, the Hildebrand form of hydrogen electrode was found to be the most convenient; the hydrogen, obtained from a supply under pressure (*e.g.*, a cylinder), could be passed through the solutions at such a rate that thorough mixing could be ensured, and its rapid passage through the electrode tended to free the platinum black from gases such as carbon dioxide and ammonia which were apt to be occluded, and also completely removed any dissolved oxygen from the solutions. The titrations were carried out in the manner already described (J., 1924, **125**, 1576). The uncertain behaviour of the hydrogen electrode (see *loc. cit.*) is no doubt responsible for many of the conflicting statements in the literature, especially with reference to its use in alkaline solutions. Thus Johnson (*Trans. Amer. Electrochem. Soc.*, 1902, **1**, 187) found the electrode to be sluggish, and Allmand (J., 1909, **95**, 2151) concluded that it was untrustworthy in alkaline solutions. Everything depends, however, on the electrode, its method of preparation and its use, for some electrodes are as satisfactory in alkaline as in acid solutions. Efficient electrodes tend to improve with continuous use, and in a few cases electrodes have remained good over a period of three months.

In precipitation reactions the efficiency of the electrode sometimes depends on the nature of the precipitate; the finer the precipitate the less likely is the electrode to give satisfactory results. In general, precipitates merely render the electrode sluggish. No electrode functions in the presence of precipitated sulphur, but this may be due, not to the fineness of the precipitate, but to interaction between the hydrogen and the sulphur.

The hydrogen electrode has some limitations, but these are not so extensive as is generally stated. It can be used in presence of reducible substances such as nitrates and chromates (compare Britton, *loc. cit.*) if the solution is dilute. No electrode gave complete satisfaction in presence of sulphites; in some titrations, however, the initial readings appeared to be approximately true.

The hydrogen electrode is, of course, inapplicable in solutions containing metals more noble than hydrogen. Moreover, Denham and Allmand (J., 1908, **93**, 424) and Denham (*ibid.*, p. 833) found that the hydrogen electrode behaves anomalously in solutions of lead, cadmium, and univalent thallium salts, owing to catalytic reduction of the kations to a state of lower valency. These observations have been confirmed by the author. It was, however,

thought just possible that by having a suitable layer of platinum black, electrodes might be prepared which would not react with these kations; but numerous attempts to do so were fruitless. In view of the fact that the hydrogen electrode is affected by lead ions in solution, it is remarkable that the lead which is usually deposited with the platinum black does not render the electrode useless; in fact, its presence in the latter seems to increase its efficiency as far as titration work is concerned. Denham and Allmand proved conclusively that lead in the electrode is absolutely without any deleterious effect, for they deposited electrolytically a layer of lead on a hydrogen electrode and found that the electrode still gave correct results.

Previous Investigations with the Hydrogen Electrode in Inorganic Chemistry.

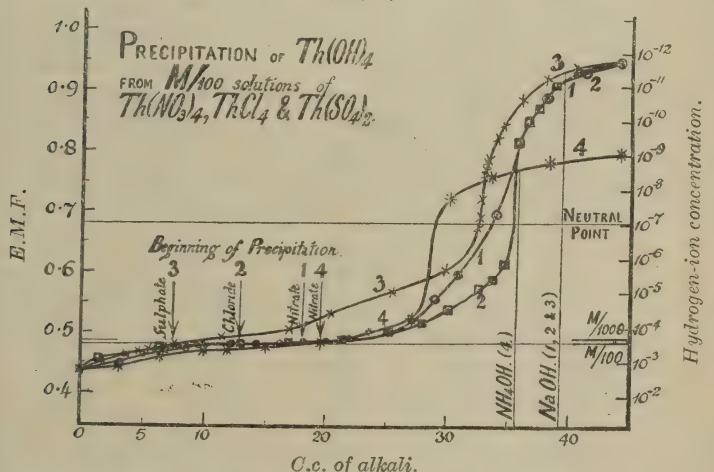
The only observations relating to reactions similar to those now described appear to have been made by Bjerrum (*Z. physikal. Chem.*, 1907, **59**, 336; 1910, **73**, 724), Sand and Grammling (*ibid.*, 1908, **62**, 1), Hildebrand and Harned (Orig. Com., 8th Internat. Cong. Appl. Chem., 1912, **1**, 217), Hildebrand (*J. Amer. Chem. Soc.*, 1913, **35**, 847), Blum (*ibid.*, p. 1499; 1916, **38**, 1282), and Hildebrand and Bowers (*ibid.*, 1916, **38**, 785).

Denham (J., 1908, **93**, 41; *Z. anorg. Chem.*, 1908, **57**, 388) employed the electrode extensively for the determination of the hydrolysis of salts. Steady *E.M.F.*'s were obtained in some cases; in others, they oscillated haphazardly from day to day, showing in the case of *M*/64-thorium sulphate solution that the degree of hydrolysis, calculated to the second step [*i.e.*, to $Th(OH)_2SO_4$] varied from 23 to 59%. The author has not observed any such changes with *M*/100-solutions of either the sulphate, chloride or nitrate at 15°, even after the solutions had been kept in stoppered bottles for several weeks. The following data show that the three salts are almost equally hydrolysed, the extent being half the lowest value obtained by Denham for *M*/64-thorium sulphate solution.

Salt.	*E.M.F.* of H_2 electrode against normal calomel.	Percentage hydrolysis calc. to $Th(OH)_4$.
Nitrate	0·434	5·70
Chloride	0·435	5·47
Sulphate	0·437	5·04

Electrometric Titrations with the Hydrogen Electrode.

(1) *Effect of Concentration, Anion, and Precipitant on the Hydrogen-ion Concentrations required for the Precipitation of Hydroxides.*—Experiments were carried out to see what was the effect of change



in concentration of salt. The following table gives the p_H values at which thorium hydroxide began to be precipitated by $N/10$-sodium hydroxide at 15° from solutions of thorium nitrate ranging in concentration from $M/1000$ to $M/100$.

Concentration.	*E.M.F.* of H_2 electrode against normal calomel.	p_H.
$0{\cdot}001M$	0·489	3·60
$0{\cdot}002M$	0·488	3·58
$0{\cdot}01M$	0·487	3·57

The difference in p_H is thus very small and this range of concentrations covers those usually employed in analytical work.

Hildebrand found that the p_H's required for the precipitation of neodymia and praseodymia from nitrate solutions were widely

FIG. 1.

(0·1016 N-NaOH, *curves* 1, 2 *and* 3. 0·1115 N-NH_4OH, *curve* 4).

different from those required in the case of chloride solutions, and he attributed this difference to the nature of the anion (see Part III). The effect of the anion and of the nature of the precipitant has been studied more fully in the case of thorium salt solutions, and again precipitation commenced at the same p_H in all cases (Fig. 1). Curves 1, 2, and 3 represent the titrations of 100 c.c. of $M/100$-solutions of thorium nitrate, chloride, and sulphate respectively, with $0{\cdot}1016N$-sodium hydroxide, and curve 4 that of 100 c.c. of $M/100$-thorium nitrate with $0{\cdot}1115N$-ammonium hydroxide, at 15°. The commencement of precipitation, *i.e.*, the first appearance of turbidity, is shown by arrows. As a rule, the *E.M.F.*'s were steady (in some cases an hour elapsed before the next reading was taken),

but they were not always so in those stages of the titration which indicated the rapid changes in hydrion concentration occurring at the end of the precipitation. The last section of curve 1 represents a gradual diminution in hydrion concentration and the readings were stationary during the intervals (5 to 15 minutes) allowed for the attainment of equilibrium. Curve 2, chloride, shows a sudden yet well-defined change, but in the case of the thorium sulphate titration (curve 3) the change was irregular and long periods were necessary before constant readings were obtained. Appreciable amounts of alkali had to be added before the commencement of precipitation, and thereafter, in the case of the nitrate and the chloride solutions, there was a distinct tendency for a constant p_H to be maintained during the addition of the greater portion of the alkali. It is probable that this corresponds to the separation of a precipitate of uniform composition.

In neither case was thorium hydroxide precipitated as such. Fig. 1 shows that precipitation was complete and the mother-liquors had become alkaline some time before the stoicheiometrical quantities of alkali had been added. The following table gives the amounts of alkali which were added before precipitation ensued and the amounts of alkali which had to be added before the solutions became neutral (p_H 7).

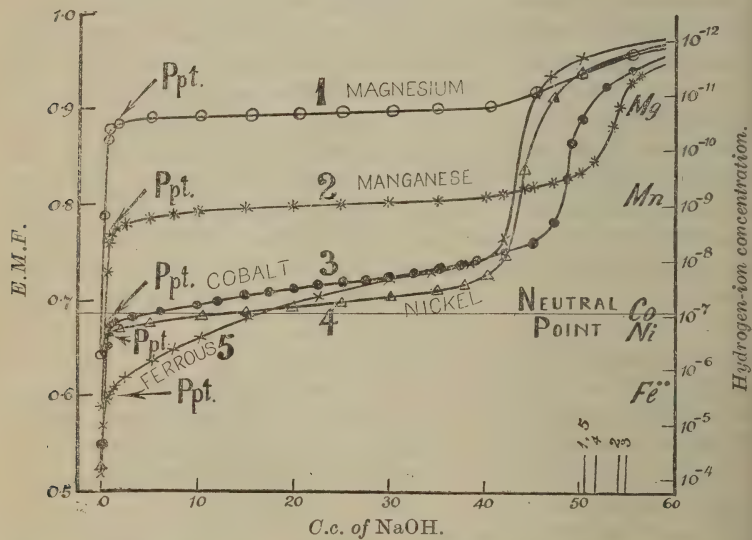
Curve.	Solution and precipitant.	Precipitation began: p_H.	Precipitation began: Equivs. of alkali.	Equivs. of alkali required for neutrality.
1	$Th(NO_3)_4$ and NaOH	3·57	1·85	3·43
2	$ThCl_4$ and NaOH	3·51	1·30	3·58
3	$Th(SO_4)_2$ and NaOH	3·53	0·78	3·31
4	$Th(NO_3)_4$ and NH_4OH	3·57	2·21	3·24

The last column of the above table shows that the precipitate formed in each titration was basic, being somewhat less so when the precipitant was ammonia. Thus the amount of precipitant required to render the solution neutral in titration No. 4 indicates that the composition of the precipitate was $Th(OH)_{3·24}(NO_3)_{0·76}$, whereas in No. 1, where sodium hydroxide was used, it was $Th(OH)_{3·43}(NO_3)_{0·57}$. The protracted inflexions produced during the last stages of precipitation show that the precipitates at first formed were less basic and suffered some decomposition on further addition of alkali. This seems to have taken place readily in the cases of the nitrate and the chloride, but the slowness with which apparent equilibrium was attained in the second part of the sulphate titration indicates that the basic sulphate was undergoing hydrolysis with much greater difficulty. It seems almost unnecessary to say that the amounts of acid radical retained by these precipitates

were too great to be accounted for by adsorption from such dilute solutions. These precipitates were not completely decomposed even when excess of alkali was added.

Halla (*Z. anorg. Chem.*, 1912, **79**, 260) made a similar observation with thorium nitrate solutions. He found that at room temperature the solution became alkaline to phenolphthalein on the addition of 3·54 equivalents of potassium hydroxide, and on boiling, with 3·60 equivalents.

Another remarkable fact arising from these titrations is that alkali ranging in amounts from 0·78 to 2·21 equivalents to one molecule of thorium salt had to be added before the appearance of a precipitate. These amounts, which vary with the nature of the anion and the precipitant, do not permit of a guess as to the way in which the thorium hydroxide, or basic complex, is held in solution until the attainment of the p_H requisite for precipitation. According to Ordway (*Amer. J. Sci.*, 1858, **26**, 197), Berzelius observed that when alkali was added to a thorium sulphate solution precipitation was delayed owing to the formation of what appeared to be *un soussel soluble*. Ordway directed attention to several other examples of "soluble basic salt" formation. It will be shown in the course of this series of papers that these so-called soluble basic salts exert a pronounced influence on some of the reactions of the metals of which they are characteristic. It is surprising that "soluble basic salts" are generally formed by those metals the valencies of which are greater than two, although this is the case neither with the tervalent rare-earths nor with bivalent beryllium, which has a remarkable property of forming these basic solutions.



(2) *The Precipitation of the Hydroxides of Magnesium, Manganese, Cobalt, Nickel, and Ferrous Iron.*—The following table gives particulars of the solutions used in typical titrations, together with the amount of alkali required to cause incipient precipitation. The courses of the titrations are shown in Fig. 2.

Titration and curve No.	Temp.	Solution titrated: 100 C.c.	Normality of NaOH.	C.c. of NaOH theoretically required.	Precipitation first began		
					E.M.F.	p_H.	C.c. of NaOH.
1	16°	0·025*M*-$MgSO_4$	0·0990	50·5	0·885	10·49	1·6
2	18	0·024*M*-$MnCl_2$	0·0900	54·0	0·770	8·41	1·0
3	18	0·0247*M*-$CoCl_2$	0·0900	54·8	0·676	6·81	0·9
4	17	0·025*M*-$NiCl_2$	0·0967	51·7	0·666	6·66	0·6
5	17	0·025*M*-$FeSO_4$	0·0990	50·5	0·599	5·49	0·8

In contrast with the thorium salt titrations, the first few drops of sodium hydroxide caused a rapid diminution in hydrion concentration until a value was obtained at which precipitation commenced. Thereafter, precipitation proceeded with very little change

in p_H until the separation was nearly complete. The titration of ferrous sulphate solutions was a matter of some difficulty. As is well known, manganous and ferrous hydroxides on exposure to air readily become oxidised, and consequently the titrations involving their precipitation were performed in vessels which were stoppered as far as possible. Even so, it was not possible to prevent some oxidation from taking place, although plenty of hydrogen was passing through the solutions. The curves, however, were reproducible and there is little doubt that the voltage readings indicated correctly the changes in hydrion concentration. Further support

FIG. 2.

for the belief that the electrodes were behaving normally may be found in the following observations. Atkins (*Trans. Faraday Soc.*, 1923, **18**, 310) found colorimetrically that the precipitation of manganous hydroxide from manganous chloride solutions took place between p_H 8·6 and 9·2 and of ferrous hydroxide from ferrous sulphate solutions between p_H 5·1 and 7·6. Patten and Mains (*J. Assoc. Off. Agric. Chem.*, 1920, **4**, 233) gave p_H 5·5 to 6·0 for ferrous hydroxide.

Precipitation was again complete in each case some time before the theoretical amount of alkali had been added. Curve No. 1, magnesium sulphate, shows that the final inflexion began when 1·64 equivalents of sodium hydroxide had been added The gradual slope of the inflexion was evidently due to the partial decomposition of the basic sulphate, originally precipitated. A similar inflexion,

but steeper, took place in magnesium chloride titrations. Hildebrand and Harned (*loc. cit.*) and Hildebrand (*loc. cit.*) have also studied by means of the hydrogen electrode the precipitation of magnesium hydroxide and have suggested that the electrometric titration of hydrochloric acid solutions of dolomite might be used for the estimation of the magnesia with an accuracy of about 1%, despite the fact that the values obtained by them showed a variation of 5%. The difficulty is that magnesium hydroxide is not precipitated simply from either chloride or sulphate solutions to give sharp inflexions, but indefinite basic precipitates are formed which give poorly defined inflexions; this renders it impossible to assign a point on the curve which exactly corresponds to the neutralisation of all the acid which was originally combined with the magnesium hydroxide. According to Kolthoff (*Rec. trav. chim.*, 1922, **41**, 787), Pinkof (Thesis, Amsterdam, 1919, p. 34) has investigated the electrometric estimation of magnesia by means of the Hg|HgO|Alkali electrode, but obtained unsatisfactory inflexions, even when an excess of alkali was added and the free alkali afterwards titrated. Kolthoff recommended shaking the magnesium salt solution with an excess of alkali and allowing to stand so as to render the decomposition of the basic salt as complete as possible before titration.

Precipitation was complete from (*a*) manganous chloride solution —curve 2—on the addition of about 1·93 equivalents of sodium hydroxide, (*b*) cobalt chloride solution—curve 3—1·75 equivalents, (*c*) nickel chloride solution—curve 4—1·66 equivalents, and (*d*) ferrous sulphate solution—curve 5—1·71 equivalents. Pickering (J., 1907, **91**, 1981) observed that complete precipitation had taken place from ferrous sulphate solutions at the point where they became alkaline to phenolphthalein, and this was when sodium hydroxide had been added in amounts which varied from 1·77 to 1·86 equivalents. He considered this sufficient justification for the assertion that the precipitate was a definite basic salt, $10FeO,SO_3$. In the present titration the alkali required was somewhat less, probably owing to the slowness with which it was added (a period of 2 hours), which caused the precipitation of a sulphate less basic than Pickering's.

Although basic precipitates were always produced, it is possible to calculate from the curves the values of the solubility products of the hydroxides, which are in good agreement with those obtained by other methods. As a rule, precipitation began somewhere near the point of the first inflexion, although often at a p_H which was a little less than that at which the main precipitation took place. This was probably due to the precipitate having been formed at a point in the solution where the precipitation value of p_H had been temporarily exceeded, and time not having been allowed for its

re-solution. If, therefore, the two straight portions of the curve be produced, it is probable that the point of intersection corresponds more nearly to the amount of alkali which had to be added to produce incipient precipitation, and also to the actual hydrion concentration at which precipitation under ideal conditions would commence. This point represents the limiting conditions necessary to form a precipitate. The concentration of metal ions can be calculated from the amount of alkali, and K_w at 18° being $0{\cdot}73 \times 10^{-14}$, the concentration of hydroxyl ions can be found. Columns 2 and 5 in the following table give the co-ordinates of these points for the curves shown in Fig. 2.

No.	*E.M.F.*	p_H.	p_{OH}.	C.c. of NaOH.	$C_{M^{\cdot\cdot}} \times 10^4$.	$[Me^{\cdot\cdot}][OH']^2$.
1	0·892	10·61	3·52	0·5	2·5	$2{\cdot}3 \times 10^{-11} = [Mg^{\cdot\cdot}][OH']^2$
2	0·794	8·85	5·27	1·0	4·5	$1{\cdot}3 \times 10^{-14} = [Mn^{\cdot\cdot}][OH']^2$
3	0·680	6·92	7·22	1·0	4·5	$1{\cdot}6 \times 10^{-13} = [Co^{\cdot\cdot}][OH']^2$
4	0·675	6·81	7·32	0·8	3·9	$8{\cdot}7 \times 10^{-19} = [Ni^{\cdot\cdot}][OH']^2$
5	0·615	5·77	8·37	0·6	3·0	$4{\cdot}5 \times 10^{-21} = [Fe^{\cdot\cdot}][OH']^2$

The method is, of course, open to the objections (*a*) the difficulty of estimating accurately the amount of alkali required, and (*b*) the fact that basic salts were actually precipitated which may have had some effect on both the hydroxyl- and the metal-ion concentrations.

As a result of their conductivity determinations at 18°, Kohlrausch and Rose (*Z. physikal. Chem.*, 1893, **12**, 241) obtained a value of $3{\cdot}4 \times 10^{-11}$ for the solubility product of magnesium hydroxide. Calculation from the solubility data of Lovén (*Z. anorg. Chem.*, 1896, **11**, 404) gives values ranging from $2{\cdot}7$ to $9{\cdot}2 \times 10^{-11}$. These values are of the same order as the one obtained in this work.

Sackur and Fritzmann (*Z. Elektrochem.*, 1909, **15**, 845) carried out a conductimetric titration of manganous sulphate with barium hydroxide and obtained the value 4×10^{-14} for $[Mn^{\cdot\cdot}][OH']^2$, in agreement with the value $1{\cdot}3 \times 10^{-14}$, given in the table.

No values appear to have been found for the hydroxides of cobalt and nickel. Those reported for ferrous hydroxide are very discrepant; Müller (*Z. Elektrochem.*, 1908, **14**, 77) records $1{\cdot}64 \times 10^{-14}$ at 18°, and Krassa (*ibid.*, 1909, **15**, 491) $8{\cdot}7 \times 10^{-14}$. On the other hand, Müller ("Das Eisen und seine Verbindungen," 1917, pp. 180, 199) calculated, from Bodländer's formula (*Z. physikal. Chem.*, 1898, **27**, 66), which involves the heat of formation of ferrous hydroxide and the decomposition potentials of the two ions, the value $2{\cdot}51 \times 10^{-21}$, which is in remarkable agreement with the value $4{\cdot}5 \times 10^{-21}$ given by titration. The observations of Hildebrand (*J. Amer. Chem. Soc.*, 1913, **35**, 847) on the titration of

ferrous sulphate are in no way similar to the present ones, for the precipitation of ferrous hydroxide did not commence until a considerable proportion of alkali had been added.

These curves throw considerable light on the function of ammonium salts in preventing the precipitation of certain hydroxides. The addition of ammonium salts to ammonia may be such that the p_H is depressed below the precipitation value of either magnesium or manganous hydroxide. The approximate hydrogen-ion concentration of a solution containing ammonium hydroxide and ammonium chloride is given by

$$[H^{\cdot}] = \frac{[NH_4Cl]K_w}{[NH_4OH]K_{NH_4OH}},$$

where $K_w = 10^{-14\cdot14}$ and $K_{NH_4OH} = 10^{-4\cdot64}$ at 18°.

If ammonium chloride is regarded as being completely dissociated, the minimum number of molecules of ammonium chloride to be added to each molecule of ammonia to increase the hydrion concentration to that required just to start precipitation of (*a*) magnesium hydroxide is 0·08, (*b*) manganous hydroxide, 4·5, (*c*) cobaltous hydroxide, 380, and (*d*) hydroxides of nickel and ferrous iron, still more. In analytical processes, the condition for the prevention of the precipitation of the hydroxides of magnesium and manganese is easily satisfied, but the sole cause of the partial or non-precipitation of the other hydroxides is the magnitude of the quantities of ammonium chloride that must be added. Herz (*Z. anorg. Chem.*, 1900, **23**, 227) believed that the behaviour of ammonium chloride in depressing the hydroxyl-ion concentration was also the cause of the non-precipitation of zinc hydroxide, but, as will be shown in the next paper, zinc hydroxide is precipitated while the mother-liquor is still very slightly acid and consequently its precipitation could not be affected by the ammonium salt in the same way as in the foregoing instances. It is more probable, as has been suggested by several investigators, that it is the ammonia itself which maintains the hydroxides of zinc, cobalt, and nickel in solution through the formation of complex ions. No explanation, however, appears to be forthcoming to account for the small effect which ammonium chloride has on the precipitation of ferrous hydroxide. The researches of Lovén (*loc. cit.*), Treadwell (*Z. anorg. Chem.*, 1903, **37**, 326), and Herz and Muhs (*ibid.*, 1904, **38**, 138) have all led to the conclusion, given more directly by these titrations, regarding the influence of ammonium salts in preventing the precipitation of magnesium hydroxide. There are no grounds for attributing it to the formation of a complex magnesium anion—an explanation which is still to be found in some text-books.

Summary.

(1) The reactions between sodium hydroxide and solutions of magnesium, bivalent manganese and iron, cobalt, nickel and thorium salts have been studied by means of the hydrogen electrode.

(2) In every case, the precipitate of hydroxide contained an appreciable proportion of unattacked acid radical.

(3) Hydrogen-ion concentrations, which are peculiar to the various hydroxides, are independent of both the anion and the precipitant, and are only slightly influenced in dilute solutions by changes in concentration of the metallic salts, have to be attained before any particular hydroxide can be precipitated.

(4) The dependence of these hydrion concentrations on the solubility products of the different hydroxides has been shown by calculation, from the respective titration curves, of solubility products which are in agreement with values obtained by other methods.

(5) The well-known effect of ammonium salts in preventing the precipitation by ammonium hydroxide of magnesium and manganous hydroxides has been shown, more directly than has been the case hitherto, to be due to the incapacity of ammonia to produce hydrogen-ion concentrations which are less than those necessary for the precipitation of the respective hydroxides, provided that the ratio of ammonium salt to ammonia be sufficiently large.

The author takes this opportunity to acknowledge his indebtedness to the Department of Scientific and Industrial Research for a personal grant, and to Prof. J. C. Philip, F.R.S., for kindly placing facilities at his disposal.

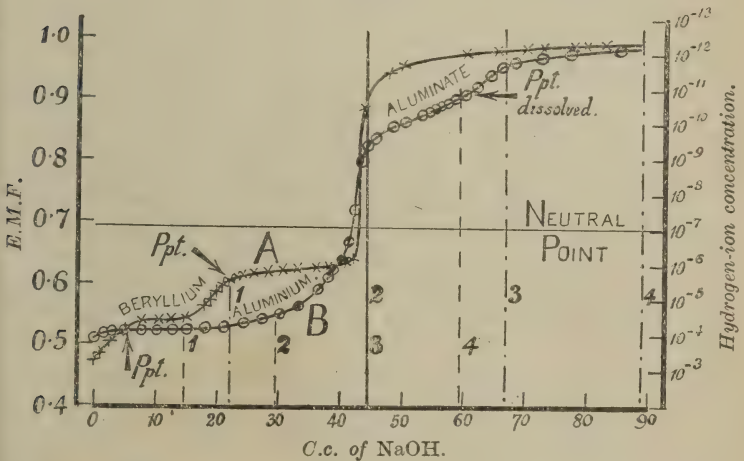
CCLXXXVIII.—*Electrometric Studies of the Precipitation of Hydroxides. Part II. The Precipitation of the Hydroxides of Zinc, Chromium, Beryllium, Aluminium, Bivalent Tin and Zirconium by Use of the Hydrogen Electrode, and their Alleged Amphoteric Nature.*



By Hubert Thomas Stanley Britton.

In this part of the work, those hydroxides, including zirconium hydroxide, which are generally supposed to have both basic and acidic properties have been studied, first with respect to their

precipitation, and secondly with respect to the changes in hydrion concentration produced when they react with sodium hydroxide in various proportions. It is very doubtful whether zirconium hydroxide is amphoteric; Hildebrand (*J. Amer. Chem. Soc.*, 1913, **35**, 847), however, has obtained electrometric evidence for the existence of zirconates.

Aluminium and Beryllium Hydroxides.—Hildebrand (*loc. cit.*) and Blum (*ibid.*, p. 1499) observed that on titrating aluminium salt solutions with sodium hydroxide, using the hydrogen electrode, a characteristic inflexion was produced in the curve which corresponded to the formation of sodium monoaluminate. It was

FIG. 1.

therefore decided to see if inflexions were also given in the titration curves of the other so-called amphoteric hydroxides.

The following two solutions (100 c.c.) were titrated at 17°, and the *E.M.F.*'s of the hydrogen electrode compared with that of the normal calomel electrode, saturated potassium chloride solution being the junction liquid. The curves are given in Fig. 1.

Soln. titrated.	Normality of NaOH.	C.c. of NaOH theoretically required.	Precipitate first appeared. *E.M.F.*	p_H.	C.c. of NaOH.
0·00667*M*-$Al_2(SO_4)_3$	0·090	44·4	0·521	4·14	5·0
0·02*M*-$BeSO_4$	0·090	44·4	0·610	5·69	23·0

Neither Hildebrand nor Blum directed attention to the fact that precipitation was complete before the theoretical amount of alkali had been added. The present titration (Fig. 1) shows that precipitation did not begin until 5 c.c. of alkali had been added,

when the dissolved aluminium sulphate had attained the composition given by the formula $Al_2O_3,2{\cdot}65SO_3$, and was complete when 42·2 c.c. (= 5·7 equivalents to 1 mol. of Al_2O_3) of alkali had been added, thereby showing that the basic precipitate contained $Al_2O_3,0{\cdot}15SO_3$. Williamson (*J. Physical Chem.*, 1923, **27**, 284) found that the precipitates formed by the addition of 2 to 4 equivalents of sodium hydroxide were of nearly constant composition and approximated to $Al_2O_3,0{\cdot}6SO_3,3H_2O$. Miller (*U.S. Public Health Reports*, 1923, **38**, 1995) investigated the precipitation from aluminium sulphate solutions by means of alkali and measured the variation in the p_H of the mother-liquors colorimetrically. For additions of sodium hydroxide up to 5 equivalents, the precipitates were similar in composition to those of Williamson, the p_H varying from 4·0 to 5·5. The curve shows that this was the variation in hydrion concentration during the addition of the first 5 equivalents of sodium hydroxide (= 37·0 c.c.) and save for that portion of the curve which corresponds to the addition of the fifth equivalent—between 29·6 and 37·0 c.c.—the gradient of the curve is both uniform and gradual such as would be expected if the precipitate formed were of uniform composition. Miller found that the greatest insolubility of the precipitate occurred when 5·5 equivalents of sodium hydroxide had been added and a hydrion concentration between $10^{-6{\cdot}7}$ and 10^{-7} had been reached. This state corresponds to the maximum decomposition of the basic sulphate which was first precipitated.

The amount of alkali required to form sodium aluminate, $NaAlO_2$, was 59·2 c.c., and although a trace of precipitate remained undissolved when that amount had been added, the solution became quite clear on the addition of a further 2 c.c. of alkali. During the process of re-solution of the aluminium hydroxide, there was a marked depression in the hydroxyl-ion concentration as shown by the inflexion of the curve which was similar to that previously observed by Hildebrand and by Blum. This inflexion seems to provide definite evidence for the existence of an aluminate in solution. As will be shown, in no other instance of the so-called amphoteric hydroxides is such an inflexion produced. Incidentally, in all cases the amounts of alkali required to dissolve the hydroxides, except that of zirconium, which does not dissolve, are considerably in excess of that denoted by the formulæ of the salts which have been said to be formed. In the case of aluminium hydroxide only is the amount of alkali required for its re-solution approximately equal to that suggested by the formula, $NaAlO_2$, and is also independent of the concentration of the sodium hydroxide used (compare Britton, *Analyst*, 1921, **46**, 363). It is possible that the other

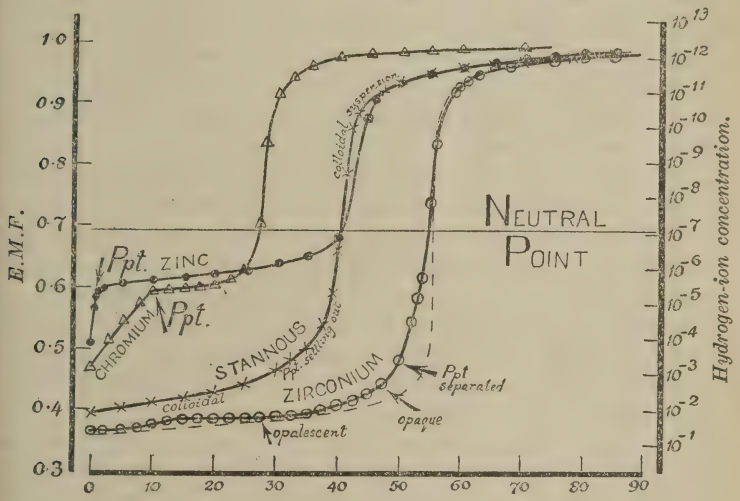
hydroxides may be acidic in their behaviour towards alkalis, but to so small an extent that the hydrogen-ion concentration of the alkali solution is scarcely affected.

The other curve in Fig. 1, which represents the titration of beryllium sulphate, has two distinct sections in the acid zone. Precipitation was delayed until the beginning of the second section had been reached, when 1·04 equivalents of sodium hydroxide had been added. Thus the beryllium sulphate had to be rendered basic to the extent shown by the formula $BeSO_4,Be(OH)_2$, before a precipitate began to separate. Although the beryllium sulphate had become so basic, the solution remained perfectly clear and betrayed no sign of colloidality. Calculation from the analytical data of Parsons (*J. Amer. Chem. Soc.*, 1904, **26**, 1433) for the liquid phases saturated with respect to basic beryllium sulphate reveals that the liquid phases all contained soluble basic sulphate whose composition appeared to be independent of the concentrations used, *viz.*, from 0·38 to 2·86% of beryllium oxide. The average ratio of beryllium oxide to sulphate in twenty-two liquid phases was $BeO,0{\cdot}547SO_3$, the ratio appearing to have varied haphazardly from 0·508 to 0·622 mol. of SO_3. (In making these calculations the analyses of two liquid phases were discarded, for it seemed certain that the solutions could not have attained anything approaching equilibrium.) Parsons' solution thus contained a little less beryllium hydroxide than was the case with this solution while undergoing titration. The fact that there was a marked inflexion in the hydrion curve just at the stage when the first half of the stoicheiometric amount of sodium hydroxide had been added seems to indicate some fundamental difference between the first and second hydroxyl groups of beryllium hydroxide which gives rise to the formation of soluble basic salts in which the first beryllium valency is attached to the weaker hydroxide group. It must be stated, however, that concentrated solutions of beryllium sulphate can be rendered still more basic to the extent of 2 mols. of $Be(OH)_2$ to 1 mol. of $BeSO_4$. It is probable, whether the basic sulphate does or does not exist in solution as a definite chemical compound, that the solution is mainly colloidal in nature, in spite of the fact that it is clear and is not coagulated by electrolytes. The colloidal aggregates of beryllium hydroxide which probably exist in some type of combination with the sulphate groups appear to be capable of ionisation, although to a less extent than would have been the case had the sulphate radicals been united with beryllium simply. If these basic solutions happen to be examples of colloidal electrolytes, it would be expected that the dissolution of beryllium hydroxide in a beryllium sulphate solution, being

brought about by the formation of aggregates of the beryllium hydroxide and the beryllium sulphate, would be accompanied either by a diminution in the number of osmotically active particles, partly present as an ionisable colloid and partly in true solution, or, in the extreme and improbable case, by no change in the number. Some support for this view is to be found in the observations of Parsons, Robinson, and Fuller (*J. Physical Chem.*, 1907, **11**, 651), who found that the effect of dissolving beryllium hydroxide in solutions of beryllium sulphate was to raise the freezing point and to reduce the conductivity.

Precipitation of beryllium hydroxide was complete when 1·91 equivalents of sodium hydroxide (= 42·5 c.c.) had been added, the precipitate containing therefore $BeO,0{\cdot}045SO_3$. The contents of the solid phases obtained by Parsons (*vide supra*) in his study of the 25°-isotherm of the ternary system $BeO–SO_3–H_2O$ show that they contained between 0·034 and 0·048 mol. of SO_3 to each mol. of BeO.

The re-solution of the beryllium hydroxide was not complete when 90 c.c. of alkali had been added, which amount was a little in excess of that required to form sodium beryllate, Na_2BeO_2, neither did the titration curve give any indication that combination had taken place.



Hydroxides of Zinc, Chromium, Bivalent Tin, and Zirconium.— The titration curves are given in Fig. 2 and the particulars of the solutions in the following table. The temperature was 18°.

Soln. titrated (100 c.c.).	Normality of NaOH.	C.c. of NaOH theoretically required.	Precipitate first appeared. *E.M.F.*	p_H.	C.c. of NaOH.
0·025*M*-$ZnSO_4$	0·090	55·55	0·583	5·20	0·6
0·005*M*-$Cr_2(SO_4)_3,K_2SO_4$ (violet)	0·100	30·0	0·591	5·34	10·0

0·01*M*-$ZrCl_4$	—	Total = 55·5	Ppt. at 0·444	2·79	47·5

The curve representing the precipitation of zinc sulphate with sodium hydroxide shows that a basic sulphate was obtained. Precipitation was complete when 1·53 equivalents of alkali had been added, which may have been due to the separation of a basic sulphate, $ZnSO_4,3ZnO$. Pickering (J., 1907, **91**, 1981), who found that precipitation was complete and the solution had become alkaline to phenolphthalein when 1·59 equivalents of alkali had been added, concluded that the basic sulphate $ZnSO_4,4ZnO$ had been produced. As in other cases, the amount of alkali required was determined by the rate at which it was added, it appearing to be a rule that

the more slowly the alkali is added the less basic is the precipitate; this, once formed, is decomposed slowly by further additions of alkali. This no doubt accounts for the greater amount of alkali required by Pickering. It is almost certain that the precipitate formed does contain at least one definite basic salt, but the evidence at present available is insufficient to establish its individuality. Of the basic sulphates which have been described, that, with varying water contents, suggested by the titration seems to be the one described by the majority of workers, among whom may be mentioned Graham (*Phil. Trans.*, 1837, **127**, 47).

Fig. 2.

Sodium hydroxide began to produce a precipitate from zinc sulphate solution at p_H 5·2. It was shown in Part I that the solubility products of magnesium and manganous hydroxides calculated from the titration curves compare satisfactorily with those given by other methods, in spite of the fact that the precipitates actually obtained are basic. If the method be applied to the zinc titration, a value is obtained which is considerably at variance with the recorded values. Thus the extrapolated *E.M.F.* at 18° = 0·600 volt, therefore $p_H = 5{\cdot}48$, and the extrapolated amount of 0·090*N*-sodium hydroxide = 0·8 c.c., therefore $C_{Zn^{\cdot\cdot}} = 3{\cdot}6 \times 10^{-4}$, and consequently $[Zn^{\cdot\cdot}][OH']^2 = 10^{-21}$ approx. The values so far recorded are those by Herz (*Z. anorg. Chem.*, 1898, **23**, 227) and Bodländer (*Z. physikal. Chem.*, 1898, **27**, 66), who found the solubility of zinc hydroxide to be 2·6 and $2{\cdot}5 \times 10^{-5}$ gram-mol. per

litre respectively, from which the respective solubility products 1·8 and 1·6 $\times$ 10^{-14} are obtained. These values appear to be incorrect, for if correct they would correspond to a hydrogen-ion concentration of about 10^{-9} at which zinc hydroxide would be precipitated, as is the case with manganous hydroxide, whose solubility product is 1·3 $\times$ 10^{-14}. It will be shown in a later paper dealing with the precipitation of basic zinc salts—chromates, carbonates—that such a hydrion concentration could not possibly be correct.

Complete re-solution of the zinc hydroxide did not take place in the course of the titration, although more than two molecules of sodium hydroxide were added in excess of that required to form zinc hydroxide. These measurements give no insight into the acidic nature of zinc hydroxide, no inflexions having appeared when either 83·3 or 111·1 c.c. of alkali, the amounts required to form the zincates having the respective formulæ $NaHZnO_2$ and Na_2ZnO_2, had been added. Calculation, however, shows that the concentration of hydroxyl-ions in the alkaline solutions was slightly less than would have been the case had no substances other than the alkali been present. For example, the p_H of the solution containing the alkali required to form $NaHZnO_2$ was 12·06 as compared with the calculated value 12·25. It is probable that the diminution in hydroxyl-ion concentration was due both to some chemical action and to adsorption having taken place. This view is supported by the conductivity measurements of Chatterji and Dhar (Faraday Soc., "Symposium on Colloids," 1921, p. 123), who state that whereas the conductivity of sodium hydroxide was not appreciably changed by the addition of the majority of amphoteric hydroxides, the change when zinc hydroxide was added was pronounced. Similar observations were made by Carrara and Vespignani (*Gazzetta*, 1900, **30**, 35) with potassium hydroxide solutions of zinc hydroxide. Hildebrand and Bowers (*J. Amer. Chem. Soc.*, 1916, **38**, 785) studied with the hydrogen electrode the reaction of alkalis with certain zinc salts and they claim to have obtained distinct evidence of the existence of monobasic zincic acid, $HHZnO_2$, for they found a sudden increase in p_H at the point where the amount of sodium hydroxide added was that required for the formation of $NaHZnO_2$. Repeated titrations have been made by the author on zinc salt solutions of the concentration used by Hildebrand and Bowers, but hitherto their observation has not been confirmed. It is interesting to recall that since Hildebrand and Bowers's paper appeared Goudriaan (*Proc. K. Akad. Wetensch. Amsterdam*, 1919, **22**, 179) has investigated the isotherm at 30° of the ternary system Na_2O–ZnO–H_2O and has found that

the only salt of sodium and zinc hydroxides is $Na_2ZnO_2.4H_2O$, which happens to exist in equilibrium with concentrated sodium hydroxide solutions containing from 27·8 to 39·2% of Na_2O. This salt is decomposed by water and so are the liquid phases with which it exists in equilibrium, for on dilution they deposit zinc hydroxide.

Chrome alum was chosen for the titration of the chromium salt, as it dissolves to give the normal violet solution. No precipitate was formed until one-third of the stoicheiometric amount of sodium hydroxide had been added—the p_H having previously rapidly increased until the precipitation p_H had been reached. The amount of alkali required to cause the beginning of precipitation seems to suggest that the basic salt retained in the solution had the formula $Cr(OH)SO_4$. It is probably a coincidence, for dissolved chromium sulphate can be rendered more basic and still remain in solution. The curve shows that the mother-liquor became alkaline when 27·5 c.c. (= 5·5 equivalents) of alkali had been added—an amount pointing to the final composition of the precipitate being $Cr_2O_3,0·25SO_3$. Williamson (*J. Physical Chem.*, 1923, **27**, 384) found, by adding varying amounts of sodium hydroxide to a decimolar solution of chrome alum, that when from 2 to 5 equivalents of alkali are added to one molecule of chrome alum the precipitates are almost constant in composition, $Cr_2O_3,0·7SO_3.3·6H_2O$, but when 6 equivalents are employed the precipitate is still more basic, as shown by the formula $Cr_2O_3,0·28SO_3,3·18H_2O$. This formula is similar to that indicated by the titration. Thus it appears that during the steady increase in p_H occurring while from 10 to 22 c.c. of alkali were being added a basic sulphate of approximately constant composition was being formed, which after precipitation became more hydrolysed by the further addition of alkali.

The titration curve affords no evidence of the constitution of alkaline solutions of chromium hydroxide, although the amount of alkali which was added was in excess of that required to form Na_3CrO_3. The amount of alkali was insufficient to dissolve the chromium hydroxide. The potential differences obtained in the alkaline solutions pointed to hydroxyl-ion concentrations which were a little less than those obtained by calculation. The difference may probably be accounted for by adsorption by the chromium hydroxide or possibly by some little union having taken place. Fricke and Windhausen (*Z. anorg. Chem.*, 1924, **132**, 273) also have shown that there is a slight difference in hydroxyl-ion concentration observable between sodium hydroxide solutions and those of chromium hydroxide in sodium hydroxide of the same concentration when measured by the Hg|HgO electrode.

Electrometric titrations were now carried out on violet and green solutions of chromium salts to see if some clue to the difference of colour could be discovered. The Werner co-ordination theory is generally held to give the most plausible explanation of the violet and green forms. Werner and Gubser (*Ber.*, 1901, **34**, 1579) first applied the theory to chromium chloride, and quite recently Lamb and Fonda (*J. Amer. Chem. Soc.*, 1921, **43**, 1154) referred to its application to chromium salts as " perhaps the most striking exemplification of the Werner theory of molecular structure." It is therefore surprising that the evidence on which Werner and Gubser based their views is quite unconvincing, and indeed, the difference might well be due to the existence in the green solutions of basic aggregates which are essentially colloidal in nature. The low conductivity of solutions of the green form of chromium chloride was regarded as evidence of the dissociation of a binary salt, $(CrCl_2,4H_2O)Cl,2H_2O$. The abnormal molecular weights calculated from the depression of the freezing point were supposed to supply fundamental evidence for this structure of the green form, for they happened to be of the order of one-half the molecular weight of hexahydrated chromium chloride. It is strange that the weight of six molecules of water should have been included in the latter molecular weight, seeing that four molecules only are supposed to be present in the nucleus of the complex chromium kation. The observed molecular weights of the violet chromium chloride were of the order of one-quarter of that of the hexahydrated salt, and this was taken as being due to $(Cr6H_2O)Cl_3$. The results show, however, that the observed molecular weights of the violet chloride in the more dilute solutions are somewhat too high—this may be regarded as due to incomplete ionisation—but it is surprising to find that the agreement between the observed and the theoretical values becomes perfect for a 12% solution, in which the dissociation must be far from complete. Werner and Gubser tried to confirm the view that only one chlorine atom in the green form was ionisable and therefore precipitable with silver nitrate, but always found that the amounts precipitated were greater than that corresponding to one atom, even in rapid estimations carried out at 0°. Similar observations have also been made on the incomplete precipitation with barium chloride from green chromium sulphate solutions. It is difficult to reconcile with the co-ordination theory the observations of Weinland and Koch (*Z. anorg. Chem.*, 1904, **39**, 296) on the precipitability of chlorine from green chromium chloride solutions with various silver salts, both in presence and in absence of free acid. The amount of chlorine precipitated depended on the nature and the quantity of the

particular silver salt used; without the addition of acids, all the silver salts precipitated at least two-thirds of the chloride. The presence of nitric acid had the effect of diminishing the amount of chloride liberated, whereas the silver salts of weak acids, such as acetic, lactic and nitrous, and silver sulphate immediately precipitated all the chloride. Silver salts of strong acids did not cause complete precipitation and free strong acids suppressed the precipitation even more. Lamb (*J. Amer. Chem. Soc.*, 1906, **28**, 1710; Lamb and Fonda, *ibid.*, 1921, **43**, 1154) tried to explain the above observations by a gradual transition from the green variety to the violet due to the hydrogen-ion concentrations ruling during the reactions, but in order to show how the transformation took place they found it necessary to postulate further that the green variety first underwent hydrolysis to form some such basic complex as $CrCl_2OH$.

The essential difference between the violet and the green salts of chromium appears to be concerned with the amount of hydrolysis and with a change in the chromium hydroxide which is probably akin to that produced by ageing. The normal or violet salts must therefore be prepared under such conditions that the hydrolysis is minimised by crystallising at as low a temperature as possible from very strongly acid solutions. The simplest way to convert the violet form into the green is by boiling. By so doing, the hydrolysis becomes enhanced and it is probable that the chromium hydroxide bound in the form of aggregates of basic salt tends to lose its reactivity. The change also seems to be linked up with the treatment to which the chromium hydroxide had been subjected previous to its solution in acids, for, as shown by Recoura (*Compt. rend.*, 1895, **120**, 1337), the change from violet to green can be effected by allowing an alkali solution of chromium hydroxide to age before dissolution in acid. It has been shown that the change in colour of chromium sulphate solutions is accompanied by the liberation of acid (see Denham, *Z. anorg. Chem.*, 1908, **57**, 361—bibliography given) with the consequent separation of a soluble basic salt. The dialysis experiments of van Cleeff (*J. pr. Chem.*, 1881, **23**, 58) and Richards and Bonnet (*Proc. Amer. Arts Sci.*, 1903, **39**, 1) show that the soluble basic aggregates are colloidal in nature, for the residue left in the dialyser from green solutions was basic whereas violet chromium sulphate passed through completely. Again, Richards and Bonnet have shown that in the precipitation of sulphate as barium sulphate from green sulphate solutions green basic chromium sulphate was always carried down.

The fact that barium chloride and silver nitrate produce incomplete precipitation appears to be a property in common with other

elements which give solutions which are almost certainly colloidal. Thus the chloride in ferric oxide hydrosols is not readily precipitated with silver nitrate, neither is it completely precipitated from solutions of either ferric or zirconium chloride in the cold, and especially after the solutions have been allowed to stand or have been boiled.

The change of violet solutions to green immediately on the addition of a little alkali is significant. The green colour of the solution containing the soluble basic chromium salt is undoubtedly connected with the existence of the green chromium hydroxide in solution in the form of basic aggregates.

Hydrogen electrode titrations have been carried out at 18° of violet solutions of both the chloride and the sulphate, and also of green solutions which were prepared by boiling the normal solutions for 5 minutes and rapidly cooling to 18°. The initial readings are given in the following table.

Salt.	Conc.	Colour.	*E.M.F.* against *N*-calomel.	p_H.	% Hydrolysis.
Chloride.....	0·0133	Blue	0·467	3·19	1·62
	0·0133	Green	0·409	2·18	16·4
Sulphate.....	0·0050	Violet	0·467	3·19	2·16
(as chrome alum)	0·0067	Green	0·395	1·94	28·7

The percentage of hydrolysis has been referred to the total amount of combined acid. It will be seen that the effect of boiling for a short time was to increase the amount of hydrolysis more than tenfold. The titration curves are similar to that given by chromium sulphate (Fig. 2), with the exception that the sections prior to precipitation in the case of the green solutions are somewhat curved, owing to the neutralisation of the liberated acid, instead of being rectilinear as in the case of the violet or blue solutions. The following table gives the important features of these titrations.

	Precipitation began.			Precipitation complete.
Salt.	*E.M.F.*	p_H.	Equivs. of NaOH to 1 equiv. of Cr.	Equivs. of NaOH.
Blue $CrCl_3$	0·588	5·28	1·07	2·78
Green $CrCl_3$	0·586	5·25	1·43	2·85
Violet chrome alum	0·591	5·30	1·00	2·75
Green chrome alum	0·587	5·27	1·21	2·71

The table shows that in each case precipitation was dependent on the attainment of a hydrion concentration, p_H 5·3, and that precipitation began from those solutions which contained chromium in the normal condition when about one equivalent of sodium hydroxide had been added, whilst the green solutions did not yield precipitates until somewhat larger proportions of alkali had

been added. The greater amounts of alkali required in the latter case show that the change produced in the solutions on turning from violet or blue to green has rendered the chromium salts more resistant in their behaviour towards alkali.

It is probable that the basic chromium complexes which seem to be present in green solutions are "micellar" in structure and constitute a colloidal electrolyte in which the kations are composed of chromium hydroxide and varying amounts of acid radical, a portion only being ionisable, and may perhaps be represented thus:

$$\left[\begin{matrix} & (OH)_{3x} \\ Cr_{(x+y+1)} & \\ & R_{3y} \end{matrix}\right] R_3 \rightleftharpoons \left[\begin{matrix} & (OH)_{3x} \\ Cr_{(x+y+1)} & \\ & R_{3y} \end{matrix}\right]^{\cdots} + 3R',$$

x and y being indefinite. Some such arrangement as this would account for the slowness with which silver chloride and barium sulphate may be precipitated from the appropriate green solutions, and this is especially so when the chromium solutions happen to be basic, such as may be prepared from the basic glassy masses obtained by evaporating solutions of chromium salts to dryness. There appears to be a tendency for one-third of the combined acid in a chromium salt, *i.e.*, the amount corresponding to that which seems to be loosely combined and gives rise to the formation of the "soluble basic salt," to be driven off on evaporation. Thus a basic salt prepared in this way had a composition corresponding to $Cr(OH)SO_4$ and gave in solution no precipitate with barium chloride; neither did it do so with ammonia except on boiling or keeping. The soluble basic complexes in the green solutions have some properties in common with chromium hydroxide. Chromium hydroxide which has been suspended in water and boiled, or has been allowed to stand, becomes difficultly soluble in acids, as is also the case with ferric hydroxide, slowly dissolving only in concentrated acid solutions. Hence it is evident why the acids present in Weinland and Koch's experiments did not immediately decompose the green salt and render the chloride available for precipitation, and why the acid actually retarded the precipitation by depressing the ionisation of the colloidal electrolyte. The conception of basic aggregates also supplies an explanation why it was only the silver salts of weak acids which caused nearly all the silver chloride to be precipitated. The first reaction taking place between the precipitant and the colloidal electrolyte is one of double decomposition, whereby the chloride anion of the chromium complex is replaced by the anion of a weak acid. This would diminish the hydrogen-ion concentration of the solution, which would therefore tend to approach the value requisite for the precipitation of

chromium hydroxide; the basic complexes would thus be rendered so unstable that the chloride radicals in them would become susceptible to reaction with the silver salt.

A qualitative comparison of the absorption spectra of solutions of equal concentrations of (*a*) violet chrome alum, (*b*) green chrome alum, and (*c*) violet chrome alum to which an excess of sodium hydroxide had been added, revealed that those of solutions (*b*) and (*c*) were similar. The main difference between (*a*) and (*b*) was that the very faint yellow band, 5750—5950 Å., in the former had become wider and more pronounced in the latter, 5660—6110 Å. There was also some absorption in (*b*) in the blue region extending up to 4840 Å.; that in (*a*) extended to 4530 Å. The spectra of (*b*) and (*c*) were identical over the short wave-lengths, but the yellow band was found to have moved a little, to 5800—6160 Å. It is probable that alkaline solutions of chromium hydroxide are largely colloidal, and the similarity of the last two spectra would suggest that some part of the green solution also was colloidal, in which case the increased absorption might be attributed to the presence of exceedingly small colloidal basic aggregates.

The stannous chloride solution used in the titration shown in Fig. 2 was turbid and became more and more so until 30 c.c. of alkali had been added, when a heavy precipitate began to settle; the precipitate passed back again into colloidal suspension as soon as the solution had become alkaline ($p_H = 8{\cdot}7$) and 41·0 c.c. of sodium hydroxide had been added. From the *E.M.F.* readings made during the titration, the amounts of hydrolysed hydrochloric acid have been calculated at the various stages, from which the compositions of the basic stannous chloride aggregates given in the following table have been calculated.

C.c. of 0·0932*N*-NaOH.	*E.M.F.*	Atoms of Cl neutralised.	Fraction of unneutralised HCl hydrolysed.	Comp. of basic stannous chloride. To 1 atom of Sn.		Mol. of HCl hydrolysed.
				Cl.	OH.	
0	0·391	0	0·336	1·33	0·67	0·67
5·1	0·401	0·24	0·269	1·29	0·71	0·47
10·0	0·412	0·47	0·208	1·22	0·78	0·32
15·2	0·418	0·71	0·204	1·03	0·97	0·26
20·0	0·428	0·93	0·173	0·88	1·12	0·18
25·15	0·440	1·18	0·145	0·63	1·37	0·12
30·0	0·463	1·40	0·085	0·55	1·45	0·05
35·0	0·499	1·63	0·033	0·36	1·64	0·01
39·0	0·585	1·82	0·002	0·18	1·82	0·0004

The table shows that the basic stannous chloride particles varied in composition from $SnCl_{1\cdot33}(OH)_{0\cdot67}$ to $SnCl_{0\cdot55}(OH)_{1\cdot45}$ during the addition of the 30 c.c. of alkali and yet remained in colloidal suspension. The last column indicates that the molecular proportion

of hydrochloric acid hydrolysed gradually grew less as the titration proceeded. It was not until the particles had become to this extent basic, and the concentration of the free hydrochloric acid with which they had existed in equilibrium had become relatively small, that the colloidal solution coagulated. The solution became neutral when 40 c.c. of alkali had been added, showing that chloride was still being retained by the stannous hydroxide, its composition having then become $SnCl_{0\cdot14}(OH)_{1\cdot86}$. The fact that peptisation of the precipitate took place immediately the mother-liquor became alkaline seems to be important, and it may be that the reaction of the alkali with the retained chloride in the precipitate was largely responsible. No inflexion was produced in the curve in the alkaline zone.

Hildebrand (*loc. cit.*), besides finding an inflexion for zinc hydroxide, found one for zirconium hydroxide also. The precipitation of zirconia from a solution in hydrochloric acid has been investigated (Fig. 2) and also the change in p_H in the mother-liquor when the precipitated zirconium hydroxide was in presence of an excess of sodium hydroxide. The present experiments fail to confirm Hildebrand's observation of a distinct inflexion, which he stated to correspond to the formation of sodium zirconate. There appear to be absolutely no grounds for regarding zirconium hydroxide as amphoteric. Unlike the other hydroxides studied in this paper, that of zirconium is not dissolved by alkalis under any conditions. In common with all other gelatinous hydroxides, it adsorbs salts from solutions in which it may be suspended, and on precipitation with an excess of alkali does naturally adsorb some alkali, the amount depending on the quantity of alkali present. These precipitates do not hold the alkali in any form of combination, as would be the case if they contained insoluble zirconates. It is remarkable that whilst alumina is one of the few oxides which can be considered with any degree of certainty to be amphoteric in the wet state, it should be the only one which is definitely amphoteric in the dry state, yielding on fusion with alkalis or with alkali metal carbonates products which are soluble.

The titration curve gives some insight into the mechanism of precipitation. The hydrochloric acid solution was prepared from a basic zirconium chloride which contained 1·737 mols. of Cl to 1 mol. of ZrO_2. The basic chloride dissolved in water to give a perfectly clear solution. An aqueous solution, 0·04 normal with respect to the chloride content, was hydrolysed immediately after preparation to the extent of 54%. The dotted line in the diagram represents the neutralisation curve of hydrochloric acid solution having the same chloride concentration as that of the acid solution

of zirconium chloride with the same alkali solution. The small but definite inflexion which occurred when 11·1 c.c. of alkali had been added is remarkable. It marks the end of the neutralisation of the excess of acid over that required to form zirconium tetrachloride and thus points to the existence in solution of zirconium chloride, although considerably hydrolysed. This is opposed to the generally accepted view that the chloride dissolves as "zirconyl chloride," $ZrOCl_2$, dissociating into "zirconyl" ions, $ZrO^{\cdot\cdot}$, and Cl', and free hydrochloric acid. The solution began to become opalescent when 27·5 c.c. of alkali had been added, and this was before the amount of alkali had been added which was necessary to form either $ZrOCl_2$ (33·3 c.c.) or the basic salt from which the solution was prepared (36·2 c.c.). As solutions of both these substances happen to be perfectly clear, it follows that the premature opalescence obtained in the titration must have been due either to the electrolytes present or to the hastened growth of the colloidal particles owing to the rate at which the alkali was added. It must have been due to the latter, for salts may be added to basic zirconium chloride solutions of similar composition without producing any perceptible effect. The zirconium chloride curve tends to approach the hydrochloric acid curve when approximately two equivalents of sodium hydroxide have been added (33·3 c.c.). At this stage the chloride radicals in combination with the zirconium were undergoing the maximum hydrolysis. The solution became increasingly colloidal in appearance as the alkali was added until it became opaque and coagulation suddenly took place (47·5 c.c.). The following table gives the fraction which had suffered hydrolysis of the portions of zirconium chloride which had not entered into the reaction at the various stages in the titration, from which has been found the composition of the unhydrolysed basic zirconium chloride together with the molar proportion of the free acid which had been hydrolysed.

C.c. of NaOH.	*E.M.F.*	Atoms of Cl neutralised.	Fraction of unneutralised HCl hydrolysed.	Comp. of basic chloride. To 1 atom of Zr. Cl.	Comp. of basic chloride. To 1 atom of Zr. OH.	Mols. of HCl hydrolysed.	Remarks.
0	0·366	0	0·529	2·12	1·88	3·12	Free HCl
11·1	0·380	0	0·579	2·32	1·68	2·38	,,
22·2	0·386	1·0	0·670	3·01	0·99	2·01	Clear
27·8	0·390	1·5	0·714	3·28	0·72	1·78	Opalescent
33·3	0·393	2·0	0·828	3·66	0·34	1·66	,,

38·9	0·406	2·5	0·685	3·53	0·47	1·03	,,
44·4	0·426	3·0	0·480	3·48	0·52	0·48	,,
47·5	0·444	3·28	0·333	3·52	0·48	0·24	Opaque
50·0	0·481	3·5	0·107	3·55	0·45	0·05	Coagulated
52·7	0·571	3·75	0·006	3·75	0·25	0·00	,,

In these calculations it has been assumed that the hydrochloric acid was completely dissociated. The degree of hydrolysis of the zirconium chloride in the free acid solution was obtained by subtracting the hydrion concentration produced by the excess of acid from the total hydrion concentration calculated from the observed voltage.

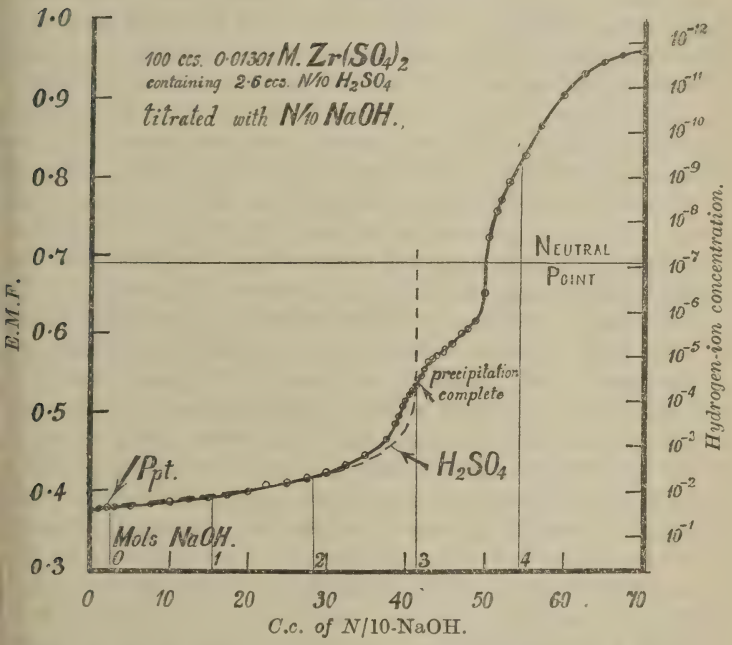
It will be seen that the maximum hydrolysis occurred when just over two atoms of chloride of the zirconium chloride had been reacted upon, and that the rapid increase in hydrolysis during the first portion of the titration was accompanied by a corresponding change in the composition of the basic zirconium chloride actually present in the solution (columns 5 and 6). Thereafter, the composition of the basic zirconium chloride remained nearly constant and corresponded roughly with the formula $Zr(OH)_{3\cdot5}Cl_{0\cdot5}$, until after coagulation ensued, when it was partially decomposed by the alkali. The first half of the titration, besides yielding a rapidly increasing basic chloride, was accompanied by a gradual decrease in the amount of free acid, which tended to render the basic zirconium chloride more and more insoluble and thus produced a gradual growth in the size of the basic chloride particles. At the beginning of the titration the particles probably approximated to molecular dimensions, but as the chloride became more and more basic these exceedingly small particles coalesced to form larger and larger aggregates until they became sufficiently big to render the solution opalescent, and this process still continued through the period when the solution had become visibly and increasingly colloidal right up to the point when coagulation occurred. The table shows that the free acid had some inhibiting effect on this growth in the size of the particles, for it was only after an appreciable proportion of the acid had been neutralised that the solution became opalescent, and, after the basic chloride particles had become uniform in composition, it was only after the amount of free acid had been almost removed that the colloidal solution coagulated.

These observations seem to suggest that the nature of basic zirconium salt solutions is essentially colloidal in spite of the fact that many of the solutions are perfectly clear. Müller (*Z. anorg. Chem.*, 1907, **52**, 316) arrived at the same conclusion from a study of the reactions of zirconium salt solutions. The observations, moreover, furnish an excellent example to show that the process of precipitation is one which involves the formation of a colloidal solution which subsequently coagulates. In the majority of precipitations the colloidal solution stage is so rapidly passed that it is not observed.

Adolf and Pauli (*Kolloid Z.*, 1921, **29**, 173) found that the hydrolysis of solutions of zirconium oxychloride, $ZrOCl_2$, of concentrations ranging from 0·0022 to 0·125*M*, after 10 days' standing, varied irregularly between 35 and 50%. As mentioned above, a freshly prepared solution of zirconium chloride containing 1Zr : 1·737Cl was hydrolysed to the extent of 54%, whereas in the solution containing the basic chloride having the same composition in the titration the hydrolysis was considerably greater, *viz.*, 83·1%. In the latter case, the solution was opalescent and therefore contained larger particles than the corresponding clear solution. Thus the degree of hydrolysis appears to be a function of the size of particle, and consequently the smaller amount of hydrolysis in the clear solutions of Adolf and Pauli must have been due to the presence of particles which had been rendered small by the solution effect of the free acid. They prepared zirconium oxide hydrosols by dialysis, which contained appreciable amounts of chloride; one contained 0·33 atom of chlorine and the other 0·26 atom to each atom of zirconium. Both sols were hydrolysed to small extents, *viz.*, 0·9 and 0·6%. It is important to note that, although the concentration of free acid was small, there was a relatively large concentration of chloride ions, 41 and 37% respectively of the total chlorine content. The ratio Zr : Cl in these hydrosols corresponds to points on the titration curve lying between those representing 3·5 and 3·75 equivalents of sodium hydroxide, *i.e.*, just after coagulation had taken place. The amount of free acid was of the same order in both the colloidal solutions and the mother-liquor in which the basic zirconium precipitate was suspended. The large concentration of chloride ions in the colloidal solutions shows that the basic chloride particles do dissociate in some way.

The degree of dispersion of colloidal basic chloride solutions appears to be dependent on the amount of acid present. Colloidal solutions of basic chloride in which some free acid is present tend to become clear on standing, no doubt owing to the tendency of the colloidal particles to pass into solution. This behaviour may possibly account for Rodd's observation (J., 1917, **111**, 396) that a basic chloride, $Zr_5O_8Cl_4,22H_2O$, separated at first from concentrated solutions of zirconia in which the concentration of hydrochloric acid had been suitably regulated. When the solution had become more acid owing to separation of the highly basic chloride, crystals of ordinary $ZrOCl_2,8H_2O$ began to separate. Rodd believed that the formation of the very basic chloride (Zr : Cl = 5 : 4) was due to some intrinsic change having taken place in the constitution of the zirconium hydroxide. The important point is

that the salt appears to have given a clear solution, whereas when the zirconium chloride present in the solution undergoing titration had acquired the same composition by the addition of 35·5 c.c. (= 3·2 equivalents) of sodium hydroxide the solution became opaque. Rodd mentions that a solution of his salt was precipitated by either sulphuric acid or sulphates generally. There seems to be no doubt that Rodd obtained his highly basic chloride through using a concentration of hydrochloric acid much less than that required for the crystallisation of the usual $ZrOCl_2,8H_2O$, and thus obtained a substance nearly as basic as that shown to exist in the solution during the second part of the titration, *viz.*, $Zr(OH)_{3\cdot5}Cl_{0\cdot5}$. Rodd's salt is $Zr(OH)_{3\cdot2}Cl_{0\cdot8}$. The fact that Rodd obtained his salt by a slow crystallisation process from an acid solution indicates that it must have been composed of very small particles, their growth having been prevented by the acid present. Hence the reason for the substance passing into a clear or nearly clear solution. The fact that sulphates in general caused its precipitation appears to be an example of the normal behaviour of electrolytes towards colloidal solutions. Rodd, however, believed these precipitations to be cases of double decomposition, as the precipitates obtained by the addition of sulphuric acid and ammonium sulphate were within a few units % of the same composition, $Zr_5O_8(SO_4)_2,14H_2O$. He was of the opinion that this formula represents a " true chemical individual," but added that there was " no evidence to show that this is a true hydrate."



Solutions of zirconium sulphate behave towards some reagents in a manner quite different from that of solutions of either the chloride or the nitrate, so much so that Ruer (*Z. anorg. Chem.*, 1904, **42**, 85) and others have postulated that the sulphate must exist in solution as a complex zirconium sulphuric acid in which the zirconium is present in a complex anion and thereby escapes precipitation. Thus oxalic acid and alkali metal oxalates fail to precipitate it, and sulphites only precipitate it slowly and incompletely. If potassium chloride be added to a zirconium sulphate solution, either before or after the addition of sodium oxalate, the solution becomes readily precipitable. Another point of difference is the behaviour towards sodium tartrate. Zirconium chloride yields a precipitate with sodium tartrate, readily soluble in excess, as compared with the precipitate which is obtained from zirconium sulphate solution, which dissolves only on boiling or on prolonged standing. The precipitate in the latter case is mainly basic zirconium sulphate. Chauvenet (*Ann. Chim. Phys.*, 1920, **13**, 82) titrated several zirconium salt solutions conductimetrically and found that the titration curves, instead of being straight lines as

in acid–alkali neutralisations, were slightly curved, such that the tangents drawn to the curves at each end intersected at points corresponding to approximately two equivalents of alkali. This he claimed to be evidence for the existence of the "zirconyl," $ZrO^{\cdot\cdot}$, radical. The data given in the previous table show that during the addition of the first two equivalents of alkali the basic chloride undergoes hydrolysis and the remaining two equivalents cause little variation in its composition, $Zr(OH)_{3\cdot5}Cl_{0\cdot5}$, except at the end. These two processes, which took place in the precipitation from zirconium chloride solution, undoubtedly account for the change in the slope of Chauvenet's curve, which had therefore nothing to do with an alleged zirconyl radical. Chauvenet also titrated a solution of zirconium sulphate by the conductivity method and obtained the point of minimum conductivity when 3 equivalents of alkali had been added; this he claimed to be due to the separation of a definite basic sulphate, $ZrOSO_4,ZrO_2$. He also claimed that an inflexion was produced when two equivalents of alkali had been added, which pointed to another definite basic salt, zirconyl sulphate, $ZrOSO_4$. In view of the peculiar properties shown by zirconium sulphate and of the contentions of Chauvenet, it was decided to subject the sulphate to titration with the hydrogen electrode.

The zirconium sulphate had the composition $ZrO_2,2{\cdot}10SO_3,2{\cdot}29H_2O$, from which a $0{\cdot}01301M$-$Zr(SO_4)_2$ solution was prepared at room temperature; therefore 100 c.c. of the solution contained uncombined sulphuric acid equivalent to 2·56 c.c. of N/10-alkali. The curve showing the titration with N/10-sodium hydroxide of 100 c.c. of this solution at 18° is given in Fig. 3. The first inflexion occurred when the added alkali was equivalent to 3 mols. to 1 mol. of zirconium sulphate. At this point precipitation was complete and the solid had the composition $ZrO_2,\frac{1}{2}SO_3,xH_2O$. Further addition of alkali (up to 50·4 c.c.) caused its partial decomposition and the mother-liquor became alkaline. The precipitate must then have contained $ZrO_2,0{\cdot}16SO_3$, but, as the slope of the curve shows, during the addition of the next few c.c. of alkali some alkali was still being withdrawn from the solution and utilised in decomposing the precipitate still more. The sulphate solution, unlike that of the chloride, began to yield a precipitate immediately the alkali was added. It is curious that by warming zirconium sulphate solution it may be made strongly basic by means of alkali without the separation of a precipitate, the solution remaining quite clear. The dotted curve given in Fig. 3 is the titration curve of 100 c.c. of sulphuric acid containing 41·6 c.c. of N/10-sulphuric acid, equivalent in concentration to three-quarters of the com-

bined acid in the zirconium sulphate solution together with the small amount of free sulphuric acid. The two curves are nearly coincident over the first half of the zirconium sulphate curve, but vary a little during the addition of the third equivalent. The curves show therefore that the zirconium sulphate solution contained a basic sulphate and free sulphuric acid in approximately the proportions 1 mol. of $ZrO_2,\frac{1}{2}SO_3$ to $1\frac{1}{2}$ mols. of H_2SO_4. The addition of alkali had the main effect of neutralising the free sulphuric acid, with the consequence that the basic sulphate with which it had existed

FIG. 3.

some kind of equilibrium was precipitated. The curves give no evidence of Chauvenet's so-called zirconyl sulphate, but do confirm his observation of the precipitation of a basic sulphate of approximately the composition $ZrO_2,\frac{1}{2}SO_3$. Further work, however, is necessary on the lines of the phase rule before its individuality can be established.

Chauvenet (*loc. cit.*) determined the molecular weight of zirconium sulphate from the depression of the freezing point of an aqueous solution, and found it to be a little more than a quarter of that of $ZrOSO_4,H_2SO_4$. He therefore argued that zirconium sulphate on solution split up into zirconyl sulphate and sulphuric

acid. If, however, the partial dissociation of sulphuric acid be taken into consideration, the anomalous freezing point might also be taken to support the constitution of zirconium sulphate solution suggested by the above titrations.

The view that these somewhat inert basic zirconium sulphate particles exist in solution in equilibrium with hydrolysed sulphuric acid gives an explanation of the abnormal behaviour of reagents towards zirconium sulphate solutions, especially that of sodium tartrate in precipitating the basic sulphate in such a state that it is not readily soluble in excess of the reagent.

Some criticism appears to be not out of place here of Chauvenet's density method (*Compt. rend.*, 1917, **164**, 864), by which he claimed to ascertain which of the many reported basic zirconium sulphates were definite individuals. He treated zirconia with various quantities of sulphuric acid and dried the products by evaporation at 200°. He stated that at this temperature the products became rigorously anhydrous. Van Bemmelen (*Z. anorg. Chem.*, 1906, **49**, 125) showed that zirconia, when dried at 200°, retained much water which was not completely driven off at 300°. The present author found that after several hours' drying at 200° water was retained to the extent shown by the formula $ZrO_2,0{\cdot}48H_2O$. The salt was found by immersion in nitrobenzene to have the density 4·02, but when rendered water-free by ignition its density was 5·47 (compare 5·489, Venable and Belden, *J. Amer. Chem. Soc.*, 1898, **20**, 273). Zirconium sulphate also requires a much higher temperature than 200° for complete dehydration. By plotting the ratio $ZrO_2 : SO_3$ against the densities, determined by immersion in nitrobenzene, he obtained a curve which had several angular points indicating definite basic salts. On plotting the curve, however, the present author found that all the points lay either on or close to a continuous curve; the small deviations from the curve could readily be accounted for by the considerable experimental errors which the method involved. The determination of the densities of amorphous substances, such as these basic sulphates, is a difficult problem, and the values at best can only be approximate on account of the difficulty of completely filling the porous particles with nitrobenzene. It is conceivable that Chauvenet's density method might be applied in cases where the densities, supposing they could be determined with sufficient accuracy, of the different basic salts were widely different. There is no agreement between Chauvenet's density of $3ZrO_2,4SO_3$, 3·02, and that, 4·1, of Hauser and Herzfeld (*Z. anorg. Chem.*, 1910, **67**, 369). It thus appears that the conclusions of Chauvenet are without satisfactory grounds.

Summary.

(1) The hydrogen-ion concentrations ruling throughout the precipitation of the hydroxides, actually basic salts, of aluminium, beryllium, zinc, chromium, stannous tin, and zirconium have been investigated.

(2) The hydrogen-ion concentrations to be attained for the precipitation of the hydroxides of aluminium, beryllium, zinc, and chromium have been found.

(3) New light has been thrown on the nature of the characteristic soluble basic salt solutions of beryllium, chromium, and zirconium.

(4) The manner of precipitation of stannous and zirconium hydroxides has been shown to be that of the formation and subsequent coagulation of a colloidal solution of dispersed basic chloride particles.

(5) It has been shown that of the bases studied in this paper aluminium hydroxide is the only one which is definitely amphoteric. No confirmation of the observations of Hildebrand on zirconium and zinc hydroxides could be obtained.

(6) The study of zirconium chloride and sulphate solutions has revealed that both are composed of highly dispersed basic particles and hydrolysed acid. No evidence could be obtained of the existence of the " zirconyl " radical.

(7) The hydrogen-ion concentration of precipitation of zinc hydroxide (actually basic sulphate) has been shown to be not in accord with the recorded solubility product data.

(8) It has been shown that the Werner co-ordination theory does not give a satisfactory explanation of the anomalous behaviour of green chromium chloride and sulphate solutions.

In conclusion, the author takes this opportunity to thank Prof. J. C. Philip, F.R.S., for facilities in carrying out this work, the Chemical Society for a grant for the purchase of salts of the rarer metals, and the Department of Scientific and Industrial Research for a personal grant.

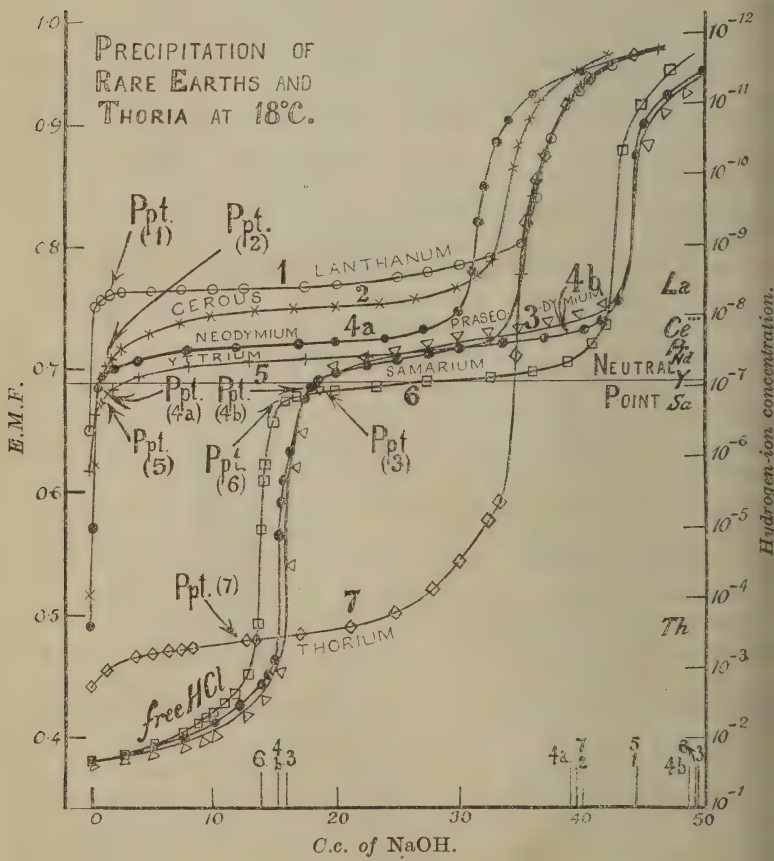
CCLXXXIX.—*Electrometric Studies of the Precipitation of Hydroxides. Part III. Precipitation in the Cerite Group of Rare Earths and of Yttrium Hydroxide by Use of the Hydrogen Electrode.*

By Hubert Thomas Stanley Britton.

The precipitation of the hydroxides of the metals of the "cerite" group and of yttrium has been investigated by means of titrations with the hydrogen electrode. The solutions used and the hydrogen-ion concentrations at which the various precipitations began are given in the table.

Titration and curve No.	Temp.	Solution titrated (100 c.c.).	Normality of NaOH.	Theor. amount of NaOH. (C.c.).	Precipitation began.		
					E.M.F.	p_H.	C.c. of NaOH.
1	17°	0·0133*M*-$La(NO_3)_3$	0·090	44·4	0·763	8·35	1·0
2	17	0·0133*M*-$CeCl_3$	0·1018	39·0	0·709	7·41	1·8
3	17	(1) 0·0163*N*-HCl	0·1018	16·0			
		(2) 0·0114*M*-$PrCl_3$		33·6	0·690	7·05	18·2
4*a*	17	0·0133*M*-$Nd(NO_3)_3$	0·1018	39·0	0·686	7·00	0·8
4*b*	17	(1) 0·0154*N*-HCl	0·1018	15·1			
		(2) 0·0114*M*-$NdCl_3$		33·6	0·687	7·02	18·0
5	18	0·0133*M*-YCl_3	0·090	44·4	0·674	6·78	1·0
6	18	(1) 0·0140*N*-HCl	0·1018	13·75			
		(2) 0·0121*M*-$SaCl_3$		35·53	0·676	6·83	16·1



The titration curves are given in the diagram. As thoria occurs with the rare earths in monazite sand, the titration curve (No. 7) of 100 c.c. of 0·01*M*-thorium chloride solution with 0·1016*N*-sodium hydroxide has been included in order that the precipitation p_H of thoria might be compared with those of the rare earths. The great difference in the hydrogen-ion concentrations accounts for the ease with which thoria can be separated from the rare earths of the "cerite" group by those methods which depend on the change in p_H. Knowing the respective hydrion concentrations it is possible to effect the separation of thorium hydroxide from the rare earths by carefully varying the p_H of the solution by means of alkalis and suitable indicators. The hydrogen-ion concentrations may be varied: (*a*) by using reagents which impart hydrion concentrations to the solutions greater than those to be attained for the precipitation

of the rare earths but less than that for thorium hydroxide, and (*b*) by fractional precipitation with bases which produce p_H's which are greater than those produced by the bases to be separated. Methods employing the former device need no control, but those based on the latter principle must be controlled, either as regards the hydrion concentrations by means of indicators or electrometric measurements, or as regards the fractions themselves by determining their chemical equivalents; which is the method usually adopted. The reagents which may be used to control automatically the hydrogen-ion concentrations required in the separation process are: zinc oxide, copper oxide, certain very weak organic bases, and salts of certain acids, such as sodium thiosulphate, and sodium azide if in presence of an excess of hydrazoic acid. Zinc hydroxide (see Part II) and copper hydroxide (see Part IV) are precipitated at a hydrogen-ion concentration of about 10^{-6}. These hydroxides will thus set up in the solution a hydrogen-ion concentration which is less than that required for the precipitation of thorium hydroxide, *viz.* $10^{-3\cdot6}$, but is insufficiently small to cause the separation of the rare earths. Separations by means of weak organic bases such as quinoline and *p*-toluidine have been studied more or less empirically by Jefferson (*J. Amer. Chem. Soc.*, 1902, **24**, 540), Allen (*ibid.*, 1903, **25**, 421), and Hartwell (*ibid.*, p. 1128). In the fractional precipitation with strong bases and oxides such as magnesium and mercuric oxides (see Parts I and IV) the fractionation is much quicker and requires careful regulation. The attainment of too high p_H's at the point where the precipitant impinges on the solution must be avoided, as this may cause the precipitation of undesired hydroxides, which redissolve very slowly.

The hydrogen-ion concentrations which were necessary for the precipitation of lanthanum and cerous hydroxides (curves 1 and 2) were appreciably less than those required for the other four earths. The differences in p_H at which the earths praseodymia, neodymia, yttria, and samaria were precipitated, although very small in the case of the first three, were sufficient to indicate that these are precipitated in the order given, which happens to be the order usually claimed. The closeness of the hydrion concentrations prevailing throughout the precipitations of the hydroxides of praseodymium, neodymium, and yttrium shows that a separation of these three earths by a hydrogen-ion concentration method is impracticable. The strongest base of the yttrium group is generally stated to be yttria, and according to these measurements, it appears to have a strength of the order of that of "didymia." Curves 4*a* and 4*b*, illustrating the respective titrations of the nitrate and chloride of neodymium, show, contrary to the observations of Hildebrand

(*J. Amer. Chem. Soc.*, 1913, **35**, 847), that the hydrogen-ion concentration required for the precipitation of neodymium hydroxide is quite independent of the nature of the anion. Hildebrand found that the p_H value required for precipitation from a chloride solution lay between 7 and 8, but from a nitrate solution between 4 and 5. The lower value obtained for the nitrate solution must have been

FIG. 1.

due to the use of an electrode whose hydrogen was catalytically reducing the nitrate. It has always been found, however, that when such reduction was taking place the *E.M.F.*'s were far from stationary.

In none of these titrations was the pure hydroxide obtained, as is shown by the following amounts (equivalents) of alkali which caused complete precipitation: from lanthanum nitrate solution,

·60; cerous chloride, 2·61; praseodymium chloride, 2·45; neo-
ymium nitrate, 2·38; neodymium chloride, 2·53; yttrium chloride,
·36; and samarium chloride, 2·48.

The separation of basic lanthanum nitrate is yet another example
n which the course of precipitation can be followed through the
ransitional colloidal stage. On the addition of 1·6 c.c. of sodium
ydroxide the solution became opalescent. During the addition
f the first 35 c.c. of alkali (=2·37 equivalents) there was a gradual
ncrease in p_H from 8·35 to 9·0, which did not cause the separation
f a precipitate, for the lanthana passed continuously into the
olloidal state, shown by an increasing turbidity of the solution.
he next 2·5 c.c. caused a rapid diminution in the hydrion concen-
ation, which was accompanied by a rapid increase in turbidity,
hilst the next c.c. caused the solution first to become opaque
nd then to coagulate completely. The hydrion concentration
ad then become $10^{-10·9}$, a value considerably less than that required
r the precipitation of lanthana. The amount of alkali required
nows that the composition of the precipitate was given by
$a(OH)_{2·6}(NO_3)_{0·4}$, indicating, as in other instances, that the
ispersed particles were basic. The sudden fall in the hydrion
oncentration towards the end of the reaction was caused by an
xcess of alkali having passed into the mother-liquor, and must have
een due to the action of this alkali on the colloidal particles which
timately brought about the coagulation of the colloidal solution.

If the order of the precipitation of the hydroxides is actually
at of their basic strengths, the basic strengths of the rare earths here
vestigated lie between those of zinc and manganous hydroxides,
nd below that of magnesium hydroxide. Lanthanum hydroxide
always stated to be the strongest base of the rare earths, and the
cerite " group of hydroxides, excepting ceric hydroxide, to be the
oup of the strongest bases. Apart from lanthanum hydroxide
nd perhaps cerous hydroxide, the other earths appear to be quite
oderate in strength and are comparable with cobalt and nickel
ydroxides. This is contrary to the view generally held. Friend
Text Book of Inorganic Chemistry," 1917, Vol. IV, p. 257)
ates that " from general chemical and thermochemical consider-
ions it may be concluded that they [the rare earths] are stronger
an magnesia, but weaker than the alkaline earths." The chemical
nsiderations are epitomised thus : " The strongly ignited oxides
e readily soluble in mineral acids, several of them combine directly
ith water and absorb carbon dioxide from the air, and all of them
erate ammonia from cold solutions of ammonium salts. Normal
lts of numerous weak acids, *e.g.*, chromic, carbonic, are readily
epared." If the hydrogen-ion concentration relationships do

give the true order of basic strengths, then zinc hydroxide is a weaker base than either of the tribasic hydroxides of the " cerite " elements; yet its oxide after ignition is readily soluble in mineral acids. The behaviour of the rare earths towards cold ammonium salt solutions is misleading. The fact that a base forms well-defined salts with weak acids probably offers no clue to its strength, if those salts happen to be almost insoluble. This is the case with the carbonates and chromates of the rare earths (*vide* Britton, J., 1924, **125**, 1875). Thus thorium hydroxide is an exceedingly weak base, but under certain conditions it forms an extremely well-defined chromate; under other conditions it behaves like other weak bases and gives precipitates which are indefinite and basic (*vide* Britton, J., 1923, **123**, 1429). The power to form well-defined salts with weak acids seems to be a property inherent in an element in conferring a small solubility on a salt and probably has nothing whatsoever to do with its power to form a strong base. There is no marked difference in the stability of soluble acetates and that of the acetates of the metals whose hydroxides are precipitated at comparable hydrogen-ion concentrations, *e.g.*, zinc, cobalt, nickel, and cadmium.

Vesterberg found (*Svensk. Kemi Tidskrift*, 1917, **29**, 101 ; *Zeitsch. anorg. Chem.*, 1917, **99**, 11, 22) that equally concentrated solutions of lanthanum acetate and ammonium acetate were equally hydrolysed. This led him to conclude hat the strengths of lanthanum hydroxide and ammonium hydroxide are nearly the same. The titration shows that lanthana was precipitated from an alkaline solution the hydrogen-ion concentration of which varied from $10^{-8\cdot35}$ to 10^{-9}. The very small concentration of lanthanum hydroxide therefore imparts to the solution a hydroxyl-ion concentration of the order of 10^{-5}, a concentration which is restricted by the small solubility of the lanthana. The actual amount of dissolved lanthanum hydroxide is too small for accurate estimation, and consequently it is not possible to calculate its degree of dissociation and its basicity constant, nor to compare the hydroxyl-ion concentrations given by equal concentrations of ammonia and lanthana. Theoretically it is possible to compare them from a knowledge of the degrees of hydrolysis of solutions of their respective salts under absolutely identical conditions. It is extremely doubtful whether this is accomplished by Vesterberg's method on account of the different nature of the two bases, for on extracting the hydrolysed acid from a lanthanum acetate solution with ether the equilibrium is disturbed in some unknown manner. The lanthanum hydroxide, unlike the ammonium hydroxide in the case of the ammonium acetate solution, will tend to become precipitated or to pass into colloidal solution, and thereby give rise to increased hydrolysis.

The hydrogen-ion concentrations at which lanthanum and cerous hydroxides are precipitated are a little greater than that necessary for manganous hydroxide. It was therefore thought that the presence of ammonium chloride in sufficient quantity might prevent their precipitation with ammonium hydroxide (see Part I). Calculation shows that, for each molecule of ammonia, 14 and 32 molecules, respectively, of ammonium chloride should be sufficient to prevent the precipitation of lanthanum hydroxide and cerous hydroxide. Actually, ammonium chloride has some inhibiting effect on the precipitation of the two hydroxides, and when the proportion of ammonium chloride to ammonium hydroxide is large, as indicated by the calculations, the precipitation can be entirely prevented.

Summary.

Hydrogen electrode titrations of solutions of several rare-earth salts with sodium hydroxide show that:

(*a*) The order of the precipitation of the earths with alkali is samarium, yttrium, neodymium, praseodymium, tervalent cerium, and lanthanum.

(*b*) The hydrogen-ion concentrations which govern the precipitation of the hydroxides of samarium, yttrium, neodymium, and praseodymium are so very close to one another—all about 10^{-7}—that the separation of these hydroxides by fractional precipitation is not possible.

(*c*) The precipitate formed in each titration is basic.

(*d*) The precipitation p_H's of the rare earths lie below those of magnesium and manganous hydroxides and above that of zinc.

(*e*) The great difference between the hydrion concentration necessary for the precipitation of thorium hydroxide and those required in the case of the rare earths accounts for some of the processes which are used to effect its separation.

(*f*) Ammonium chloride, if present in sufficient quantity, prevents the precipitation of lanthanum and cerous hydroxides.

The author avails himself of this opportunity to thank Prof. Philip, F.R.S., for facilities in carrying out this work, the Chemical Society for a grant which covered the cost of the materials, and the Department of Scientific and Industrial Research for a personal grant.

CCXC.—*Electrometric Studies of the Precipitation of Hydroxides. Part IV. Precipitation of Mercuric, Cadmium, Lead, Silver, Cupric, Uranic, and Ferric Hydroxides by Use of the Oxygen Electrode.*

By Hubert Thomas Stanley Britton.

Attention was directed in Part I (this vol., p. 2110) to the limited applicability of the hydrogen electrode, and consequently resort has been made to the oxygen electrode in order to study the precipitation reactions described in the following pages. Although oxygen electrodes cannot be used to follow with accuracy the changes in hydrogen-ion concentration which may take place during a reaction, they are sufficiently responsive to show the character of the changes and under certain conditions an approximate idea of the hydrogen-ion concentrations may be obtained from the titration curves. The oxygen electrode appears to have been employed for a similar purpose by Ralston (*Trans. Amer. Electrochem. Soc.*, 1923, **43**, 87), who found it of considerable use in the hydrolytic purification of electrolytes, such as the freeing of copper sulphate solutions from ferric hydroxide.

It was shown (Britton, J., 1924, **125**, 1572) in oxygen electrode titrations of chromic acid that, if the hydrogen-ion concentrations were known of solutions at two remote stages of the titration, rough estimates of the p_H of intermediate solutions could be obtained by assuming the voltages to be proportional to the p_H. This method, however, was found later to introduce errors sometimes as great as a whole p_H unit (this vol., p. 1915). The method has been further tested in the present titrations by using solutions which contained a known concentration of free acid, from which the initial p_H could be calculated, and continuing the titrations until the solutions had become alkaline and of known p_H. Table I gives particulars of the solutions titrated and the concentrations of free acid initially present. The titrations were performed with 100 c.c. of solution at 18° in each case by the method described for the previous acid titrations, the normal calomel half-element being used; as junction liquid in titrations 3 and 4 saturated potassium nitrate solution was employed instead of potassium chloride for obvious reasons. Each titration was followed by at least two oxygen electrodes and the solution was kept thoroughly mixed by a rapid current of oxygen, flowing throughout the whole titration.

The curves given by each pair of electrodes were as a rule similar, although by no means coincident, and tended to become closer to

TABLE I.

Titration and curve No.	100 C.c. of solution contained : free acid.	salt.	Sodium hydroxide. Normality.	C.c. for acid.	C.c. for salt.	Total.

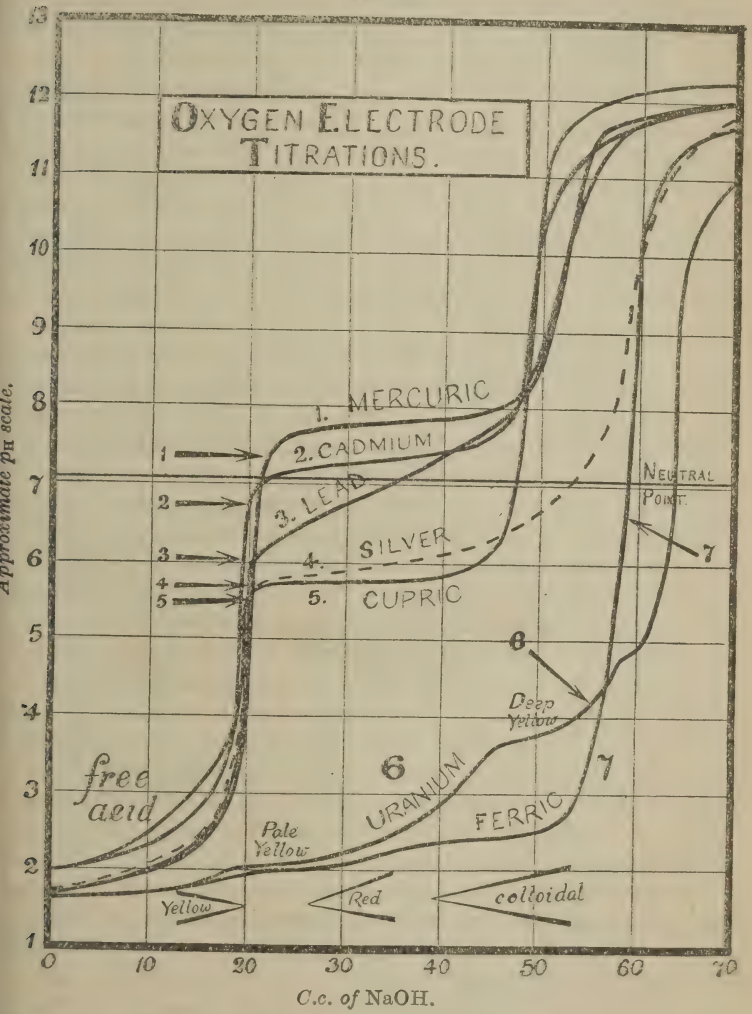
one another on repeated use; continued use, however, impaired the sensitiveness of the electrodes to changes of hydrion concentration. The differences between the typical *E.M.F.*'s given by the oxygen–normal calomel combination at the beginning and at the end of the titrations, and the corresponding *E.M.F.*'s which ordinarily would have been given by the hydrogen electrode in solutions of identical hydrion concentration, against the normal calomel half-cell, are given in Table II. These differences are, in effect, the *E.M.F.*'s of the oxygen–hydrogen cells set up in the various solutions.

TABLE II.

Titration No.	Solution.	*E.M.F.* of O_2 | solution | H_2 (volts). Beginning.	End.
1	HCl and $HgCl_2$	0·98	1·05
2	H_2SO_4 and $CdSO_4$	1·09	1·08
3	HNO_3 and $Pb(NO_3)_2$	1·04	1·05
4	HNO_3 and $AgNO_3$	0·96	1·13
5	H_2SO_4 and $CuSO_4$	0·94	1·06
6	HNO_3 and $U(NO_3)_6$	0·85	0·96
7	HCl and $FeCl_3$	0·97	1·03

Both the hydrogen-ion concentration and the oxidising agents which may be undergoing titration, have some influence on the oxygen electrode *E.M.F.* If the latter happens to be either small or almost independent of the hydrogen-ion concentration, then the proportional hydrogen-ion concentration scale may be expected to give a fairly accurate measure of the hydrion concentration. The extrapolated *E.M.F.*'s of the oxygen–hydrogen cell in the case of the uranium nitrate titration are much lower than usual, and it is probable that the small increase in potential difference was uniformly distributed over the whole titration, for the p_H's indicated by the scale at the various stages of the reaction were,

as far as could be ascertained colorimetrically, in approximate agreement. The low potential differences which were obtained in all the uranium titrations had nothing to do with the ageing of the platinum black, as in many instances freshly platinised electrodes were employed. A regular increase in the potential difference of the oxygen–hydrogen cell could not have taken place in the silver nitrate titrations, for according to the proportional hydrion scale the silver oxide was precipitated at p_H 6, whereas calculation from the solubility product of silver hydroxide showed that the true precipitation p_H lay between 9 and 10. By comparing the voltage actually observed when the precipitation began, 0·40 volt, with that which would be given by a hydrogen electrode indicating p_H 9, each compared with the normal calomel electrode, the *E.M.F.* of the oxygen–hydrogen cell is found to be 1·21 volts. This value is greater than either the initial (0·96) or the final (1·13) value, and was probably caused by the instability of the silver oxide. The remaining solutions investigated showed much less variation in their extrapolated *P.D.*'s, and when isolated p_H's were found by means of indicators and compared with those given by the scales, they were generally found to agree within half a p_H unit.



The differences in the actual voltage readings, which covered equal ranges of hydrion concentration, were usually unequal in any two titrations. Thus the change in p_H from 1·7 to 12·0 (say) would be indicated by the hydrogen and normal calomel electrodes by a variation in *E.M.F.* from — 0·381 to — 0·975 volt, a difference of 0·594 volt. In the case of the lead titration, the oxygen electrode *E.M.F.*'s moved over the same range with an almost equal change in voltage, *viz.*, from 0·667 to 0·067, a difference of 0·600 volt. In the other extreme titration, that of silver nitrate, the *E.M.F.* varied from 0·578 to 0·167 volt, a difference of 0·411 volt only.

In order to represent these titrations graphically (Fig. 1), it has been found necessary to convert the observed voltages into the approximate p_H values by simple proportion (this vol., p. 1915); these values are plotted as ordinates, and the number of c.c. of alkali added as abscissæ. Curve No. 4, representing the titration of silver nitrate, is dotted, for, as previously shown, the proportional hydrion scale is inapplicable. The arrows denote the beginning of precipitation.

The precipitation of basic mercuric chloride (curve No. 1) began when p_H 7·4 was attained; the precipitate, at first white, became brown as more alkali was added. Precipitation was complete when three-quarters of the amount of alkali required for the complete decomposition of the mercuric chloride had been added. At this point—50·3 c.c. of sodium hydroxide—the addition of more alkali

caused a rapid increase in p_H. The basic chloride was readily decomposed on the addition of an excess of alkali. The fact that exactly 1·5 equivalents of sodium hydroxide were sufficient to

FIG. 1.

transform 1 molecule of mercuric chloride completely into an insoluble basic precipitate seems to furnish good evidence that the precipitate first formed was a definite salt, *viz.*, $HgCl_2,3HgO$. Some decomposition took place immediately an excess of alkali was added, for after precipitation was complete about 2 c.c. of

alkali had to be added before the solution attained a marked alkalinity. The partial investigation by Toda (*Memoirs Coll. Sci. Kyoto*, 1921, **4**, 305) of the ternary system HgO–HCl–H_2O at 35° failed to establish the individuality of $HgCl_2,3HgO$. A crystalline basic chloride of this composition is stated to occur naturally as kleinite and mosesite, and has also been prepared by several workers (compare Mellor's " Treatise," 1923, Vol. IV, p. 842).

Curve No. 2 shows that the precipitate obtained from the cadmium sulphate solution was also basic. It was heavy and flocculent and its composition must have been $CdSO_4,3Cd(OH)_2,xH_2O$, for 49 c.c. (= 1·5 equivalents) of sodium hydroxide were required for its precipitation. Harned (*J. Amer. Chem. Soc.*, 1917, **39**, 252) arrived at the same conclusion by conductimetric titration, and Pickering (J., 1907, **91**, 1981) found that a solution of cadmium sulphate was rendered alkaline to phenolphthalein by the addition of 1·46 equivalents of alkali.

Curve No. 3, illustrating the precipitation of lead as a basic nitrate, is remarkable for the considerable change in hydrion concentration which is shown to have taken place. The mode by which the precipitate was formed is yet another example showing that precipitation is often brought about by the coagulation of a colloidal solution, initially formed. A faint opalescence occurred on the addition of 20·5 c.c. of sodium hydroxide ($p_H = 6$), but immediately after another 0·5 c.c. had been added a heavy, white precipitate appeared, only to pass, in the course of a few seconds, into colloidal solution. Further additions of alkali merely intensified the turbidity of the solution, which became opaque after the addition of 33·5 c.c. The colloidal solution coagulated when 38 c.c. of alkali had been added. Once again, 1·5 equivalents of alkali were required for complete precipitation, showing that the composition of the precipitate was $Pb(NO_3)_2,3Pb(OH)_2,xH_2O$. The existence of such a salt has been claimed by several workers.

Silver does not appear to give a basic precipitate under these conditions, as will be seen from curve No. 4.

The precipitation of basic copper sulphate is an excellent example to show how the composition of the precipitate may be influenced by the manner in which the precipitant is added. When the sodium hydroxide was added slowly to a copper sulphate solution, and the solution was thoroughly agitated, the precipitate was pale blue, amorphous, and heavy, but when the alkali was added quickly, no care being taken to ensure thorough mixing, the precipitate was green and gelatinous and, in contrast to the former precipitate, turned black either on standing or on heating. Provided the amount of alkali added was insufficient to render the solution

alkaline, the gelatinous precipitate, on shaking, gradually became converted into the less basic, amorphous precipitate. The precipitate obtained in the titration was amorphous and, as will be concluded from the amount of alkali (1·47 equivalents) required for its precipitation and to render the solution alkaline, contained CuO and SO_3 in the molar ratio 4 : 1. In his experiments on copper sulphate solutions, Pickering (*loc. cit.*) found that whilst 1·53 equivalents of sodium hydroxide actually produced complete precipitation as basic sulphate, the solution on treatment with alkali did not become alkaline to phenolphthalein until about 1·7 equivalents had been added. This initial alkalinity gradually disappeared until approximately 1·8 equivalents had been added. It is evident that Pickering obtained complete precipitation as $CuSO_4,3Cu(OH)_2,xH_2O$ in one case. The fact that the initial alkalinity did not coincide with the end of precipitation was due to the way in which the alkali was added during the testing with phenolphthalein. In the present electrometric titration, complete precipitation and alkalinity to phenolphthalein took place simultaneously. Pickering believed that the greater amount of alkali pointed to the precipitation of a mixture of basic sulphates, $4CuO,SO_3$ and $10CuO,SO_3$; the individuality of the latter he thought to be sufficiently established by the amount of alkali required to cause final alkalinity. Harned (*loc. cit.*), by titrating with a copper electrode, also found that precipitation was complete when 1·7 equivalents of sodium hydroxide had been added. Harned's observation, as was Pickering's, was due to the manner in which the precipitant was added. In a subsequent paper, it will be shown that the pale blue, amorphous precipitate is a definite basic salt, $4CuO,SO_3,4H_2O$.

The uranic solution used in the titration was prepared by dissolving so-called uranyl nitrate in nitric acid. The colour of the solution was pale yellow, but important changes in the intensity occurred during the titration. Curve No. 6 shows that a slight inflexion occurred immediately after the acid in excess of that required to form uranic nitrate had been neutralised with 14·9 c.c. of alkali; this, perhaps, may be due to the presence of sexavalent uranium nitrate in the solution (compare the titrations of the chlorides of zirconium and ferric iron). This small inflexion was repeatedly obtained. No appreciable change in colour was observed until 45 c.c. of sodium hydroxide had been added, the composition of the solute then being $U(NO_3)_{2\cdot38}(OH)_{3\cdot62}$. Thereafter the solution, though remaining clear, gradually became deeper in colour until 55·8 c.c. of alkali had reacted, the solution then containing $U(NO_3)_{1\cdot08}(OH)_{4\cdot92}$; at this stage a yellow precipitate began to

separate. It happened that this change corresponded exactly to a new section of the curve, and the point of inflexion corresponded to the solution in which the change in shade of yellow was first noticed. The diminished hydrion concentrations of the deeply coloured solutions, about p_H 3·7, were close to that at which precipitation began, p_H 4·2. The deepening in colour of the highly basic solutions seems to have been due to a gradual increase in the size of the basic particles, the uranium hydroxide being held in solution in a state closely akin to that of a colloid. The hydrion concentration of the solution when 48 c.c. of alkali had been added was $10^{-3·7}$; the solution then contained the proportions of uranium and nitrate present in uranyl nitrate but was much deeper in colour than that obtained by dissolving uranyl nitrate crystals. The explanation of this difference probably lies in the fact that uranyl nitrate is crystallised from strongly acid solutions. On solution in water, it tends to revert to a state which is probably colloidal, as shown by the changes in colour and in conductivity which it undergoes on standing and especially at higher temperatures (Dittrich, *Z. physikal. Chem.*, 1899, **29**, 449). If the increase in conductivity which takes place on standing is due to the formation of particles which are essentially colloidal, these particles must be capable of some kind of ionisation. There seems to be very little support for the belief that uranyl salt solutions contain the " uranyl " kation; none is to be found in conductivity measurements, which show that the increases in conductivity with dilution of solutions of the nitrate, chloride, and sulphate are anomalous.

The diagram shows that precipitation was complete when 64 c.c. of alkali had been added as compared with the 64·7 c.c. which were required for the complete formation of uranic hydroxide. Hence the precipitate was uranic hydroxide containing a very small quantity of undecomposed nitrate. The text-books state that alkalis precipitate " diuranates " and not uranium hydroxide; *e.g.*, with sodium hydroxide, the precipitate is stated to be $Na_2U_2O_7$ (compare Roscoe and Schorlemmer's " Treatise," Vol. II, p. 1154, revised 1923). Jolibois and Bossuet (*Compt. rend.*, 1922, **174**, 1625) found that the precipitates produced by the action of sodium hydroxide on uranyl nitrate solutions contained no nitrate; the small quantities of sodium hydroxide present, varying from 1·2 to 8% they considered to be adsorbed.

Dilute acid solutions of uranium nitrate or uranyl salt solutions themselves, when gently heated, underwent some profound change; the colour became deeper and the reverse change on cooling took place very slowly. They became alkaline to phenolphthalein when

the theoretical amount of alkali was added, but a precipitate separated only when an appreciable excess of alkali had been added or the solution had been boiled for some time. The opalescence of the alkaline colloidal solution depended on the temperature to which the original solution had been heated. The deep yellow solutions formed by gentle heating were almost clear, whereas those which had been boiled became visibly colloidal. If not too great an excess of alkali had been added, the resulting colloidal solutions remained quite stable for several days. They were coagulable on addition of 1 or 2 c.c. of saturated potassium chloride solution. Heating thus appeared to have caused some change in the state of aggregation of the particles of uranium hydroxide or more likely of highly basic salt, which were probably in equilibrium with free nitrate ions and were thereby enabled to enter into reaction with alkalis so that the uranium hydroxide complexes remained in colloidal solution.

Curve 7 represents the titration of an acid solution of ferric chloride and correlates the changes in hydrion concentration with the changes in colour. It is something more than a coincidence that the colours of solutions containing basic salts should be similar to those of their respective hydroxides. The colour of solutions of both the basic salts of chromium with strong acids and chromium hydroxide is green, and the uranium solutions are pale yellow but become intensely yellow as they become more basic and are then identical in colour with uranium hydroxide. As is well known, ferric chloride solutions freshly prepared or containing an excess of free acid, are only slightly coloured; on standing, the solution reddens and its colour approaches that of red ferric hydroxide. In the present titration the end of the neutralisation of the free acid appears to be indicated by an inflexion, at 20·1 c.c. of sodium hydroxide. As the solution was rendered more basic, the colour gradually changed from yellow to red. It became quite red after addition of 30 c.c. of sodium hydroxide, when the composition of the solute had become $Fe(OH)_{0\cdot74}Cl_{2\cdot26}$, and with 39 c.c. it began to opalesce. Afterwards the solution became increasingly colloidal and became opaque at p_H 3, which, as will be seen from the curve, occurred just when the sudden change in hydrion concentration had begun. Coagulation set in when the p_H had become 6·6 and 58 c.c. of alkali had been added, the composition of the basic chloride then being $Fe(OH)_{2\cdot85}Cl_{0\cdot15}$.

As the colloidal solution persisted until nearly all the chloride had reacted, experiments were made to see if it were possible to prevent coagulation while the solution was being subjected to a sudden fall in hydrion concentration. As in the case of basic

uranium nitrate solutions, this possibility depended on the changes which had taken place in the ferric chloride solutions before treatment with alkali. Aqueous solutions of ferric chloride more dilute than $N/25$, on boiling, acquired a deep red colour, and often remained colloidal on treatment with $N/10$-alkali in slight excess. Small, red, amorphous precipitates separated in some cases, but even then the precipitation was incomplete and the solids did not settle until several hours had elapsed. The presence of a little hydrochloric acid in the solutions before heating had some stabilising effect on the colloidal solutions which were subsequently produced. In one case the colloidal solution remained stable for nearly 3 months. This solution was prepared by adding 55 c.c. of $N/10$-sodium hydroxide to 500 c.c. of a boiling solution containing 100 c.c. of $N/25$-ferric chloride and 10 c.c. of $N/10$-hydrochloric acid. It seems certain that the red colour of boiled ferric chloride solutions was due to dispersed ferric hydroxide particles, and consequently the increase in the size of the basic chloride particles caused by rendering the solution alkaline was not so great as that occurring in an unboiled solution, and therefore did not produce coagulation. The increased stability of the colloidal solutions prepared from acidified ferric chloride solutions was probably due to the effect of the acid in suppressing the growth of the colloidal particles on boiling, thereby giving rise to a more highly dispersed and more stable colloidal solution. Prolonged boiling decomposed these alkaline colloidal solutions, and they were readily coagulated on addition of electrolytes in sufficient amounts.

It is probable that the solubility product of very weak bases such as ferric hydroxide has very little meaning, but in view of the recent work of Jellinek and Gordon (*Z. physikal. Chem.*, 1924, **112**, 235) it is interesting to compare their value for $[Fe^{\cdots}][OH']^3$, *viz.*, $10^{-37\cdot9}$, with that given by the titration curve. They measured the hydrogen-ion concentrations with the hydrogen electrode of solutions of ferric chloride, containing potassium chloride to coagulate the colloidal solutions, to which varying amounts of sodium hydroxide had been added. The concentration of ferric ions in the mother-liquor was determined colorimetrically as thiocyanate. The latter method is probably unsatisfactory, because the acid used would materially affect the concentration of ferric ions in a basic ferric chloride solution. If it be assumed that in the titration the appearance of opalescence marked the point at which ferric hydroxide actually began to separate, and that the amount of free ferric ions was equivalent to the remaining amount of alkali to be added to decompose the ferric chloride completely, the value for the solubility product becomes $10^{-37\cdot7}$. Thus opalescence occurred

on the addition of 39 c.c. of $N/10$-alkali; $p_H = 2{\cdot}3$. Hence $[OH'] = 10^{-11{\cdot}8}$ and $[Fe'''] = 20{\cdot}9/39{\cdot}8 \,.\, 100/139 \,.\, 0{\cdot}0133 = 10^{-2{\cdot}3}$. Müller ("Das Eisen und seine Verbindungen," 1917, p. 281) calculated the value $6{\cdot}5 \times 10^{-47}$ from Bodländer's formula (*Z. physikal. Chem.*, 1898, **27**, 66).

Arrangement of Metals in the Order of the Hydrogen-ion Concentrations required for the Precipitation of their Hydroxides.

It was stated in Part I that no principle has yet been found which leads to a satisfactory arrangement of the metals such that the order is that of the basic strengths of their hydroxides. The titrations described in the foregoing pages show that for each hydroxide there is a definite hydrogen-ion concentration at which its precipitation normally takes place. It is true that the majority of the hydroxides are thrown out of solution as basic precipitates, but the hydrogen-ion concentrations at which these are precipitated probably do not differ greatly from those of the particular hydroxides. The table gives the metals in the order of the hydrogen-ion concentrations at which their respective hydroxides are precipitated from dilute solutions. Although it is not certain that this order is that of the actual basic strengths of the hydroxides, it can be stated, as will be shown later, that it is these hydrogen-ion concentration relationships which underlie many of the reactions of the various metallic salt solutions.

Hydrion conc.		Hydrion conc.		Hydrion conc.	
10^{-11}	Magnesium		Cadmium		Copper
10^{-10}			Praseodymium		Chromium
10^{-9}	Silver		Neodymium	10^{-5}	
	Manganous		Yttrium		Aluminium
	Lanthanum	10^{-7}	Samarium	10^{-4}	
	Mercuric		Ferrous (?)		Uranic
10^{-6}	Cerous		Lead (?)		Thorium
	Cobalt	10^{-6}	Zinc	10^{-3}	
	Nickel		Beryllium		Stannous
					Zirconium
					Ferric

An arrangement now widely adopted is that based by Abegg and Bodländer (*Z. anorg. Chem.*, 1899, **20**, 453) on their theory of electroaffinity, which states that the electrolytic potential constitutes an approximate measure of the basic strength of the metal. Comparison with the present arrangement brings out the following important differences. According to the position of aluminium in the table, aluminium hydroxide is an extremely weak base, weaker than chromium hydroxide, yet aluminium occurs higher than chromium in the electropotential series. There is no doubt

that both aluminium and chromium hydroxides are much weaker bases than manganous hydroxide, and this is also indicated by the present scheme, but according to the electropotential series they are both placed above manganese. Heyrovský (*Proc. Roy. Soc.*, 1923, *A*, **102**, 628) has pointed out that the thallous potential is small, which necessitates placing thallium relatively close to hydrogen in the electropotential series, in spite of the fact that thallous hydroxide is a strong base and is not precipitated by alkalis. If it be assumed that the electrolytic potentials of metals under identical conditions are a measure of their electroaffinities, *i.e.*, the free energies by which the elements take up electric charges, it cannot be concluded, as was admitted by Abegg and Bodländer, that the potentials as determined are in any way parallel to the electroaffinities, for nothing is known of the relative atomic solubilities of the various metals in water. Unless it is known that the number of atoms of the different metals which pass into solution is the same, no guarantee can be obtained that an arrangement accruing therefrom is in any way true. Heyrovský attempted to amend the above method by introducing such factors as the mass of the kation, and obtained an order which he stated "comes out right." Heyrovský's system indicates that lead hydroxide is a stronger base than magnesium hydroxide, and that mercuric oxide is a very weak base, weaker than zinc hydroxide. The present table suggests the contrary in both cases. It is well known that water becomes alkaline (to litmus) when shaken with mercuric oxide, but remains neutral when shaken with zinc oxide.

It is probable that the present table provides as satisfactory an arrangement as any that has been hitherto advanced, as far as the general reactions which involve the strength of the base are concerned. The position of the hydroxides in the table is the important factor in processes for separating hydroxides or basic salts, as was shown to be the case in the separation of thoria from the rare earths (see Part III). The basic acetate and basic succinate methods for the separation of manganese from iron depend on the great difference in hydrogen-ion concentration required to precipitate their respective hydroxides. Lundell and Knowles (*J. Amer. Chem. Soc.*, 1923, **45**, 676) have shown that the separation may equally well be performed by fractional precipitation with ammonia in presence of ammonium chloride, the precipitation of the ferric hydroxide being controlled by rendering the solution just alkaline to methyl-red, *i.e.*, about p_H 6·3. The reason for this is apparent from the hydrion table of the hydroxides. The table also explains why mercuric oxide can be used as a separating agent for various bases. Thus E. F. Smith and Heyl (*Z.*

anorg. Chem., 1894, **7**, 87) showed that mercuric oxide caused the complete precipitation in the cold of ferric, aluminium, and chromium hydroxides, the partial precipitation of zinc, cobalt, nickel, uranium, beryllium, cerous, and lanthanum hydroxides, and failed to precipitate manganous hydroxide. The table shows that the hydrogen-ion concentration peculiar to mercuric oxide is greater than that required to precipitate manganous hydroxide, is approximately equal to that required for lanthana, is somewhat less than that required by those hydroxides which were partly precipitated, and is considerably less than that of the three bases which were completely precipitated.

Summary.

(1) The reactions between sodium hydroxide and salt solutions of certain metals have been followed with the oxygen electrode, the hydrogen electrode being inapplicable.

(2) A scale of hydrogen-ion concentrations has been applied to the observed voltages, accurate to the extent of about 0·5 p_H unit except in the case of the silver nitrate titration.

(3) Basic precipitates, probably containing definite basic salts, were obtained from solutions of mercuric chloride, copper sulphate, cadmium sulphate, and lead nitrate.

(4) The precipitate obtained from uranium nitrate solution was the hydroxide containing a little nitrate, and not sodium diuranate as is often stated.

(5) Significant changes in colour were observed in the titrations of both uranic and ferric salts.

(6) The twenty-five hydroxides which have been investigated have been arranged in the order of their respective precipitation hydrogen-ion concentrations.

In conclusion, the author wishes to thank Prof. J. C. Philip, F.R.S., for kindly placing facilities at his disposal, and the Department of Scientific and Industrial Research for a personal grant.

IMPERIAL COLLEGE OF SCIENCE AND TECHNOLOGY,
SOUTH KENSINGTON, S.W. 7. [*Received, July 1st*, 1925.]

CCXCI.—*The Interaction of Ethyl Acetoacetate and o-Hydroxydistyryl Ketones. Part II.*

By ISIDOR MORRIS HEILBRON, THOMAS ALFRED FORSTER, and ABRAHAM BRUCE WHITWORTH.

THE condensation of ethyl acetoacetate with *o*-hydroxydistyryl ketones was shown by Heilbron and Forster (J., 1924, **125**, 2064) to lead to the formation of *cyclo*hexenones and not, as in the case

of the *o*-hydroxymonostyryl derivatives, to pyrones. Further, it was found that the position taken up by the β-ketonic ester in the conjugated system can be arrived at owing to the fact that when it attaches itself to the styryl residue containing the *o*-hydroxyl the resulting *cyclo*hexenone is free of the carbethoxy-group. Thus, the interaction of 2′-methoxy-2-hydroxydistyryl ketone with ethyl acetoacetate leads to the formation of two *cyclo*hexenones the structures of which have been proved to be in accord with the following formulæ :

$$\begin{array}{l} \quad\quad\quad\

giving in the first place the saturated *cyclo*hexane derivative (VI), from which water can easily be removed with formation of (VII).

$$\underset{\text{(VI.)}}{\mathrm{CO_2Et{\cdot}CH{-}CO{-}CH_2 \\ Me_2N{\cdot}C_6H_4{\cdot}CH{\cdot}CH_2{\cdot}C(OH)Me}} \xrightarrow{-H_2O} \underset{\text{(VII.)}}{\mathrm{CO_2Et{\cdot}CH{-}CO{-}CH \\ Me_2N{\cdot}C_6H_4{\cdot}CH{\cdot}CH_2{\cdot}CMe}}$$

It is thus apparent that the *p*-dimethylamino-group, although normally acting as a retarding factor, does not necessarily rule out the structure given in (IV). That this truly represents the constitution of the ketone under consideration was finally proved by oxidising the *cyclo*hexenone with potassium permanganate in acetone solution, when salicylic acid was isolated from the decomposition products. That the anomalous behaviour is closely connected with the peculiar activity of the ketone is evident, for, as shown below, it disappears on methylation of the free hydroxyl group, which reaction destroys the activity of the compound (Heilbron and Buck, *loc. cit.*). Further, with 4′-dimethylamino-4-methoxy-2-hydroxydistyryl ketone, in which the "active" properties of the parent ketone are also entirely suppressed (compare Heilbron and Whitworth, J., 1923, **123**, 238), ethyl acetoacetate yields a *cyclo*hexenone with the carbethoxyl eliminated and which consequently must possess the structure (VIII).

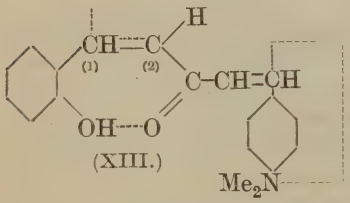
$$\mathrm{MeO{\cdot}(HO)C_6H_3{\cdot}CH{\cdot}CH_2{\cdot}C(CH{\cdot}CH{\cdot}C_6H_4{\cdot}NMe_2){=}CH} \quad \text{(VIII.)}$$

On the other hand, the isomeric 4′-dimethylamino-3-methoxy-2-hydroxydistyryl ketone and also the 5-methoxy-compound, both of which are "active" (Heilbron and Whitworth, *loc. cit.*), yield as main products of the condensation *cyclo*hexenones similarly constituted to that obtained from 4′-dimethylamino-2-hydroxydistyryl ketone itself.

$$\mathrm{MeO{\cdot}C_6H_4{\cdot}CH{\cdot}CH_2{\cdot}C(CH{\cdot}CH{\cdot}C_6H_4{\cdot}NMe_2){=}CH} \quad \text{(IX.)}$$

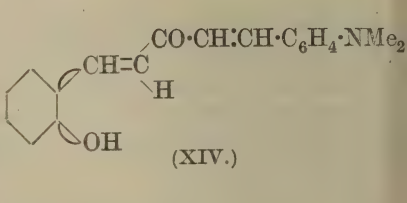
$$\mathrm{Me_2N{-}\text{----------}{-}OMe} \quad \text{(X.)}$$

$$\mathrm{HO{\cdot}C_6H_4{\cdot}CH{\cdot}CH_2{\cdot}CO{\cdot}CH{\cdot}CH{\cdot}C_6H_4{\cdot}NMe_2} \quad \text{(XI.)}$$



$$\mathrm{Me_2N{-}\text{----------}{-}OH} \quad \text{(XII.)}$$

With 4′-dimethylamino-2-methoxydistyryl ketone, two isomeric compounds of empirical formula $C_{26}H_{29}O_4N$ were isolated. The higher-melting *cyclo*hexenone (m. p. 164°), which is only formed in minute amount, was shown to be identical with the methyl ether of (IV) and consequently must possess the structure (X). The isomeride



of m. p. 114° must accordingly have the constitution (IX), the reaction in this case having followed the normal course.

The primary object of the investigation has been achieved in definitely proving that, in all the cases examined, *cyclo*hexenones alone are formed as products of the condensation, and the facts harmonise well with the mechanism previously suggested to account for the elimination of carbethoxyl during the condensation (Heilbron and Forster, *loc. cit.*).

As regards the point at which ethyl acetoacetate enters the molecule, this must certainly depend largely on the polar character of the substituent groups and their total effect upon the doubly-conjugated system. The authors feel, however, that the question is too complex to allow of an immediate explanation and that no good purpose would be served by attempting this until the effect of polar influences in less complicated molecules is more thoroughly understood. It is also possible that other factors have to be taken into account and that steric influences play a part in determining the position taken up by the entering group. Thus in the case of 4′-dimethylamino-2-hydroxydistyryl ketone it is conceivable that ethyl acetoacetate, probably through the intermediate formation of a labile addition product, brings about a transformation of the co-ordinated *cis*-form of the ketone (XIII) into a *trans*-isomeride (XIV), a rearrangement which must necessarily modify the distribution of residual affinity effects.

(XIII.)

(XIV.)

This suggestion is supported to some extent by the observation recorded by Heilbron and Buck (*loc. cit.*) that, whereas 4′-dimethylamino-2-hydroxydistyryl ketone is characterised by the ease with which it forms molecular addition compounds and is indeed exceedingly difficult to isolate free from solvate addenda, this may be readily accomplished by crystallisation from ethyl acetoacetate. Again the profound effect which this ester exerts on the configuration of unsaturated ketones is exemplified in the yellow form of *o*-hydroxystyryl methyl ketone, which is readily transformed into its colourless isomeride by crystallisation from this substance (McGookin and Heilbron, J., 1924, **125**, 2099). On the other hand, ethyl cyanoacetate does not induce isomerism of this type (unpublished work)

and it might consequently be expected that in this case addition would take place at the usually reactive unsaturated centre. In presence of 50% sodium hydroxide a condensation product of empirical formula $C_{22}H_{23}O_6N$ was isolated to which either formula (XI) or (XII) could be ascribed. That the former correctly represents the structure of the compound was shown by treatment of the dicarboxylic acid with concentrated potassium hydroxide solution, when fission of the molecule occurred with production of *p*-dimethylaminobenzaldehyde. In considering the formation of this aldehyde, it has to be borne in mind that the effect of the strong alkali might possibly produce a type of reversed Michael reaction, in which case the presence of the *p*-dimethylaminobenzaldehyde would simply result through disintegration of the distyryl ketone, fission occurring at the double bonds. That this, however, was not the case was evident from the fact that no trace of salicylaldehyde was found in the reaction mixture.

Experimental.

Ethyl 3-p-*Dimethylaminophenyl*-5-o-*hydroxystyryl*-Δ^5-cyclo*hexene*-1-*one*-2-*carboxylate* (IV).—A solution containing 4′-dimethylamino-2-hydroxydistyryl ketone (4 g.), ethyl acetoacetate (8 c.c.), absolute alcohol (20 c.c.), and potassium hydroxide solution (3 c.c. of 20%) was allowed to stand at room temperature for 24 hours. The precipitated product (2 g.) was collected and crystallised from either absolute alcohol or benzene. It separates in orange-yellow prisms (m. p. 196°) containing 1 mol. of solvent, from which it can be freed by heating in the steam-oven. It dissolves in concentrated sulphuric acid, giving the deep red solution characteristic of this type of *cyclo*hexenone (Found in material crystallised from alcohol: C, 72·0; H, 7·4; N, 3·1. $C_{25}H_{27}O_4N,C_2H_6O$ requires C, 71·9; H, 7·3; N, 3·1%. Found in material crystallised from benzene: C, 76·8; H, 6·9; N, 2·9. $C_{25}H_{27}O_4N,C_6H_6$ requires C, 77·0; H, 6·9; N, 2·9%. Found in anhydrous compound: C, 73·9; H, 6·7; N, 3·1. $C_{25}H_{27}O_4N$ requires C, 74·1; H, 6·7; N, 3·4%).

Oxidation.—About 1 g. of the substance dissolved in acetone was treated at room temperature with finely-powdered potassium permanganate, added in very small portions at a time. When the oxidation was complete, the mixture was filtered and the residue suspended in water and treated with sulphur dioxide until the manganese dioxide had dissolved. As no solid separated, the solution was made strongly acid with hydrochloric acid and ether-extracted. On removal of solvent, colourless needles were obtained and identified as salicylic acid by mixed m. p. with an authentic specimen of the acid and also by the characteristic ferric chloride coloration.

3-p-*Dimethylaminophenyl*-5-ô-*hydroxystyryl*-Δ^5-cyclo*hexene*-1-*one*-2-*carboxylic Acid*.—The previous ester was saponified by heating for 3 hours on the steam-bath with sodium hydroxide solution. The red, pasty mass was dissolved in water, and the acid precipitated by addition of dilute acetic acid. The pure compound crystallised from alcohol in yellow plates, m. p. 225° (Found : C, 73·3; H, 6·0. $C_{23}H_{23}O_4N$ requires C, 73·3; H, 6·1%).

3-p-*Dimethylamino*-5-o-*hydroxystyryl*-Δ^5-cyclo*hexene*-1-*one*.—The free acid was dissolved in glacial acetic acid and boiled for 1 hour with 20% sulphuric acid. After cooling, the green liquid was carefully neutralised with dilute alkali, and the precipitated *cyclo*hexenone crystallised from methyl alcohol, from which it separated in yellow, felted needles, m. p. 232° (Found : C, 78·9; H, 6·9. $C_{22}H_{23}O_2N$ requires C, 79·3; H, 6·9%).

Ethyl 3-p-*Dimethylamino*-5-o-*methoxystyryl*-Δ^5-cyclo*hexene*-1-*one*-2-*carboxylate* (X).—By direct methylation of the corresponding hydroxy-compound by the usual methods, only uncrystallisable products were obtained. The pure methyl ether was readily produced, however, by methylation in acetone solution according to Heilbron and Buck's method (*loc. cit.*). It separates from high-boiling ligroin in lemon-yellow prisms, m. p. 164°, and dissolves in alcoholic potash to a yellow, and in concentrated sulphuric acid to a red solution (Found : C, 74·4; H, 7·0. $C_{26}H_{29}O_4N$ requires C, 74·5; H, 6·9%).

Ethyl 3-o-*Methoxyphenyl*-5-p-*dimethylaminostyryl*-Δ^5-cyclo*hexene*-1-*one*-2-*carboxylate* (IX).—A solution of 4′-dimethylamino-2-methoxydistyryl ketone (3 g.) and 3 c.c. of ethyl acetoacetate in 10 c.c. of alcohol was heated for 3 hours on the steam-bath with potassium hydroxide solution (3 c.c. of 20%), the colour changing from deep red to orange. On gradual dilution with water a semi-solid mass was deposited which proved exceedingly difficult to crystallise, but this was finally accomplished by means of alcohol in presence of animal charcoal. Microscopic examination of the crystals revealed the presence of two substances, which were separated by repeated fractionation from carbon disulphide into a main fraction of the above ester (m. p. 112°) and a small quantity of a substance, m. p. 160°, which was identical with the methyl ether obtained by methylation of the hydroxy-*cyclo*hexenone (IV).

Ethyl 3-o-*methoxyphenyl*-5-p-*dimethylaminostyryl*-Δ^5-cyclo*hexene*-1-*one*-2-*carboxylate* can be conveniently prepared in good yield free from the higher-melting isomeride by treating an alcoholic solution of the ketone (6 g.) and ethyl acetoacetate (8 c.c.) at room temperature with potassium hydroxide solution (6 c.c. of 20%). After a few hours the red solution was inoculated with a crystal of the lower-

melting ether and kept for 2 days. The crude product (5 g.) crystallises from ether in orange needles (m. p. 114°) which are extremely hygroscopic and change colour to brick-red on standing in moist air (Found: C, 74·2; H, 7·2. $C_{26}H_{29}O_4N$ requires C, 74·5; H, 6·9%).

Ethyl 1-*Methoxy*-3-o-*methoxyphenyl*-5-p-*dimethylaminostyryl*-$\Delta^{1:5}$-cyclo*hexadiene*-2-*carboxylate*.—This substance was prepared by dissolving the corresponding *cyclo*hexenone (m. p. 114°) in sodium ethoxide solution and heating under reflux with methyl iodide for 2 hours. It separates from ether in pale yellow needles, m. p. 148° (Found: C, 74·2; H, 7·4. $C_{27}H_{31}O_4N$ requires C, 74·8; H, 7·2%).

Ethyl 3-p-*Dimethylaminophenyl*-5-p-*dimethylaminostyryl*-Δ^5-cyclo*hexene*-1-*one*-2-*carboxylate* (V).—A solution containing 3·2 g. of 4 : 4′-tetramethyldiaminodistyryl ketone (Sachs and Lewin, *Ber.*, 1902, **35**, 2576), ethyl acetoacetate (5 c.c.), and alcohol (10 c.c.) was heated under reflux for 1 hour with sodium hydroxide solution (1 c.c. of 50%). The clear red liquid was filtered from deposited sodium carbonate, and the *cyclo*hexenone, which separated on cooling, repeatedly crystallised from absolute alcohol. It forms orange-yellow needles, m. p. 174—175°; the *phenylhydrazone* melts at 239° (Found: C, 74·8; H, 7·5; N, 6·7. $C_{27}H_{32}O_3N_2$ requires C, 75·0; H, 7·4; N, 6·5%).

Ethyl 3-p-*Dimethylaminophenyl*-5-*methyl*cyclo*hexane*-5-*ol*-1-*one*-2-*carboxylate* (VI).—A hot alcoholic solution of 4-dimethylaminostyryl methyl ketone (4 g.) and ethyl acetoacetate (6 c.c.) was treated with sodium hydroxide (1 c.c. of 50%), and the resulting red solution kept for 12 hours at room temperature. The *cyclo*hexane crystallises from high-boiling ligroin in colourless needles, m. p. 149° (Found: C, 67·7; H, 8·1; N, 4·4. $C_{18}H_{25}O_4N$ requires C, 67·8; H, 7·9; N, 4·3%). The *phenylhydrazone* separates from absolute alcohol in colourless crystals, m. p. 179° (Found: N, 10·3. $C_{24}H_{31}O_3N_3$ requires N, 10·3%).

Ethyl 3-p-*dimethylaminophenyl*-5-*methyl*-Δ^5-cyclo*hexene*-1-*one*-2-*carboxylate* (VII) is formed on heating an alcoholic solution of the above compound with excess of 10% sodium hydroxide solution, when an oily mass is produced which slowly solidifies. The *cyclo*hexenone crystallises from methyl alcohol after treatment with charcoal in glistening plates, m. p. 66° (Found: N, 4·8. $C_{18}H_{23}O_3N$ requires N, 4·7%).

Ethyl 3-p-*dimethylaminophenyl*-5-(3′-*methoxy*-2′-*hydroxy*)*styryl*-Δ^5-cyclo*hexene*-1-*one*-2-*carboxylate* was prepared by boiling an alcoholic solution of 4′-dimethylamino-3-methoxy-2-hydroxydistyryl ketone (5 g.) and ethyl acetoacetate (2 mols.) for 3 hours under reflux with sodium hydroxide solution (3 c.c. of 40%). After removal of inor-

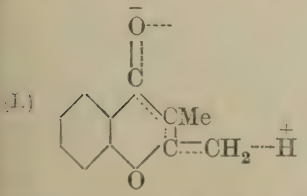
ganic material by filtration, the crude *cyclo*hexenone was purified by repeated crystallisation first from absolute alcohol and finally from high-boiling ligroin. It forms yellow crystals, m. p. 197—198°, readily soluble in chloroform and benzene, sparingly soluble in alcohol (Found : C, 71·6; H, 6·5. $C_{26}H_{29}O_5N$ requires C, 71·8; H, 6·7%).

3-(4′-*Methoxy*-2′-*hydroxy*)*phenyl*-5-p-*dimethylaminostyryl*-Δ^5-cyclo*hexene*-1-*one*.—An alcoholic solution containing 4′-dimethylamino-4-methoxy-2-hydroxydistyryl ketone (6 g.) and ethyl acetoacetate (8 g.) was heated for ½ hour on the steam-bath with 6 c.c. of 50% sodium hydroxide. After cooling, the solution was filtered from a small quantity of material which could not be further purified, and the filtrate diluted with water. The red, amorphous solid thus obtained was dried and repeatedly crystallised from benzene. The pure *cyclo*hexenone forms orange-red crystals, m. p. 218° (Found : C, 75·8; H, 6·9. $C_{23}H_{25}O_3N$ requires C, 76·0; H, 6·9%).

Ethyl 3-p-*Dimethylaminophenyl*-5-(5′-*methoxy*-2′-*hydroxy*)*styryl*-Δ^5-cyclo*hexene*-1-*one*-2-*carboxylate*.—4′-Dimethylamino-5-methoxy-2-hydroxydistyryl ketone (4 g.) and ethyl acetoacetate (8 g.) were treated in alcoholic solution with aqueous sodium hydroxide (8 c.c. of 20%). After 3 days, the solution was filtered from a small quantity of solid, and the filtrate slowly diluted with water, when the *cyclo*hexenone ester was precipitated. It crystallises from benzene with 1 mol. of solvent of crystallisation in yellow crystals, m. p. 196—197° (Found : C, 74·9; H, 7·2. $C_{26}H_{29}O_5N,C_6H_6$ requires C, 74·8; H, 6·8%). The residue was washed with water to remove inorganic material and crystallised from aqueous pyridine. It separated in orange crystals, m. p. 250°. Analysis of this compound shows that the carbethoxyl has been split off, from which it follows that its structure corresponds to 3-(5′-methoxy-2′-hydroxy)-phenyl-5-*p*-dimethylaminostyryl-Δ^5-*cyclo*hexene-1-one (Found : C, 75·9; H, 6·9. $C_{23}H_{25}O_3N$ requires C, 76·0; H, 6·9%).

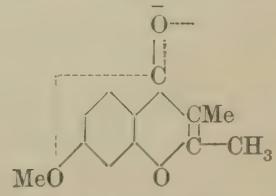
γ-p-*Dimethylaminocinnamoyl*-β-o-*hydroxyphenylpropane*-αα′-*dicarboxylic Acid* (XI).—A mixture containing 4′-dimethylamino-2-hydroxydistyryl ketone (8·2 g. of chloroform addition product) and 8 c.c. of ethyl cyanoacetate in 25 c.c. of hot alcohol was treated with sodium hydroxide solution (8 c.c. of 50%), when a deep red coloration rapidly developed and ammonia was evolved. After 16 hours the reaction mixture was filtered from tarry and inorganic material, diluted to 2000 c.c., and the clear orange-red solution rendered acid with dilute acetic acid. As an examination of the precipitated product after crystallisation from benzene indicated that two substances were present, the whole was boiled with sodium hydroxide solution until all evolution of ammonia had ceased. After again

rendering acid, the precipitated product was purified by repeated crystallisation from nitrobenzene, when glistening, orange needles, m. p. 220°, were obtained (Found: C, 66·3; H, 5·8. $C_{22}H_{23}O_6N$ requires C, 66·5; H, 5·8%). That the ethyl cyanoacetate had entered the molecule at positions 1 and 2 (XIII) was proved by slowly running a concentrated alkaline solution of the acid from a dropping-funnel on to boiling potassium hydroxide solution (50 c.c. of 70%) contained in a distillation flask, fitted with a condenser. Pale green crystals (m. p. 66°) separated from the collected steam distillate and were identified as *p*-dimethylaminobenzaldehyde by mixed m. p. determinations with an authentic specimen and by the formation of the phenylhydrazone. The residue left in the flask was carefully examined for the presence of salicylaldehyde, but no trace either of this or of salicylic acid could be found.



The authors desire to thank the Council of the Department of Scientific and Industrial Research for a grant in aid to one of them (T. A. F.) which has enabled this work to be carried out.

The University, Liverpool. [*Received, July 10th*, 1925.]

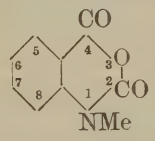


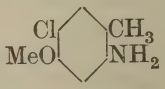
CCXCII.—*Chemical Reactivity and Conjugation. Part II. The Reactivity of the 2-Methyl Group in the 4-Quinazolone Series.*

By Isidor Morris Heilbron, Francis Noel Kitchen, Edward Burdon Parkes, and George Donald Sutton.

It has previously been demonstrated (Heilbron, Barnes, and Morton, J., 1923, **123**, 2559) that the reactivity of the 2-methyl group in 2 : 3-dimethylchromone is conditioned by its capacity to pass into the activated polarised form (I) and that this effect can be entirely suppressed by replacement of hydrogen for methoxyl in position 7, the substituted 7-methoxy-2 : 3-dimethylchromone (II) being entirely unreactive owing to neutralisation of partial valency forces.

(I.)





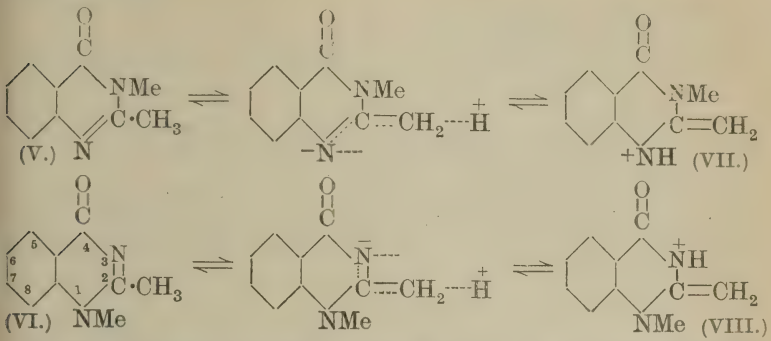
(II.)

The examination of this phenomenon has now been extended to the 4-quinazolone series, which has been widely investigated by

Bogert and his collaborators. That 2 : 3-dimethyl-4-quinazolone (V) contains a reactive methyl group has been demonstrated by the preparation of 2-styryl-3-methyl-4-quinazolone (Bogert, Beal, and Amend, *J. Amer. Chem. Soc.*, 1910, **32**, 1654) and we have now been able to show that the isomeric 1 : 2-dimethyl-4-quinazolone (VI) also is capable of yielding styryl derivatives.

This latter compound was first prepared by Weddige (*J. pr. Chem.*, 1887, **36**, 152) by direct methylation of anthranilamide followed by acetylation and subsequent loss of water from the acetyl methyl derivative. On testing this method, it was found that the yield of methylanthranilamide produced was poor owing to simultaneous formation of anthranilamide dimethyl ether. Other methods were therefore sought, starting from methylanthranilic acid itself. As distillation of the ammonium salt failed to yield the amide, an attempt was made to obtain the 1 : 2-dimethyl-4-quinazolone directly by distillation of the ammonium salt of acetylmethylanthranilic acid, but although some of the desired substance was obtained the yield was again unsatisfactory.

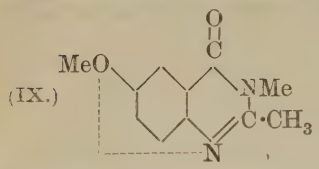
(III.) 



(IV.)

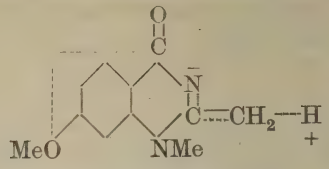
As these methods failed to give the required amide, attention was next directed to an investigation of Niementowski and Rozanski (*Ber.*, 1889, **22**, 1672), who found that isatoic anhydride was readily converted into anthranilamide by 0·88 ammonia. The preparation of methylisatoic anhydride (III) proved a simple matter, a quantitative yield of this substance being obtained on treatment of methylanthranilic acid successively with chloroformic ester and acetyl chloride (compare Bredt and Hof, *Ber.*, 1900, **33**, 27). With concentrated ammonia, it passes readily into methylanthranilamide, a reaction which incidentally furnishes fresh proof of the correctness of the anhydride structure of isatoic acid (compare Erdmann, *Ber.*, 1899, **32**, 2159).

As in the case of 2 : 3-dimethylchromone, both the 1 : 2-dimethyl-4-quinazolone and the isomeric 2 : 3-dimethyl compound readily condense at room temperature with aromatic aldehydes in presence of alcoholic sodium ethoxide to yield 2-styryl derivatives, the more drastic conditions of boiling the reactants together as employed by Bogert, Beal, and Amend (*loc. cit.*) being unnecessary.



In both these compounds we consider that the reactivity of the methyl group is conditioned by the tendency of the unsaturated nitrogen atoms, as with the carbonyl oxygen atom of 2 : 3-dimethyl-

chromone, to acquire a slight negative charge, thus producing an activated phase of the molecule which, in its final state, may be represented as completed isomeric change into the methylene forms (VII and VIII).



It will be observed that in the case of VI a conjugated system, analogous to that contained in 2 : 3-dimethylchromone, is present and it is thus conceivable that, if the activity is conditioned by the presence of this system, substitution of methoxyl for hydrogen in the 7-position might be capable of suppressing the reactivity of the 2-methyl group owing to neutralisation of valency forces. In order experimentally to test this point, 7-methoxy-1 : 2-dimethyl-4-quinazolone was prepared from 4-methoxyanthranilic acid (Ullmann and Dootson, *Ber.*, 1918, **51**, 9) by a series of reactions similar to those detailed in the preparation of the unsubstituted 1 : 2-dimethyl-4-quinazolone. On treatment of this compound with piperonal in presence of alcoholic sodium ethoxide a styryl derivative was readily formed, thus showing that the reactivity of the 2-methyl group in this case is dependent mainly on the activation of the nitrogen atom in position 3. 7-Methoxy-2 : 3-dimethyl-4-quinazolone has also been prepared and, as was to be anticipated, proved to be a reactive substance, the reactivity in this case being conditioned by the nitrogen atom in position 1. An examination of the formula representing the polarised form of 2 : 3-dimethyl-4-quinazolone reveals the fact that in the case of 6-methoxy-2 : 3-dimethyl-4-quinazolone there is a possibility of complete neutralisation of valency forces being effected (IX), and if this occurred the nitrogen atom in position 1 would be rendered inactive. The preparation of this compound and also the isomeric 6-methoxy-1 : 2-dimethyl-4-quinazolone was carried out as described in the experimental portion. Under no conditions, however, could 6-methoxy-2 : 3-dimethyl-4-quinazolone be induced to condense with aromatic aldehydes, the compound being recovered unchanged even when the reactants were heated to high temperatures in presence of a con-

densing agent. On the other hand, 6-methoxy-1 : 2-dimethyl-4-quinazolone, which is incapable of forming a closed valency

(IX.)

(X.)

circuit, readily yields styryl derivatives when an alcoholic solution of the components is treated with sodium ethoxide.

As regards the degree of activity noted, it appears general that the 1 : 2-dimethyl-4-quinazolones are more reactive than the corresponding 2 : 3-dimethyl isomerides. This enhanced effect is probably due to the presence of the conjugated system $O{=}C{-}N{=}C{\cdot}CH_3$ in the former series, and in agreement with this it is found that a certain retardation of activity is noticeable in the case of 7-methoxy-1 : 2-dimethyl-4-quinazolone, thus showing that neutralisation effects (X), although not sufficient to prevent reaction, do nevertheless come into play.

An interesting point worthy of record was noted during the preparation of 4-methoxyanthranilic acid from *o*-nitro-*p*-cresol methyl ether. Ullmann and Dootson recommend direct oxidation of this compound to the corresponding 2-nitro-4-methoxybenzoic acid with subsequent reduction to the anthranilic acid. As this method is somewhat laborious, attempts were made first to reduce the nitrocresol methyl ether to the amino-compound and then to oxidise the acetylamino-derivative to the acid as detailed by Friedländer, Buchner, and Deutsch (*Annalen*, 1912, **388**, 44). *o*-Amino-*p*-cresol methyl ether was first prepared by Knecht (*Annalen*, 1882, **215**, 83) by reduction of *o*-nitro-*p*-cresol methyl ether with tin and hydrochloric acid and described as a colourless solid, m. p. 47°. On repeating this experiment, an amine (m. p. 112°) was obtained from the steam distillate, which after recrystallisation melted at 116°, and was apparently identical with the compound, m. p. 111°, originally obtained by Limpach (*Ber.*, 1889, **22**, 791; 1891, **24**, 4136). On examination of this substance, we found that it is actually a chlorinated amine to which the constitution IV has been assigned, the reaction obviously having followed a similar course to that occurring during the reduction of *p*-nitrophenetole under similar conditions (Hurst and Thorpe, J., 1915, **107**, 924).

Experimental.

2 : 3-*Dimethyl*-4-*quinazolone* was prepared in good yield by treatment of acetanthranil with methylamine solution according to

Bogert and Seil's method (*J. Amer. Chem. Soc.*, 1907, 29, 529). It forms colourless needles (from water) containing 1 mol. of solvent, m. p. 72°. The anhydrous compound is obtained by heating in the steam-oven and melts at 112°.

Condensation Products.—In all cases, unless otherwise stated, these were prepared by allowing an alcoholic solution of the reactants to stand at room temperature in presence of sodium ethoxide as condensing agent. The styryl derivative either separates out directly from the alcoholic solution or on dilution with water.

2-*Styryl*-3-*methyl*-4-*quinazolone* was originally prepared by Bogert, Beal, and Amend (*loc. cit.*) by boiling 2 : 3-dimethyl-4-quinazolone with benzaldehyde. It is also readily produced by the method described above and forms pale yellow, silky needles, m. p. 167° (Bogert gives 170°).

4′-*Methoxy*-2-*styryl*-3-*methyl*-4-*quinazolone* forms bright yellow needles from alcohol, m. p. 146°, soluble in dilute hydrochloric acid, giving an orange-coloured solution (Found : N, 9·5. $C_{18}H_{16}O_2N_2$ requires N, 9·6%).

3′ : 4′-*Dimethoxy*-2-*styryl*-3-*methyl*-4-*quinazolone* separates in yellow plates from benzene, m. p. 208° (Found : N, 8·6. $C_{19}H_{18}O_3N_2$ requires N, 8·7%).

3′ : 4′-*Methylenedioxy*-2-*styryl*-3-*methyl*-4-*quinazolone* forms bright yellow needles, m. p. 185° (Found : N, 9·0. $C_{18}H_{14}O_3N_2$ requires N, 9·2%).

4′-*Dimethylamino*-2-*styryl*-3-*methyl*-4-*quinazolone* crystallises from alcohol in orange-red needles, m. p. 175°. The solution in dilute hydrochloric acid is dark red (Found : N, 13·8. $C_{19}H_{19}ON_3$ requires N, 13·8%).

Methylisatoic anhydride was produced from methylanthranilic acid according to the method employed by Bredt and Hof (*loc. cit.*) for the production of isatoic anhydride. The acid was refluxed with chloroformic ester (3 mols.) until a clear solution resulted, after which a slight excess of acetyl chloride was added and the heating continued until all evolution of hydrogen chloride had ceased. On cooling, *methylisatoic anhydride* separated in quantitative yield in colourless prisms, m. p. 180° (Found : N, 7·9. $C_9H_7O_3N$ requires N, 7·9%).

The *carbethoxy*-derivative of methylanthranilic acid forms colourless crystals, m. p. 108° (Found : N, 6·4. $C_{11}H_{13}O_4N$ requires N, 6·3%).

Methylanthranilamide was produced in quantitative yield by boiling methylisatoic anhydride with 0·88 ammonia. The thick, white precipitate was filtered off and crystallised from alcohol, from which the pure amide separated in colourless needles, m. p. 162°.

1 : 2-*Dimethyl*-4-*quinazolone* was obtained in excellent yield by

boiling *N*-methylanthranilamide with excess of acetic anhydride until the volume of the solution had been reduced to about one-half, after which it was diluted with water, rendered alkaline, and again boiled for about 10 minutes. The crude quinazolone separated on cooling and was purified by crystallisation from water, forming silky needles containing water of crystallisation. The anhydrous compound (m. p. 203°) is obtained by heating in the steam-oven (Weddige gives 199°).

2-*Styryl*-1-*methyl*-4-*quinazolone* crystallises from aqueous alcohol in cream-coloured needles, m. p. 245° (Found : N, 10·8. $C_{16}H_{13}ON_2$ requires N, 10·7%).

4′-*Methoxy*-2-*styryl*-1-*methyl*-4-*quinazolone* forms bright yellow needles from aqueous alcohol, m. p. 94°, containing $2H_2O$. The anhydrous compound melts at 156° and dissolves in dilute hydrochloric acid with a deep yellow colour (Found : N, 9·6%). 3′ : 4′-*Methylenedioxy*-2-*styryl*-1-*methyl*-4-*quinazolone* forms yellow needles, m. p. 264° (Found : N, 9·1%). 4′-*Dimethylamino*-2-*styryl*-1-*methyl*-4-*quinazolone* forms orange needles, m. p. 274°. The solution in dilute hydrochloric acid is bright red (Found : N, 13·7%).

6-*Nitro*-3-*hydroxybenzaldehyde*.—*m*-Hydroxybenzaldehyde was nitrated as detailed by Pschorr (*Annalen*, 1912, **391**, 28). The crude nitration product was boiled under reflux with four times its weight of benzene for ½ hour, allowed to cool to 50°, and rapidly filtered. Employing this temperature instead of the lower temperature of 45° used by Pschorr rendered the separation much more complete. 6-Nitro-3-hydroxybenzaldehyde * separates from boiling water in long, yellow needles, m. p. 166° (yield 34% of theory).

6-*Nitro*-3-*methoxybenzaldehyde* was originally obtained by Pschorr, but no details of his method are given. A 95% yield of the ether is readily obtained by the following procedure : 6-Nitro-3-hydroxybenzaldehyde (50 g.) was dissolved in the calculated amount of potassium hydroxide solution and warmed at 60°, after which methyl sulphate (56 c.c.) was added and the mixture well shaken. After cooling, the solution was made alkaline; the methyl ether, which rapidly separated, crystallised from alcohol in colourless needles, m. p. 82°.

6-*Nitro*-3-*methoxybenzoic Acid*.—The oxidation of the aldehyde was carried out by suspending it (20 g.) in 1500 c.c. of warm dilute potassium hydroxide solution (1 mol. KOH) and gradually adding the calculated amount of a 2% solution of potassium permanganate, the whole being mechanically stirred. The alkaline filtrate was

* The preparation of this compound in good yield (87%) has been much simplified by Mason (this vol., p. 1195), whose paper appeared after the completion of the work described in this communication.

rendered acid, the solution saturated with salt and ether-extracted. After removal of solvent the crude acid was crystallised from alcohol, separating in colourless needles, m. p. 97° (yield 87%). It is essential to employ the pure aldehyde in this oxidation, otherwise the yield of acid is largely reduced. This substance was found to contain 1 mol. of water of crystallisation, the anhydrous acid which is obtained by heating in the steam-oven melting at 133° as given by Pschorr.

5-*Methoxyanthranilic acid* was prepared by Pschorr (*loc. cit.*) by reduction of the nitro-acid with ferrous sulphate and ammonia. A more satisfactory method is to carry out the reduction by means of stannous chloride and concentrated hydrochloric acid, when a 75% yield of the required acid results.

5-*Methoxyacetanthranil*.—The method employed was similar to that described by Bogert (*J. Amer. Chem. Soc.*, 1911, **33**, 949). 5-Methoxyanthranilic acid was gradually added to excess of boiling acetic anhydride, when a vigorous reaction occurred with precipitation of a yellow solid which dissolved on further heating. On allowing the solution to cool, the anthranil was deposited in quantitative yield. It crystallises from benzene in colourless, prismatic needles, m. p. 124° (Found : N, 7·5. $C_{10}H_9O_3N$ requires N, 7·3%).

6-*Methoxy*-2-*methyl*-4-*quinazolone*.—On boiling the anthranil for 1 hour under reflux with a large excess of 0·88 ammonia, it gradually dissolved and as the reaction proceeded the quinazolone separated out. It forms glistening needles (from aqueous alcohol), m. p. 270° (Found : N, 14·7. $C_9H_{10}O_2N_2$ requires N, 14·7%).

6-*Methoxy*-2 : 3-*dimethyl*-4-*quinazolone* was prepared in an analogous manner by employing alcoholic methylamine solution and was also easily obtained by the action of methyl sulphate on an alkaline solution of the 2-methylquinazolone. It separates from boiling water in colourless needles containing 1 mol. H_2O, m. p. 87°. The anhydrous compound is readily formed on heating the hydrated substance in a steam-oven and melts at 133° (Found : N, 13·9. $C_{11}H_{12}O_2N_2$ requires N, 13·7%).

Attempts were made to condense this quinazolone with aromatic aldehydes by condensation in presence of alcoholic sodium ethoxide both in the cold and heat, but in each case unchanged substance was recovered. The quinazolone was also heated with piperonal alone under precisely similar conditions to those employed by Bogert (*loc. cit.*), but on extracting the melt practically the whole of it was recovered unchanged. This experiment was repeated in presence of zinc chloride as condensing agent, but here again unchanged quinazolone was obtained.

5-*Methoxymethylanthranilic acid* was prepared according to

Willstätter and Kahn's method (*Ber.*, 1904, **37**, 408) by direct methylation of the sodium salt of the acid with methyl sulphate in the cold. It separates from benzene after treatment with animal charcoal in yellow needles, m. p. 163°. Both the ethereal and the aqueous solution exhibit a strong blue fluorescence (Found : N, 7·7. $C_9H_{11}O_3N$ requires N, 7·7%).

6-*Methoxymethylisatoic anhydride* was prepared as previously described. It crystallises from acetone in colourless needles, m. p. 233° (Found : N, 6·6. $C_{10}H_9O_4N$ requires N, 6·8%). On refluxing with excess of 0·88 ammonia, it is converted into 5-*methoxymethylanthranilamide*, which separates from boiling water in colourless needles, m. p. 145° (Found : N, 15·5. $C_9H_{12}O_2N_2$ requires N, 15·6%).

6-*Methoxy*-1 : 2-*dimethyl*-4-*quinazolone*.—On treatment of the amide with acetic anhydride as described in the preparation of the unsubstituted 1 : 2-dimethyl-4-quinazolone, it is quantitatively converted into 6-methoxy-1 : 2-dimethyl-4-quinazolone, which crystallises from water in long, colourless needles, m. p. 220° (Found : N, 13·8%).

6-*Methoxy*-3′ : 4′-*methylenedioxy*-2-*styryl*-1-*methyl*-4-*quinazolone*.—Unlike the inactive isomeric 6-methoxy-2 : 3-dimethyl-4-quinazolone, the 1 : 2-dimethyl compound reacts readily with aromatic aldehydes, the condensation with piperonal being completed in the cold after 12 hours. By warming on the water-bath the reaction is much accelerated, the condensation product commencing to separate after 10 minutes. The crude product was purified by recrystallisation from alcohol and formed microscopic, yellow needles, m. p. 284° (Found : N, 8·2. $C_{19}H_{16}O_4N_2$ requires N, 8·3%).

4-*Methoxymethylanthranilic acid* was prepared from 4-methoxyanthranilic acid by direct methylation with methyl sulphate. It separates from alcohol in colourless needles, m. p. 165° (Found : N, 7·8%). The conversion of this acid into 7-*methoxymethylisatoic anhydride* follows the directions previously given. The substance crystallises from acetone in colourless prisms, m. p. 200° (Found : N, 6·9%). On treatment with 0·88 ammonia it is quantitatively converted into 4-*methoxymethylanthranilamide*, which crystallises from alcohol in colourless needles, m. p. 138° (Found : N, 15·6%).

7-*Methoxy*-1 : 2-*dimethyl*-4-*quinazolone* was prepared in an analogous manner to that of the isomeric 6-methoxy-compound, and after treatment with animal charcoal separated from absolute alcohol in colourless crystals, m. p. 193°. It crystallises from water with 1 mol. H_2O and melts indefinitely at about 135° (Found : N, 12·6. $C_{11}H_{12}O_2N_2$, H_2O requires N, 12·6%).

7-*Methoxy*-3′ : 4′-*methylenedioxy*-2-*styryl*-1-*methyl*-4-*quinazolone* forms yellow needles (from ethyl alcohol), m. p. 280° (Found : N, 8·3%)

7-*Methoxy*-4′-*dimethylamino*-2-*styryl*-1-*methyl*-4-*quinazolone* is best prepared by refluxing an alcoholic solution of the constituents in presence of sodium ethoxide and precipitating the styryl derivative with water. It separates from alcohol in bright red cubes, m. p. 266° (Found : N, 12·8. $C_{20}H_{19}O_2N_3$ requires N, 12·5%).

4-*Methoxyacetanthranil*, prepared by boiling 4-methoxyanthranilic acid with excess of acetic anhydride, crystallises from water in colourless needles, m. p. 128° (Found : N, 7·4%).

7-*Methoxy*-2-*methyl*-4-*quinazolone* prepared by the usual method crystallises from alcohol in colourless needles, m. p. 272° (Found : N, 14·6. $C_{10}H_{10}O_2N_2$ requires N, 14·7%). On treatment with methyl sulphate it is immediately converted into 7-*methoxy*-2 : 3-*dimethyl*-4-*quinazolone*. This substance is equally readily prepared by the direct treatment of 4-methoxyacetanthranil with methylamine solution, a reaction which definitely fixes its constitution. The quinazolone crystallises from water with 1 mol. H_2O in colourless needles, m. p. 80°. The anhydrous compound melts at 149° Found : N, 13·7. $C_{11}H_{12}O_2N_2$ requires N, 13·7%).

7-*Methoxy*-3′ : 4′-*methylenedioxy*-2-*styryl*-3-*methyl*-4-*quinazolone* separates from alcohol in yellow crystals, m. p. 193° (Found : N, 9·3%).

5-*Chloro*-2-*amino*-4-*methoxytoluene*.—*o*-Nitro-*p*-cresol methyl ether was reduced by warming with tin and concentrated hydrochloric acid in the usual manner, the solution diluted with water, rendered alkaline, and subjected to steam distillation. The amine (m. p. 112°) crystallised from benzene in colourless plates, m. p. 116° (Found : N, 8·5. $C_8H_{10}ONCl$ requires N, 8·2%). The *acetyl* derivative melts at 183—184° (Found : N, 6·8. $C_{10}H_{12}O_2NCl$ requires N, 6·6%).

In conclusion, we desire to thank the Directors of the United Alkali Company for a grant to one of us (F.N.K.) which has enabled this work to be carried out.

The University, Liverpool. [*Received, July 10th*, 1925.]

NOTES.

Preparation of the Phenylcarbamyl Derivatives of Nitrophenols.

By Oscar L. Brady and Jack Harris.

Nitrophenols do not react readily with phenylcarbimide and the following method for the preparation of their phenylcarbamyl derivatives is an improvement on those previously described (Dumpert, *J. pr. Chem.*, 1885, **32**, 278; Michael and Cobb, *Annalen*,

1908, **363**, 91; Vallée, *Ann. Chim. Phys.*, 1908, **15**, 331; Busche, Blume, and Pungs, *J. pr. Chem.*, 1909, **79**, 534).

The nitrophenol (4·8 g.) is gently boiled with phenylcarbimide (5 g.) in toluene under reflux for 3 hours. On cooling, the phenylcarbamyl derivative crystallises; in the case of *o*-nitrophenol it may be necessary to boil off some toluene, as its derivative is considerably more soluble than the others. After being washed with cold 2*N*-sodium hydroxide and crystallised once from chloroform the pure nitrophenyl phenylcarbamates are obtained. *m-Nitrophenyl phenylcarbamate* forms bulky, colourless needles, m. p. 129° (Found: N, 11·1. $C_{13}H_{10}O_4N_2$ requires N, 10·9%).—University College, London. [*Received, July 21st*, 1925.]

---

d-*Mannitol from* Gardenia turgida. By Martin Onslow Forster and Keshaviah Aswath Narain Rao.

On requesting Mr. R. S. Pearson, C.I.E., Forest Economist, Dehra Dun, to supply Dekamali resin in quantity sufficient for completing the investigation of gardenin, it was found that this gum from *Gardenia lucida* was extremely scarce; but we were supplied instead with an exudation from *G. turgida* entirely different in appearance and properties from the material examined by Stenhouse (*Annalen*, 1856, **98**, 316; Stenhouse and Groves, *ibid.*, 1880, **200**, 311). The product from *G. turgida* has a faintly pleasant smell in place of the odour suggesting cat's urine, and consists of loose fragments in which colourless crystals can be recognised under the lens. It dissolves almost completely in cold water with slight frothing, forming a pale brown, viscous liquid, slow to filter and depositing a brown syrup on evaporation. Furfurol is not produced on boiling with hydrochloric acid, and the tests for nitrogen, aldehydes, and ketones were negative.

The powdered substance (50 g.) dissolved in water (200 c.c.) was shaken with tribasic lead acetate (15 g.) added in small quantities, and filtered after 20 hours, when the lead was precipitated completely by hydrogen sulphide; the concentrated filtrate from lead sulphide deposited silky, white needles identified as *d*-mannitol (dimorphous, soft needles or hard prisms; m. p. 165—166°, unchanged by admixture with *d*-mannitol; solubility 14·7 parts in 100 H_2O at 19°; $[\alpha]_D$ in borax solution, 19·7°; m. p. of hexa-acetyl derivative, 120°). The yield corresponds to about 40% of the dried exudation.

Our thanks are due to Mr. R. S. Pearson for kindly supplying us with this material.—Indian Institute of Science, Bangalore, S. India. [*Received, June 29th*, 1925.]

CCXCIII.—*The Velocity of Benzylation of certain Amines. Part II.*

By David Henry Peacock.

In a previous paper (J., 1924, **125**, 1975), the energies of activation for the reaction between benzyl chloride and aniline or *p*-toluidine, and between *p*-nitrobenzyl chloride and aniline or *p*-toluidine were calculated from the velocity coefficients at two temperatures; no evidence was found that these energies are additive in character. The results of some further experiments are now described, but before their bearing on the nature of the process of activation is discussed the effect of substitution and other factors will be dealt with.

m-Nitrobenzyl chloride always reacted faster than *p*-nitrobenzyl chloride with the bases used. Olivier (*Rec. trav. chim.*, 1922, **41**, 646) obtained similar results in their hydrolysis. Slator and Twiss (J., 1909, **95**, 99) found that the order was reversed with sodium thiosulphate, where reaction is taking place with the negative thiosulphate ion. These results can be explained on the alternate polarity hypothesis. With bases such as aniline and dimethylaniline nitrobenzyl chlorides react more slowly than does benzyl chloride, although it might be expected that the general polar effect of the nitro-group would make the chlorine more reactive in nitrobenzyl than in benzyl chloride. These results may be explained by assuming that before reaction occurs the base and the halogen compound combine loosely and the negative substituent in the benzyl chloride then weakens the tendency of the nitrogen to form part of a positive ion and so reduces the rate of reaction. The results of other experiments described below show that the introduction of a nitro-group into the nucleus of the base considerably reduces the reaction velocity.

Additional evidence in support of this assumption can be obtained from the results of Jones and Preston (J., 1912, **101**, 1931) and of Thomas (J., 1913, **103**, 595), who obtained the following velocity coefficients in alcohol at 40° with dimethylaniline: benzyl bromide 6·34, *m*-xylyl bromide 8·62, *p*-xylyl bromide 23·2, *p*-bromobenzyl bromide 6·03. The positively substituted benzyl bromide reacts faster, and the negatively substituted benzyl bromide more slowly, than the unsubstituted bromide.

The effect of substitution in the nucleus of the base upon the velocity coefficient can be seen from the data given later. *m*-Nitroaniline reacts faster than *p*-nitroaniline, and *p*-toluidine faster than *o*-toluidine; results in accordance with the alternate polarity hypothesis.

The effect of concentration on the velocity coefficients and energies

of activation is sometimes considerable and, as will be seen from the tabulated results, depends on the character of the base employed. Attention is also directed to the difference in the effect of alteration in concentration upon the velocity and energy of activation of the reaction between benzyl chloride and dimethylaniline.

Velocity coefficient and concentration.

Base.	Conc.	Conc. of benzyl chloride.	$k_{35°} \times 10^3$.	$k_{45°} \times 10^3$.	E, calories.
Aniline	0·4	0·2	3·62	8·5	16550
	0·8	,,	3·68	9·2	17770
	1·6	,,	4·07	10·55	18460
	1·6	0·4	4·25	11·2	18780
o-Toluidine	0·8	0·2		5·96	
	1·6	,,		7·1	
p-Toluidine	0·8	,,	5·96	14·7	17440
	1·6	,,	6·21	15·1	17230
p-Chloroaniline	0·4	,,		5·15	
	0·8	,,		5·08	
Monoethylaniline.....	0·8	,,		1·138	
	1·6	,,		1·13	
Dimethylaniline	0·8	,,	2·78	6·09	15210
	1·6	,,	2·23	5·06	15890
Diethylaniline	0·8	,,		0·400	
	1·6	,,		0·303	

Examination of the results obtained showed also an interesting connexion between energy of activation and the constitution of the substituted benzyl chloride used. When the energies of activation of *m*- and *p*-nitrobenzyl chlorides with aniline, *p*-toluidine, *o*-toluidine, and dimethylaniline are compared, it is seen that, although there is apparently no strictly quantitative additive relation, there is a qualitative relationship, the energy of activation for *m*-nitrobenzyl chloride being less than that for *p*-nitrobenzyl chloride. The alternate polarity theory would lead us to expect that the chlorine in *m*-nitrobenzyl chloride should be more reactive than that in *p*-nitrobenzyl chloride. This conclusion is seen to be confirmed, not only by the velocity data, but also by the activation energy data. Applying the Bohr theory of atomic structure, it may be said that the displacement of electrons postulated by the alternate polarity theory decreases the amount of energy required to take an electron in the chlorine atom to its activated position.

Energies of Activation in Methyl Alcohol.

Base.	Benzyl chloride.	*m*-Nitrobenzyl chloride.	*p*-Nitrobenzyl chloride
Aniline	17770	17280	18030
p-Toluidine.....	17440	14480	17100
o-Toluidine	15420	14210	17680
Dimethylaniline.....	15210	13120	15960

The results described below also throw some light on the process of activation. The influence of a nitro-group in the benzyl chloride on the velocity of reaction is similar to the influence of a nitro-group in the nucleus of the amine. Also there is no evidence that, in general, the energy of activation is an additive property (Arrhenius, *Z. physikal. Chem.*, 1889, **4**, 226). It is now suggested that the formation of a loose molecular complex precedes activation and the energy of activation measured in the cases cited is the energy of activation of such a complex.

Experimental.

The method of estimation was that already described (*loc. cit.*). The constants were calculated by the modified equation, taking into account the base combined with the liberated hydrochloric acid; Moore, Somervell, and Derry (J., 1912, **101**, 2459) have already directed attention to this omission in Menschutkin's calculations and their work should have been mentioned in the previous paper.

Tertiary bases gave much more constant values of the velocity coefficient than primary; difficulty was also experienced in getting concordant results with *p*-nitrobenzyl chloride. The bases used were crystallised as their hydrochlorides or acetyl compounds in the case of primary and secondary bases. The tertiary bases were tested for freedom from primary or secondary bases by the usual acetic anhydride test. The results are tabulated below.

BURMA. [*Received, April 27th* 1925.]

CCXCIV.—*A New Peroxide of Barium.*

By MARGARET CARLTON.

WHEN hydrogen peroxide is added to a well-cooled, aqueous solution of barium hydroxide, white, crystalline $BaO_2,8H_2O$ is formed. If, however, excess of hydrogen peroxide be added, the appearance of the crystals changes and a granular precipitate is formed which rapidly settles after shaking. This becomes buff-coloured on standing. If this substance be filtered off and dried in a vacuum desiccator over phosphorus pentoxide, the colour slowly darkens for a day or two, until a deep buff colour is reached; on further standing, the colour fades and a creamy powder remains. This seems to suggest the formation and decomposition of an oxide higher than BaO_2.

A study of the action of excess of hydrogen peroxide on baryta was made by Schöne (*Annalen*, 1878, **192**, 257), and he showed the existence of a white, crystalline compound, BaH_2O_4, which turned yellow on standing. He suggested that this yellow compound might be BaO_3 or BaO_4, but he did not investigate the matter further. Traube and Schulze (*Ber.*, 1921, **54**, 1626) obtained a substance which on analysis seemed to be BaO_2 with not more than 5% BaO_4.

On the suggestion of Professor Baker, I have undertaken an examination of the action of hydrogen peroxide on barium hydroxide.

A preliminary analysis of the wet substance obtained by precipitation with hydrogen peroxide was therefore carried out, by means of potassium permanganate and dilute sulphuric acid, to determine the oxygen and barium, and this indicated the presence of a substance which seemed to be almost entirely BaO_3 or BaO_4.

Fresh samples of the substance were prepared in the following way: Pure crystalline barium hydroxide (10 g.) was dissolved in 200 c.c. of water, and 10 c.c. of 30% hydrogen peroxide were slowly added with repeated shaking, the temperature of the solutions being about 15°. For the first two preparations the mixture was

kept over-night at the ordinary temperature; the following morning, the precipitate was faintly buff-coloured and was washed by decantation with cold water and finally filtered through an alundum crucible, washed again with cold water, and finally with alcohol and ether, and dried in a vacuum over phosphorus pentoxide. Later on, the substance was kept only for 10—20 minutes after the addition of the hydrogen peroxide, for the precipitate to settle; it was then washed by decantation, filtered off, and washed with water only and dried in a vacuum over phosphorus pentoxide.

Properties.—The substance is a cream-coloured, non-crystalline powder, which darkens on standing.

When it is heated gently in a dried tube, moisture collects on the walls; this does not liberate iodine from potassium iodide and therefore is not hydrogen peroxide.

On extracting with ether and testing the extract for hydrogen peroxide, no trace was found, showing the absence of free hydrogen peroxide and also of hydrogen peroxide of crystallisation.

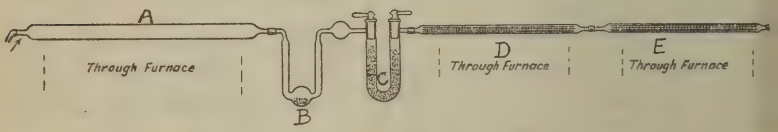
The solid substance decolorises neutral potassium permanganate more rapidly than barium dioxide, giving a brown colour and evolution of oxygen.

It does not liberate iodine from neutral potassium iodide even on standing, but when a few drops of dilute nitric acid are added, iodine is rapidly liberated; more iodine separates than from a similar amount of barium dioxide.

With neutral potassium bromide there is no action but on acidifying with a few drops of either nitric or hydrofluoric acid, bromine is freely liberated, whereas only a trace of bromine is produced from barium dioxide.

With strong hydrochloric acid, there is a vigorous action and chlorine is liberated freely; with barium dioxide only a trace of chlorine is produced.

When it is heated with flowers of sulphur a very vigorous action takes place; a peculiar odour is observed afterwards but no sulphur dioxide (compare barium dioxide, where there is a fairly vigorous action with formation of sulphur dioxide).



The foregoing tests show the presence of a very vigorous oxidising agent, and attempts to determine the amount of oxygen in the compound were made. Analyses had to be carried out before the substance was completely dry, owing to its instability. The oxide was only dried for about an hour over phosphorus pentoxide, in a vacuum; the first sample was then taken for analysis. Two analyses were made at the same time, by different methods. The first analysis consisted in determining the oxygen and water given off when the substance was heated in an atmosphere of

nitrogen. The apparatus used is shown in the accompanying sketch.

A weighed amount of the substance (1—2 g.) was introduced into a weighed Jena glass bulb, B. This was connected through a ground joint to a U-tube, C, containing calcium chloride and to the two tubes, D and E, containing freshly-reduced copper gauze. The tubes C, D, and E were weighed before and after each experiment.

Nitrogen, from which traces of oxygen were removed by passage over the heated tube, A, of copper, was slowly passed through the apparatus and when all the air had been displaced, the tubes, D and E, containing the copper gauze, were heated by means of electric furnaces to 500—600°. When these were hot, the bulb B was heated in a water-bath until the whole of the water in the oxide appeared to have been removed. This sometimes took as long as 3 hours; the bath was then removed and the bulb gently heated nearly to dull redness for a few minutes. The bulb was then allowed to cool; when it was cold, the furnaces heating D

Fig. 1.

and E were switched off and the whole apparatus was left to cool with the nitrogen bubbling through. When cold, the nitrogen was displaced by a slow current of dry air and the tubes C, D, and E and the bulb B were weighed.

The formula was calculated on the assumption that the residue was barium dioxide. This was found not always to be the case; barium dioxide decomposes somewhat when heated in a vacuum to 450° and, since the partial pressure of oxygen is here very small, possibly the same effect is produced and the proportion of oxygen calculated in this way may be rather high.

The weight of water collected in C was subtracted from the actual weight of oxide taken, to give the amount of anhydrous salt used in each experiment. The values of x in BaO_x are given in the table.

The second analysis of the substance was performed while the analysis described above was being carried out. A second sample of the oxide was examined for available oxygen and for barium.

A weighed amount of the salt, dissolved in dilute nitric acid, was titrated with potassium permanganate; the barium was then precipitated from the same solution and weighed as barium sulphate.

This gave an independent estimate of the barium and oxygen present.

The equation used in calculating the composition of the substance is :—

$$BaO_x + \tfrac{2}{5}(x-1)KMnO_4 + \{\tfrac{3}{5}(x-1)+1\}H_2SO_4 = BaSO_4 + \frac{x-1}{5}K_2SO_4 + \tfrac{2}{5}(x-1)MnSO_4 + \{\tfrac{3}{5}(x-1)+1\}H_2O + (x-1)O_2.$$

From which we get that 137 g. of barium correspond to $\frac{2}{5}(x-1)16$ g. of oxygen. And so the value of x can be calculated.

The results are given in the table.

Owing to the uncertainty as to the decomposition of the barium dioxide, a second method was used in liberating oxygen from the compound. Instead of heating the BaO_x in an atmosphere of nitrogen, the air was displaced from the apparatus as before and the weighed tubes containing the copper were heated, then a slow current of carbon dioxide was passed and the oxide heated as before; the residue was obtained as barium carbonate, which is quite stable at the temperature used.

Results bracketed together are different analyses of the same preparation.

* The preparation and determination of this sample were kindly carried out by Mrs. Muriel Baker.

Conclusion.

(1) By the action of an excess of hydrogen peroxide on barium hydroxide at temperatures below 20° a new substance is formed.

(2) This substance is unstable and is a vigorous oxidising agent, being much more reactive than barium dioxide, *e.g.*, liberates bromine from potassium bromide and chlorine very freely from hydrogen chloride.

(3) The results of analysis indicate that it probably has the formula BaO_3.

It is proposed to use this substance in an attempt to prepare a new peroxide of hydrogen. The work will be done in conjunction with Professor Baker and Mrs. Baker, repeating and extending experiments which they have already made with potassium tetroxide.

I wish to express my thanks to Professor Baker for his kind help and encouragement in this research.

CCXCV.—*The Action of Aldehydes on the Grignard Reagent. Part III.*

By JOSEPH MARSHALL.

ONLY when an aldehyde in less than one molecular proportion is allowed to react with an ethereal solution of a magnesium alkyl halide is the expected secondary carbinol the chief product of the reaction; if an excess is added, almost the whole of the excess is combined in some manner with the magnesium complex and the product obtained on decomposition of the mass with water is a mixture containing as one of its constituents the primary alcohol corresponding to the aldehyde used in the reaction (J., 1914, **105**, 527; 1915, **107**, 509). Papers recently published (Meisenheimer, *Annalen*, 1925, **442**, 180; Hess, *Annalen*, 1924, **437**, 256; Rheinboldt, *J. pr. Chem.*, 1925, **109**, 175) agree with the results of the author up to this point, but they differ both as to the mechanism by which the alcohol is supposed to be formed in the reaction and also as to the nature of the other products. Meisenheimer and Hess, whilst not in accord in detail, both suggest that the original co-ordination compound of magnesium ethyl bromide and benzaldehyde is capable of resolution in two directions indicated by the schemes :—

$$\text{(1) PhCHEt·OMgBr} \longleftarrow \text{PhCHO} + \text{MgEtBr} \longrightarrow \text{PhCH}_2\text{·OMgBr} + \text{C}_2\text{H}_4 \quad \text{(2)}$$

the second of these resolutions taking place to a much smaller extent than the first.

The reduction of the aldehyde is represented by this theory as being due to the addition of a hydrogen atom from the alkyl halide, and hence the alkylene evolved should be equivalent to the alcohol

produced. Meisenheimer points out that he has never observed this equivalence, but suggests that some isomerisation takes place.

When an aryl halide is used in the reaction, the author has shown that a primary alcohol is again formed. The scheme representing this would appear to be

$$PhCHO + MgPhBr \longrightarrow PhCH_2{\cdot}OMgBr + C_6H_4< \quad . \quad (3)$$

and this might reasonably be expected to result in the production of diphenylene, which, however, has never been observed in this reaction.

This theory does not explain the production of substances in the Grignard reaction under discussion other than the secondary alcohol, which is the normal product, and the primary alcohol corresponding to the aldehyde used in the reaction; the presence of any other compounds in the product of the reaction would entail a considerable extension of the theory.

The author (*loc. cit.*) showed that along with the primary and secondary alcohols obtained in a Grignard reaction the ketone corresponding to the secondary alcohol is formed, with condensation products of this ketone and the aldehyde used in the reaction. Thus, when benzaldehyde in excess reacts with magnesium methyl iodide, the products which may be isolated are benzyl alcohol, acetophenone, phenyl styryl ketone, and dibenzoylmethane, while the phenylmethylcarbinol which, normally, would be the main product of the reaction is almost entirely absent. Again, when benzaldehyde in excess reacts with magnesium phenyl bromide, the only products are benzyl alcohol and benzophenone, whilst with magnesium benzyl bromide, benzaldehyde produces, besides benzyl alcohol and deoxybenzoin, a large amount of phenyldibenzoylmethane.

The suggestion was hazarded in one of the earlier papers that the new reaction was analogous to Cannizzaro's reaction, in which one molecule of benzaldehyde oxidises a second molecule of the same aldehyde to benzoic acid, being itself reduced to benzyl alcohol. If this suggestion be correct, it is evident that when cinnamaldehyde is allowed to react with magnesium ethyl iodide as described by Meisenheimer, there is the possibility of the formation of styryl ethyl ketone and other condensation products along with cinnamyl alcohol and styrylethylcarbinol.

Since styryl methyl ketone is more easily identified than the ethyl compound, the experiment was first carried out with magnesium methyl iodide, with the result that whilst styryl methyl ketone was isolated as the phenylhydrazone in good yield, the only alcohol which could be obtained was cinnamyl alcohol. This was isolated

as the *p*-nitrobenzoyl ester (m. p. 76°; compare Meisenheimer, *loc. cit.*) and there was no indication of the presence of styrylmethylcarbinol either as its ester or as phenylbutadiene, which might have been formed as phenylpentadiene is produced when *p*-nitrobenzoyl chloride acts on styrylethylcarbinol. The corresponding reaction with magnesium ethyl iodide was performed with results similar to those obtained with magnesium methyl iodide, but in this case, by longer boiling of the reaction product, an attempt was made to secure the formation of more complicated products.

Since it has been shown in earlier papers that alkyl aldehydes are capable of reacting in a manner analogous to that in which aromatic aldehydes react, it was of interest to determine whether the simplest aldehyde, formaldehyde, would react similarly. The normal product of this reaction is the primary alcohol (*Compt. rend.*, 1902, **134**, 107), and it would be expected that excess of formaldehyde would oxidise part at any rate of the primary alcohol to the aldehyde. Accordingly, the reaction between magnesium phenyl bromide and trioxymethylene was investigated, with the result that a considerable quantity of benzaldehyde was isolated, although the chief product of the reaction was benzyl bromide (compare J., 1914, **105**, 534).

Experimental.

Action of Cinnamaldehyde on Magnesium Methyl Iodide.—An ethereal solution of cinnamaldehyde (132 g.; 1 mol.) was added to the Grignard solution prepared from magnesium powder (24 g.; 1 mol.) and methyl iodide (142 g.; 1 mol.), cooled in a freezing mixture. At first a yellow precipitate formed which immediately dissolved on shaking, but when about half the aldehyde had been added a greyish-white solid began to separate. Three hours later, a second molecule of cinnamaldehyde in ether was added quickly, whereby the precipitate was changed into a viscous, yellowish-brown material. After 12 hours, the mixture was heated on the steam-bath during 10 hours and cooled, and the ether was poured into ice and hydrochloric acid, separated, and shaken with sodium bisulphite solution, when about 2 g. of the bisulphite compound of cinnamaldehyde separated. From the residual ether 2 g. of a dark-coloured, sticky material was obtained which was not examined.

The heavy, yellow mass from which the ether had been poured was shaken with ice and hydrochloric acid and a further quantity of ether until solution was effected. The ethereal extract was shaken several times with concentrated bisulphite solution, and 20 g. of cinnamaldehyde bisulphite compound were obtained corresponding to about half this weight of aldehyde. The ether was washed with

sodium carbonate solution and from this, 4 g. of cinnamic acid were isolated. The ether was now evaporated and the residue distilled in a vacuum. A fraction (165 g.) was obtained, b. p. 150—180°/15 mm., while a second fraction (20 g.) distilled at 220—260°. As this did not crystallise, it was not examined; heat was developed when it was mixed with phenylhydrazine. The main fraction was cooled in a freezing mixture and inoculated with a crystal of styryl methyl ketone. The crystals produced could not be isolated owing to the rapidity with which fusion occurred. The whole of the material was dissolved in alcohol and warmed with phenylhydrazine (80 g.) during 2 hours on the water-bath. The yellow crystals which had separated after 12 hours melted at 158° after being washed with alcohol (yield 100 g.). The mother-liquor was evaporated, and after removal of a second crop of crystals, the thick residue was poured into water, washed with dilute hydrochloric acid, separated from the acid, and steam-distilled. The product in the distillate was extracted with ether and, after removal of the ether, was treated with *p*-nitrobenzoyl chloride in pyridine solution. Addition of water precipitated an oil which immediately solidified and, after recrystallisation from alcohol, the compound melted at 76°. It was compared with and found identical with the corresponding ester of cinnamyl alcohol.

The phenylhydrazone (m. p. 158°) was compared with that obtained from styryl methyl ketone and the identity of the two compounds was proved. After heating in a vacuum, and subsequent distillation, both boiled at 245—250°, and the distillate in each case solidified, yielding, after recrystallisation from spirit, white, crystalline prisms, m. p. 113°, and giving with a nitrite solution the magenta colour which is characteristic of 1 : 5-diphenyl-3-methylpyrazoline.

Action of Cinnamaldehyde on Magnesium Ethyl Iodide.—Magnesium (24 g.; 1 mol.) and ethyl iodide (156 g.; 1 mol.) were allowed to react in anhydrous ether with cooling, and cinnamaldehyde (264 g.; 2 mols.) added as in the experiment with methyl iodide. A brownish-yellow mass was again obtained which was heated during 20 hours on the steam-bath and then decomposed with ice and hydrochloric acid; a bright orange, crystalline material (20 g.) not very soluble in ether then separated which melted at 158° after recrystallisation from spirit and has not yet been identified.

After the ether solution had been washed with bisulphite solution, the ether was removed and the residue thoroughly steam-distilled. From the distillate was extracted an oil, of which a quantity was allowed to react with half its weight of phenylhydrazine. Evolution of heat occurred and after cooling the addition of a little spirit induced the crystallisation of the phenylhydrazone, m. p. 102°, of styryl ethyl ketone. From a second part of the oil cinnamyl

p-nitrobenzoate was obtained by the action of *p*-nitrobenzoyl chloride in pyridine solution.

Action of Trioxymethylene on Magnesium Phenyl Bromide.—The Grignard reagent prepared from bromobenzene (157 g.; 1 mol.) (after separating from unchanged metal) was boiled with trioxymethylene (60 g.; 2 mols.) for 48 hours, a brownish-yellow, viscous mass forming. After decomposition of this material with dilute acid the ethereal extract was shaken with sodium bisulphite solution, 20 g. of the bisulphite compound of benzaldehyde were filtered off, and the ethereal solution remaining was fractionated, 35 g. of benzyl bromide and about 10 g. of diphenyl being obtained.

The author desires to thank the Directors of Boots Pure Drug Co., Ltd., for permission to carry out this work in their laboratories and for the assistance of the Analytical Department of the firm in the analysis of the products obtained.

[*Received, July 7th,* 1925.]

CCXCVI.—*Optical Activity and the Polarity of Substituent Groups. Part II. Menthyl Esters of Substituted Acetic Acids.*

By HAROLD GORDON RULE and JOHN SMITH.

POLARITY as applied to substituent effect has, at the present time, at least two distinct meanings in chemistry. On the one hand it is used in the phrase, *general polar effect*, in connexion with a series such as

$$NO_2,\ CN,\ CO_2H,\ Cl,\ Br,\ I,\ OMe,\ H,\ Me,$$

representing the relative influence of the groups on the acidic strength of an aliphatic acid. This sequence has also been traced in the effect of the substituents on velocity of reaction and molecular inductive capacity (see Rule and Paterson, J., 1924, **125**, 2155).

On the other hand, groups are frequently described as positive and negative, either in reference to their directive influence on benzene substitution (Vorländer), or by deduction from Lapworth's principle of induced alternate polarities, or from the electronic theory. On this last basis, it has been shown (Rule, J., 1924, **125**, 1121) that the polarity of substituents, as deduced from the views of J. J. Thomson, leads to the *polar series*

$$NO_2,\ CN,\ CO_2H,\ H,\ Me,\ I,\ Br,\ Cl,\ F,$$

and that this closely corresponds to the relative influence of the

groups on the nitration of benzene, and also on the optical activity of the menthyl esters of *o*-substituted benzoic acids and of certain derivatives of amyl alcohol. Hence the suggestion was advanced that, in general, positive and negative groups influence the rotation of a parent compound in opposite directions, in accordance with the polar series above. The optical activity of other series of compounds was also quoted in support of this suggestion, but very little definite evidence relating to positive groups could be obtained.

In investigations summarised in *Gazzetta*, 1923, **53**, 417, Betti has determined the rotatory powers of a large number of products prepared by condensing an active base with substituted benzaldehydes, with results which show a remarkably close agreement between rotatory powers and the dissociation constants of the corresponding benzoic acids. The measurements, however, all referred to the one solvent, benzene, and to light of one wave-length. Only one positive group (NO_2) is included in the list of substituents examined by Betti, and it is known that solvents may exert a marked preferential effect on the rotation of compounds containing certain substituents, as is seen from the abnormally high rotation of menthyl *o*-nitrobenzoate in benzene solution (Cohen and Armes, J., 1905, **87**, 1190).

In the present communication are recorded the rotatory powers of menthyl esters of the acids $CH_2X{\cdot}CO_2H$, where X = CN,* CO_2H, OH, OMe, and OEt. Determinations were carried out at temperatures between 20° and 95° with the compounds in the homogeneous state, where feasible, and for light of four wave-lengths.

Discussion of Results.

In all cases it was found that the observed rotations could be expressed within the limits of experimental accuracy by a Drude equation of one term. It appears, therefore, that the dispersion is in every case normal and simple. The values of the optical constants and of the dispersion ratio, α_{gr}/α_D, obtained for the acetic derivatives are summarised in Tables I and II.

It will be seen that the substituents affect the rotatory power in the order $CN > OH > OMe > OEt > CO_2H$ and that the values undergo little change with temperature. The values of λ_0^2 vary between 0·0238 and 0·0316 for the homogeneous esters. A number of observations were also made with cyanoacetic ester, glycollic ester, and the hydrogen malonic ester in benzene and chloroform solution. In these cases also the dispersion was apparently simple in character.

* The rotatory power of menthyl cyanoacetate in benzene solution for the D line has been determined by Lapworth (J., 1904, **85**, 43).

λ_0^2	0·0276	0·0255	0·0257	0·0198	0·0334
α_{gr}/α_D	1·185	1·185	1·185	1·181	1·187
$[M]_D$	155·1°	161·2°	180·1°	178·3°	186·9°

* For other concentrations, see Experimental section.

The values of the ratio α_{gr}/α_D for the homogeneous and dissolved compounds remain very constant in the neighbourhood of 1·182.

When the above molecular rotations are compared with rotations recorded in the literature for menthyl esters of other mono-substituted acetic acids, and arranged in order of increasing values, we obtain the following list:

X.	H.	CO_2H.		Me.	OEt.		OMe.		OH.	Br.	Cl.	CN.
$[M]_D$	−157°	158·8°	157·6°	160·2°	160·6°	162·8°	165·0°	162·9°	165·6°	169°	171°	174·1°
Temp.°	*	59·5	90·5	*	*	90	*	90	94·3	*	*	91·3

* Room temperature.

The relative effect of the substituents on optical activity in this case is therefore,

I. $CN > Cl > Br > OH > OMe > OEt > Me > CO_2H > H.$

This corresponds closely with the general polar effect of the groups, as may be seen by comparison with series II, representing

their influence on molecular inductive capacity (see Rule and Paterson, *loc. cit.*), and with series III, representing their influence on the acidity of acetic acid.

II. $CN > CO_2H(?) > OH > Cl > Br > (OMe,OEt) > CO_2H(?) > Me > H$.
III. $CN > CO_2H > Cl > Br > OMe > OH > H > Me$.

The position of the carboxyl group in series II is somewhat doubtful, formic acid having a high inductive capacity and acetic and propionic acids low values.

The analogy between the effect of substitution on optical activity and acidic strength which has previously been drawn by Betti (*loc. cit.*) is therefore confirmed and amplified. Among the menthyl esters of acetic acid there is no indication of positive groups affecting the rotatory power in an opposite sense to negative groups, as is the case with the benzoates.

It may therefore be concluded that the two types of group effect previously observed, namely, the general effect visible in inductive capacity, acidic strength and chemical reactivity, and the polar effect, as deduced from the electronic theory and traceable in benzene substitution and electromagnetic rotation, are both to be found in optical activity.

Experimental.

The menthol used was specially purified material, with a rotation of $[\alpha]_D^{18^\circ}$ $-49{\cdot}50^\circ$ in 5% ethyl-alcoholic solution.

The ethoxy- and methoxy-acetic esters were prepared by the method described in U.S. Pat. 836914, and D.R.-P. 191547, in which, however, no mention is made of rotatory power.

l-*Menthyl methoxyacetate* was prepared from the corresponding acid chloride, menthol and pyridine, in benzene solution. On being fractionated under reduced pressure, it was obtained as a colourless, odourless liquid, b. p. 141°/16 mm. After the second fractionation, a repetition of the process produced no change in rotatory power. It has not previously been recorded that *l*-menthyl methoxyacetate is a solid of m. p. 18° (Found: C, 68·4; H, 10·45. Calc. for $C_{13}H_{24}O_3$, C, 68·4; H, 10·5%).

l-*Menthyl ethoxyacetate*, prepared in a similar way, boiled at 150°/18 mm. It also was odourless (Found: C, 69·4; H, 10·7. $C_{14}H_{26}O_3$ requires C, 69·4; H, 10·7%).

l-*Menthyl glycollate* is also described in the same brief manner in the patent specification, D.R.-P. 136411. It was prepared by heating glycollic acid (3 mols.) with menthol (1 mol.) on a steam-bath for 14 hours, dry hydrogen chloride being passed through

the mixture for 10 minutes in each hour. The cooled mass was extracted with ether, washed, and dried. After removal of ether, the menthol was distilled under diminished pressure (oil-bath at 130°). The resulting dark solid was finally recrystallised from light petroleum until of constant rotation. The pure ester crystallises in long, white needles, m. p. 87·5° (above specification quotes 87°). It is moderately soluble in benzene and readily soluble in chloroform (Found: C, 67·3; H, 10·3. Calc. for $C_{12}H_{22}O_3$, C, 67·3; H, 10·3%).

l-*Menthyl cyanoacetate* was obtained from ethyl cyanoacetate by the method of Lapworth (*loc. cit.*).

l-*Menthyl Hydrogen Malonate.*—Dimenthyl malonate was first prepared by a modification of the method of Hilditch (J., 1909, **95**, 1571), using, however, pyridine as condensing agent.

The pure diester had a rotation of $\alpha^{20°}_{5461} = -9·36°$ (4·98% chloroform solution; $l = 2$). Hall (J., 1923, **123**, 109) quotes −9·32°.

In the preparation of menthyl hydrogen malonate, the diester (22 g.), dissolved in 96% alcohol (1 litre), was hydrolysed at 0° by gradual addition of the requisite amount of sodium ethoxide in alcoholic solution. On recrystallisation from ethyl acetate, it was obtained in plates, m. p. 58·5—59° (Found: C, 64·4; H, 9·1. $C_{13}H_{22}O_4$ requires C, 64·5; H, 9·1%).

Densities and Rotatory Powers of the Esters in the Homogeneous State.

Rotations generally refer to a 50 mm. tube (* indicates 100 mm.) and are all negative in sign.

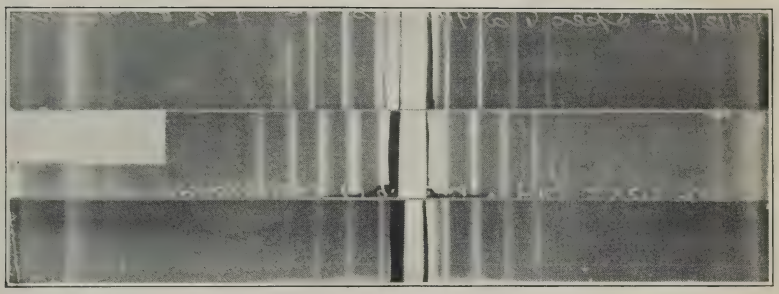
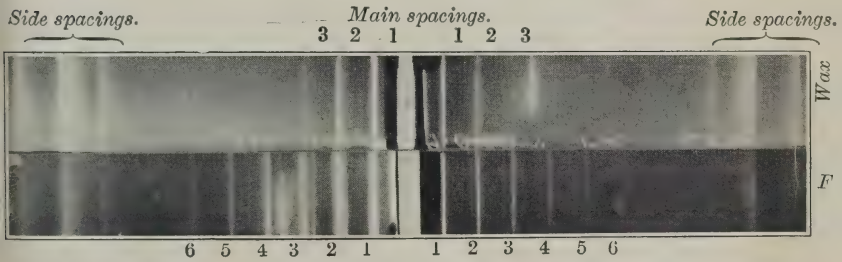
In conclusion, the authors desire to thank the Earl of Moray Fund for a grant which has covered most of the expenses involved.

DEPARTMENT OF CHEMISTRY,
UNIVERSITY OF EDINBURGH. [*Received, July 4th,* 1925.]



CCXCVII.—X-*Rays and the Constitution of the Hydrocarbons from Paraffin Wax.*

By STEPHEN HARVEY PIPER, DENNIS BROWN, and STANLEY DYMENT.



SINCE the distance apart of the main cleavage planes of the crystals of long-chain compounds has a definite relation to the length of the constituent molecules (Müller and Shearer, J., 1923, **123**, 2043, 3153; this vol., pp. 592, 600), *X*-ray examination of the spacing of such planes of unknown crystals may give important information as to the nature of the structural molecules. The nature of the hydrocarbons composing paraffin wax is unknown, although it has been conjectured, on slender evidence, that they are higher members of the normal methane series. It was hoped that *X*-ray examination of the crystals of the individual hydrocarbons would throw some light on their constitution.

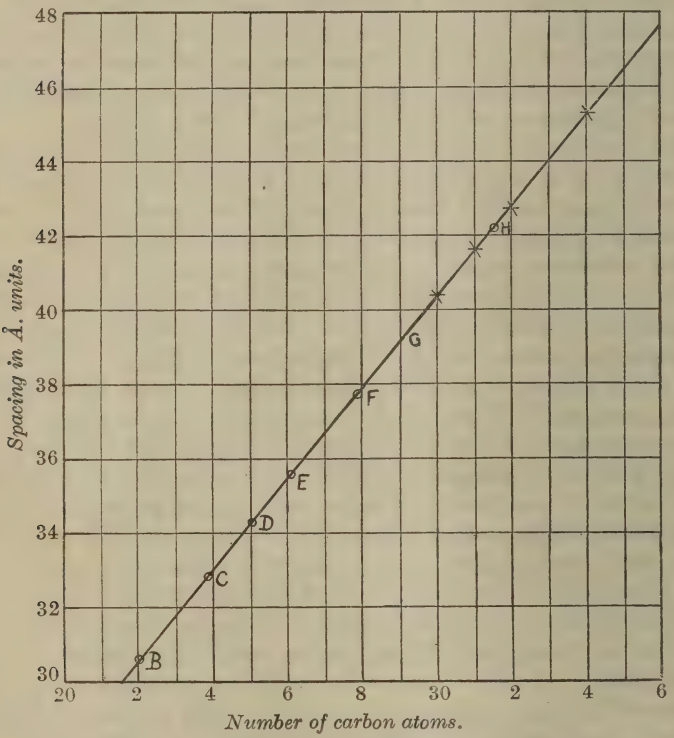
Origin of the Hydrocarbons.—The seven solid hydrocarbons, an investigation of which forms the subject of this communication, were isolated by Prof. Francis and his students from Scotch paraffin wax by long-continued fractionation in high vacua (J., 1922, **121**, 1529). These authors believed that 80% of the original material was composed of seven hydrocarbons, boiling at constant temperature; and their opinion that these hydrocarbons were not mixtures was strengthened by their later work (*loc. cit.*, p. 2804), which showed

FIG. 1.

* *Dotriacontane.*

[*To face p.* 2194.]

that, on oxidation of each fraction by air, the small amounts of hydrocarbon which escaped this process were identical in every case with the original material.



Krafft (*Ber.*, 1907, **40**, 4779) isolated eighteen hydrocarbons by fractionation of Saxon paraffin wax in the " vacuum of the cathode rays," and identifying these with those he had synthesised from materials of known constitution, drew the conclusion that the wax was composed of a large number of the higher normal members of the paraffin hydrocarbons. Francis has pointed out, however, that five fractionations of such a complex mixture were quite insufficient to indicate the presence of constant-boiling substances, that pure hydrocarbons could not have been isolated, and hence no satisfactory deduction could be drawn from a comparison between these impure substances and synthetic normal hydrocarbons.

The seven solid hydrocarbons obtained by Francis, and here lettered B to H in ascending order of melting points, appeared to differ in some respects from normal hydrocarbons, and it seemed possible that *X*-rays might show if they varied in crystalline form.

The substances were melted on glass strips, and the reflection spectra yielded by iron *K*-rays from a Shearer tube were photographed on a Müller spectrograph. All the specimens gave good photographs, some of which are reproduced in Fig. 1. All showed one set of planes with a large spacing, and two or three smaller " side spacings." These side spacings were the same for all the substances examined, but the large spacings increased with molecular weight and the appearance of the plates suggested that they belonged to a series of some kind. For the sake of comparison, synthetic triacontane, dotriacontane, and tetratriacontane were photographed. The main spacings measured for these substances are plotted in Fig. 2 against the number of carbon atoms they contain, and the spacings obtained from the unknown hydrocarbons isolated from paraffin wax have been set out on the straight line drawn through these points. It will be seen that, with the exception of H, each hydrocarbon spacing agrees almost exactly with a whole number of carbon atoms, and this number we consider to be the number of carbon atoms in the substance. The number of carbon atoms so obtained does not, however, in the cases of B, E, F, and G agree with the value deduced from the molecular weight determinations and published by Francis (J., 1922, **121**, 1531). In Table I, columns 3 and 4, the two sets of values are compared. We considered that our graph showed definitely the presence of the seven different hydrocarbons in column 3, and our belief in the method was strengthened by a measurement made on a hydrocarbon synthesised by the electrolysis of what was believed to be pure stearic acid, and which

therefore should have been tetratriacontane. The photograph of this hydrocarbon, however, only showed the lines corresponding to dotriacontane, and further examination proved that the specimen actually was this hydrocarbon. An investigation of the stearic acid used in the preparation showed the presence of a quantity of palmitic acid; consequently the reaction must have taken place between the radicals of palmitic and stearic acids rather than of stearic acid only. A specimen of a hydrocarbon prepared by the

FIG. 2.

× *Synthetic hydrocarbons.* ○ *Hydrocarbons from paraffin wax.*

same method from carefully purified stearic acid gave the spacing expected for tetratriacontane. A redetermination of the molecular weights of the hydrocarbons from the paraffin wax was obviously desirable, and this was undertaken by Dr. Christie of the Chemical Department, to whom our best thanks are due.

The difficulty of obtaining trustworthy results by the Beckmann ebullioscopic method is well known, in spite of the fact that, a definite experimental procedure always being adopted, very

concordant observations may be made. Using benzene as a solvent, Prof. Francis (*loc. cit.*) had obtained data agreeing among themselves in many cases to 1%. In order to vary the procedure, Dr. Christie employed the newer method of Menzies and Wright (*J. Amer. Chem. Soc.*, 1921, **43**, 2314), which is stated by these authors to give more accurate results. The constant for benzene, 26·1, given by them gave too low a value for the molecular weight of dotriacontane, which was regarded as a standard; the value 26·67 has therefore been used throughout these determinations, which in all cases were carried out under precisely similar conditions.

The mean molecular weight determined for dotriacontane was 452 in both chloroform and benzene. The calculated value is 450 and in each solvent individual determinations did not differ by as much as 1%.

Fraction B. The old value 325 was confirmed, four determinations in benzene giving 321 with a maximum variation of just over 1%. $C_{23}H_{48}$ requires *M*, 324.

Fraction C. The previous value was 332. Using benzene as a solvent, the mean of eight determinations by the new method was found to be 336 with an extreme variation of just under 2%. In chloroform the mean of seven determinations gave 338 with a variation of about 1%. $C_{24}H_{50}$ requires *M*, 338.

Fraction D. Only a small quantity of this fraction was available. The old value was 358, but in benzene *M* was now found to be distinctly higher, *viz.*, 368 with a maximum variation of about 1%. This appears to be $C_{26}H_{54}$ (*M*, 366).

Fraction E. Old determination 394. The mean of eight observations in benzene was 369, and of four in chloroform 366, the variation being about 1%. This agrees with the molecular weight of $C_{26}H_{54}$, in which case E is isomeric with D, although the photographs are quite different.

Fraction F. Old value 419. The mean of eight observations in benzene was 390, and of nine in chloroform 396. Probably the substance is $C_{28}H_{58}$ (*M*, 394).

Fraction G. Old value 449 corresponding to $C_{32}H_{66}$. The photographs of G and of dotriacontane, reproduced in Fig. 1, are quite different. Three measurements in benzene with the new apparatus gave *M* 407. Three more by another investigator gave the same mean value. Three in chloroform gave 408, by the other observer 410. This hydrocarbon appears to be $C_{29}H_{60}$ (*M*, 408).

Fraction H. Previous value 434. Five determinations of *M* in benzene now gave a mean value of 443, and it is considered probable that this hydrocarbon is $C_{31}H_{64}$ (*M*, 436). It certainly is not dotriacontane (see Fig. 1).

These new magnitudes are shown in Table I, column 5.

* Müller and Saville, this vol., p. 600.

In the case of hydrocarbons C, E, F, and G the number of atoms deduced from Dr. Christie's observations agrees with our estimate, for D there is agreement with the Beckmann value, whilst B and H differ. We give reasons below for considering that our measure of the spacing of hydrocarbon H corresponds to a value of n of 31; and we believe that the hydrocarbon B is $C_{22}H_{46}$, or at any rate contains this substance. A difference of one carbon atom in the chains of two of these hydrocarbons will separate the third-order lines in the photographs by about 0·33 mm. (see Fig. 1, H and dotriacontane), and as it is possible to measure a good plate to 0·01 mm. it is almost impossible to confuse two different substances. As is mentioned below, an absolutely uniform method of mounting the specimens is necessary.

We consider that the photographs show that the hydrocarbons obtained from paraffin wax are identical in constitution with the synthetic normal hydrocarbons for the following reasons.

(1) If the chains differed in nature, the unknown hydrocarbon line would not coincide in slope with the line on which the synthetic hydrocarbons lie.

(2) The intensity of the lines falls off uniformly with increasing order. There cannot be, therefore, a side chain attached to the main chain (Shearer, this vol., p. 597). If the end groups differed, then one line would lie above the other, the larger end groups being on the upper line. As the spacing measurement gives the minimum number of carbon atoms in the substance, the general agreement between this number obtained from the photographs and that deduced from the molecular-weight determinations makes it certain

that there are no more carbon atoms in the substances than are accounted for in the chains.

Whilst these experiments were in progress Müller and Saville completed a series of measurements of the spacings of the normal paraffin hydrocarbons, and found that the lower members had two modifications, A and B (this vol., p. 600). A comparison between our values and theirs shows differences much greater than the possible experimental error. This discrepancy is due to a difference in technique; Müller and Saville pressed crystal flakes on a glass plate, whilst we melted our specimens on the glass. Our measurements do not correspond to either the A or B modifications, from which we conclude that the lattice has been distorted by the melting on glass. We have been able to verify this by a measurement of hentriacontane, most kindly given to us by Dr. Müller. This substance when melted gives a spacing that falls on the line given by our other synthetic hydrocarbons; it is plotted in Fig. 2. The spacing we found for the same substance when its crystals were pressed on glass was much higher. An investigation into this behaviour is nearly completed and will be discussed in a separate communication. It is sufficient to state here that uniform treatment of the substances under investigation gives consistent results. Hydrocarbon H, when its crystals are pressed on glass, gives a spacing which agrees with that obtained by Müller and Saville (*loc. cit.*) for hentriacontane (see Table I). This substance is therefore hentriacontane. It remains to account for the anomalous value given by the melted substance.

Mixed Substances, melted together.—A photograph of crude paraffin wax is shown in Fig. 1 above that of fraction F. The lines of the two substances coincide—a remarkable fact, since fraction F only furnishes about 16% of the mixture; in fact it is not the most plentiful constituent. Measurement of the lines shows a very slight difference between the spacings, but as we have not been able to obtain more than three orders from the wax this difference may be partly experimental error. In general, however, we find that a mixture containing F shows only the F lines, slightly modified, provided the mixture is *melted* on the glass. Other mixtures, when melted together, usually yield modified lines of the longer chain, but if crystals of the two substances are pressed on the mounting the lines of both photograph unaltered. We consider that the anomalous spacing given by the melted specimen of hydrocarbon H may be ascribed to the presence of some impurity, too small in amount to show its lines in the photograph of the pressed substance. It will be noticed that the redetermination of the molecular weight of this substance does not give very satisfactory results; a similar

explanation will account for this. We believe the other hydrocarbons supplied by Prof. Francis to be fairly pure; the lines obtained fall very exactly on the normal hydrocarbon curve. Certainly those preceding and following F are not contaminated by this hydrocarbon to any appreciable extent. In the present state of our knowledge of the behaviour of mixed substances when examined by this method it is dangerous to generalise, but we believe that a normal spacing is at least an indication of a pure substance.

These experiments were carried out with the aid of a grant from the University Colston Research Society.

THE UNIVERSITY, BRISTOL. [*Received, July 15th,* 1925.]

CCXCVIII.—*Constituents of* Myoporum laetum, *Forst (the "Ngaio"). Part I.*

By FREDERICK HENRY McDOWALL.

THE first section of this paper deals with the aqueous extracts of various parts of the "ngaio" tree. Mannitol is present in the leaves to the extent of 0·2% (calculated on the weight of green leaves used), in the berries, which contain formic acid also, and in the wood to the extent of 0·25%.

The second section deals with the essential oil, 86% of which consists of an oxygenated sesquiterpene ketone, $C_{15}H_{22}O_3$, for which the author proposes the name "*ngaione*" (pronounced "ny-one") after the Maori name for the tree. Ngaione is characterised by its crystalline p-*nitrophenylhydrazone* and by its *semicarbazone*. The substance contains only one carbonyl group, and no methoxy- or methylenedioxy-group. It is reduced by sodium and alcohol to a secondary alcohol, *ngaiol*, which forms a monoacetate and a monomethyl ether. It is concluded that alcoholic hydroxyl groups are absent and that the molecule contains two separate oxide rings, since the presence of an organic peroxide ring would probably render the substance unstable (compare ascaridole, *loc. cit.*). The molecular refraction indicates that ngaione contains two ethylenic linkings. Since these remain unattacked by sodium and alcohol, they cannot be in the αβ-position to the carbonyl group, or conjugated with each other. Ngaione is thus probably an open-chain diolefinic ketone.

A solid paraffin hydrocarbon, $C_{32}H_{66}$ or $C_{34}H_{70}$, is also present in the essential oil.

Maiden (J., 1899, **55**, 665) isolated a resin from the exudations of *Myoporum platycarpum*, R. Br. No similar exudations occur on

Myoporum laetum, Forst. None of the species of *Myoporum* has been examined for essential oil.

Only a few substances of a like nature to ngaione have been isolated from essential oils. Apart from the well-known cineole, these are: Ascaridole, $C_{10}H_{16}O_2$ (Nelson, *J. Amer. Chem. Soc.*, 1911, **33**, 1404; Wallach, *Annalen*, 1912, **392**, 59); kessyl alcohol, $C_{14}H_{24}O_2$ (Bertram and Gildemeister, *Arch. Pharm.*, 1890, **228**, 483); calameone, $C_{15}H_{26}O_2$ (Soden and Rojahn, *Chem. Zentr.*, 1901, I, 1893; Thoms and Beckstrom, *Ber.*, 1901, **34**, 1021; 1902, **35**, 3187); kaempferia ketone, $C_{24}H_{28}O_4$ (Goulding and Roberts, J., 1915, **107**, 314); daucol, $C_{15}H_{26}O_2$ (Richter, *Arch. Pharm.*, 1908, **247**, 391); and dicitronelloxide, $C_{20}H_{34}O$ (Spornitz, *Ber.*, 1904, **47**, 478). Carlina oxide, $C_{13}H_{10}O$ (Semmler and Ascher, *Ber.*, 1909, **42**, 2355), is an aromatic compound, and elsholtzione, $C_{10}H_{14}O_2$ (Asahina and Murayama, *Arch. Pharm.*, 1914, **252**, 435; Asano, *J. Pharm. Soc. Japan*, 1919, **454**, 999), a furan derivative. Of the terpenic substances, the only one to which a constitution has been assigned is ascaridole (Wallach, *loc. cit.*). Many of these compounds, like ngaione, have a relatively high density.

Experimental.

Non-volatile Aqueous Extract.

(a) *Extraction of Leaves.*—The green leaves, after the essential oil had been removed by steam distillation, were extracted with water, and the filtrate was evaporated in a vacuum at 60°. The green residue gave to chloroform, ether, benzene, and light petroleum only a small quantity of colouring matter, but a hot alcoholic extract deposited, on cooling, white needles of mannitol, $[\alpha]_D$ (5% solution in presence of borax) +20·7°. After four crystallisations, this, alone or mixed with a genuine specimen, melted at 164—165°. On acetylation, it gave hexa-acetyl mannitol, m. p. 120°. The yield of mannitol was 10 g. from 5 kilo. of green leaves.

(b) *Extraction of Berries.*—The aqueous extract of the crushed berries was freed from tannin with lead acetate, boiled with animal charcoal, and evaporated in a vacuum. The residue yielded mannitol on extraction with hot alcohol.

(c) *Extraction of Wood.*—The residue from the aqueous extract of 1 kilo. of undried sawdust gave, when treated with alcohol, 2·5 g. of crude mannitol.

The Essential Oil.

The leaves and terminal branchlets (80 kilo. at a time) were distilled with superheated steam, 120 litres of distillate generally proving sufficient for complete extraction. The aqueous layer was

siphoned from the underlying layer of oil, and was then extracted twice with light petroleum. The yields ranged from 0·12% to 0·30%, varying with season and sample. The oil was cooled to −20° and the solid that separated (yield 0·01% of the crude oil) was recrystallised six times from hot absolute alcohol; m. p. 62—63° (Found: C, 85·4; H, 14·9; *M*, cryoscopic and ebullioscopic in benzene, 470. $C_{32}H_{66}$ requires C, 85·2; H, 14·8%; *M*, 450. $C_{34}H_{70}$ requires C, 85·3; H, 14·7%; *M*, 479). The substance is therefore a paraffin hydrocarbon of probable formula $C_{32}H_{66}$ or $C_{34}H_{70}$. The literature records the isolation of several similar compounds from essential oils (compare especially rose oil, *Bull. Soc. chim.*, 1904, **31**, 934).

The crystals were easily soluble in benzene, ether, chloroform, etc., slightly soluble in hot alcohol, but practically insoluble in cold alcohol. They were unaffected by bromine water or bromine in ether and were stable towards permanganate.

The clear oil, after removal of stearoptene, was of a reddish-brown colour and had a sweet malt-like odour; $d_{20^\circ}^{20^\circ}$ 1·0203; $[\alpha]_D$ −26·54°, $n_D^{20^\circ}$ 1·4823, saponification value, by direct titration after 2 hours' heating with alcoholic potash, 17·9. It was soluble in half its volume of 90% alcohol and in 4½ volumes of 70% alcohol. No seasonal variation was observed in the values of the constants. No nitrogen- or sulphur-containing substances were present (Found for crude oil: C, 71·5; H, 9·5%). The high density and high oxygen content seemed to indicate the presence of phenolic compounds, but treatment with caustic soda gave a yield of only 0·41% of phenols, and a methoxyl determination showed the absence of methylated phenols. From the low saponification value it was evident that lactones or esters were not present to any appreciable extent. The oil yielded no trace of aldehyde or ketone sodium bisulphite compound.

Repeated distillation of 850 g. gave the following fractions: up to 200°, 2 g.; 200—268° (in seven fractions), 22 g.; 160—166°/27 mm., 6 g.; 166—176°/27 mm., 8 g.; 176—182°/27 mm., 8 g.; 182—183°/27 mm., 730 g.; 183—189°/27 mm., 20 g.; non-volatile residue, 30 g.; loss, 24 g.

Ngaione.—The main fraction, b. p. 182—183°/27 mm., constituting 86% of the oil, is the only one so far examined. It was divided into three portions by repeated distillation, the refractive index of the last drop of liquid issuing from the condenser being used as a means of division in the absence of a boiling-point range. The middle portion (600 g.) was a lemon-yellow oil with a faint odour, $d_{20^\circ}^{20^\circ}$ 1·0276, $[\alpha]_D$ −26·20°, $n_D^{20^\circ}$ 1·4804. The substance is profoundly altered by distillation at ordinary pressures; b. p. 300°,

n_D, of distillate, 1·4900. Duplicate analyses indicated very consistently the formula $C_{16}H_{24}O_3$ (see, however, analyses of crystalline derivatives and of purified ketone, which agree closely with $C_{15}H_{22}O_3$) (Found for three separate samples: C, 72·6, 72·3, 72·6; H, 9·3, 9·3, 9·0; *M*, cryoscopic in benzene and ethylene bromide, 250. $C_{16}H_{24}O_3$ requires C, 72·7; H, 9·2%; *M*, 264. $C_{15}H_{22}O_3$ requires C, 71·9; H, 8·9%; *M*, 250).

The p-*nitrophenylhydrazone* was prepared by heating a filtered solution of 1 g. of *p*-nitrophenylhydrazine in 7 g. of alcohol and 7 g. of glacial acetic acid with 1·8 g. of the substance for 1 hour on the water-bath. After 24 hours, the emulsion produced on addition of water was extracted with ether. The extract was washed with dilute sulphuric acid and with sodium carbonate solution, dried, and the solvent evaporated over sulphuric acid. The residue of large, bright yellow tablets was washed with cold alcohol and recrystallised from warm alcohol; m. p. 103° (Found: C, 65·5, 65·4; H, 7·4, 7·1. $C_{21}H_{27}O_4N_3$ requires C, 65·4; H, 7·1. $C_{22}H_{29}O_4N_3$ requires C, 66·1; H, 7·3%).

The ketone (6 g.) and thiosemicarbazide (2·2 g.) were heated together in 30 c.c. of 63% alcohol on the water-bath for 12 hours; the alcohol was then evaporated, and the residue extracted with ether. From the extract a thick, reddish-brown oil, which could not be crystallised, was obtained (Found: S, 6·6. *Ngaione thiosemicarbazone*, $C_{16}H_{25}O_2N_3S$, requires S, 9·9%). The substance was treated in alcoholic solution with silver nitrate (2 equivs. were necessary for complete precipitation), and the yellow *silver* salt was filtered, washed with alcohol and ether, and dried (Found: Ag, 32·7. $C_{16}H_{24}O_2N_3SAg$ requires Ag, 25·0%. The double salt with silver nitrate requires Ag, 35·9%). The solid was therefore probably an impure double salt. Ngaione thiosemicarbazone was recovered from the silver salt as a thick syrup which could not be crystallised.

The silver compound (6·5 g.) was steam-distilled with excess of phthalic anhydride; the oil extracted from the distillate with light petroleum (yield 1·8 g.) had b. p. 185°/29 mm. (188° corr.), $d_{20^\circ}^{20^\circ}$ 1·0273, $^{*}n_D^{20^\circ}$ 1·4794, $[R_L]_D$ 69·10. $C_{15}H_{22}O_3$, requires $[R_L]_D$ 69·43 (Found: C, 71·9; H, 8·9. $C_{15}H_{22}O_3$ requires C, 71·9; H, 8·9%). This analysis and that of the *p*-nitrophenylhydrazone definitely establish the formula of ngaione as $C_{15}H_{22}O_3$.

Ngaione slowly reduced ammoniacal silver nitrate and Fehling's solution, more rapidly in presence of alcohol. It did not affect Schiff's reagent. In alcoholic solution it gave a bright green fluorescence with *m*-phenylenediamine hydrochloride, the colour being much more pronounced than that due to alcohol alone. It

did not, however, give a solid bisulphite compound under all conditions tried (compare kaempferia ketone, *loc. cit.*).

In an oximation experiment 63% of ngaione was converted in ½ hour and 76% in 2½ hours (Bennet, *Analyst*, 1909, 14). An alcoholic solution of ngaione (1 mol.) was heated with hydroxylamine hydrochloride (1¼ mols.) and sodium hydroxide (1⅝ mols.) on the water-bath for 5 hours. After removal of alcohol in a vacuum water was added, and the heavy oil extracted with ether. By distillation under reduced pressure the *oxime* was isolated as a lemon-yellow, viscous oil which could not be crystallised; b. p. 201°/27 mm., $d_{20°}^{20°}$ 1·0640, $[\alpha]_D$ (in 10% solution in chloroform) −13·51°, $n_D^{23°}$ 1·5008, $[R_L]_D$ 73·37. *Ngaione oxime*, $C_{15}H_{23}O_3N$, requires $[R_L]_D$ 73·74 (Found: C, 67·6; H, 8·6; N, 5·5. $C_{15}H_{23}O_3N$ requires C, 67·9; H, 8·7; N, 5·3%). The carbanilide of the oxime is a syrup.

The *semicarbazone* was prepared in aqueous alcoholic solution. After the mixture had been allowed to stand for a fortnight, water was added, and the precipitated solid dried on porous tile. No suitable crystallising medium could be found, the substance being extremely soluble in all solvents. Purified by reprecipitation several times from alcohol by the addition of water, it melted at 120—122° (decomp.) (Found: C, 62·9; H, 8·5. $C_{16}H_{25}O_3N$ requires C, 62·5; H, 8·2%).

The phenylhydrazone and *p*-bromophenylhydrazone are liquid. The substance would not form a semioxamazone even in the un diluted state at 170°; and under the conditions laid down by Doebner (*Ber.*, 1894, **27**, 852) as applicable to all aldehydes, it failed to yield a β-naphthacinchoninic acid. It also did not combine with freshly distilled pyruvic acid in presence of caustic soda (Lubrzynska and MacLean, *Chem. Zentr.*, 1914, 561), neither did it give a cyanoacetic acid compound. The failure to react with these aldehyde reagents, the slow nature of its combination with hydroxylamine, thiosemicarbazide, etc., the inertness towards sodium bisulphite and semioxamazide, all lead to the conclusion that the substance is a ketone. This conclusion is supported by the fact that an acid of the same number of carbon atoms cannot be obtained either by the use of oxidising agents or through dehydration of the oxime and subsequent hydrolysis. The reducing action toward Fehling's solution and silver nitrate is very sluggish, and, moreover, it does not appear to be due to the presence of the carbonyl group alone, since the purified alcohol (see below) also is slowly oxidised.

With boiling acetic anhydride ngaione is partially converted into the enolic acetate (saponification value 73. $C_{15}H_{21}O_2{\cdot}O{\cdot}CO{\cdot}CH$

requires 192). Ngaione decolorised bromine water very slowly; bromine in ether was rapidly absorbed, but the product was tarry.

Ngaiol.—With sodium (8 times the theoretical quantity) and absolute alcohol, ngaione formed an alcohol, *ngaiol* (yield 86%), which was purified through the acid phthalate, the usual proportions of benzene and phthalic anhydride being heated with the oil on a water-bath for 120 hours. The slowness of the reaction indicates the presence of a secondary alcohol, confirming the conclusion that the original substance is a ketone (combination takes place more rapidly without solvent at 130—140°, but is accompanied by a certain amount of racemisation). Ngaiol was thus obtained as a lemon-yellow oil with a faint sweet odour, b. p. 191—192°/29 mm. (195—196° corr.), $d_{20^\circ}^{20^\circ}$ 1·0163, $[\alpha]_D$ −25·00°, $n_D^{20^\circ}$ 1·4784, $[R_L]_D$ 70·28. $C_{15}H_{24}O_3$, $\equiv_2$, requires 70·94 (Found: C, 71·3; H, 9·8; M, cryoscopic in benzene, 260. $C_{15}H_{24}O_3$ requires C, 71·4; H, 9·6%; *M*, 252). These figures further check the formula suggested for the ketone. No trace of a pinacol was observed.

Treatment with the calculated quantity of chromic oxide in glacial acetic acid, instead of regenerating the ketone, completely disrupts a small proportion of the ngaiol, leaving the remainder intact.

All attempts to obtain a crystalline derivative of ngaiol have been unsuccessful (compare farnesol, which gives no crystalline derivatives). The acid phthalate and its *p*-nitrobenzyl ester (Reid, *J. Amer. Chem. Soc.*, 1917, **34**, 1249) are viscous syrups, and the phenyl- and α-naphthyl-urethanes are non-crystalline. The *methyl xanthate* (Tschugaev, *Ber.*, 1899, **32**, 213, 3332, etc.), purified from volatile products by steam distillation, is a mobile, light-yellow liquid (Found: S, 19·2. $C_{17}H_{26}O_3S_2$ requires S, 18·7%).

Ngaiol acetate, which is easily prepared in the usual way with acetic anhydride and sodium acetate, is a yellow oil, b. p. 190—192°/29 mm., $d_{20^\circ}^{20^\circ}$ 1·0337, $n_D^{20^\circ}$ 1·4720, $[R_L]_D$ 79·60. $C_{15}H_{23}O_2{\cdot}O{\cdot}CO{\cdot}CH_3$, $\equiv_2$, requires 80·31. Saponification value, 192. Theory for monoacetate, 185. The acetate decomposes slightly on distillation and for this reason always contains a small amount of free acetic acid. Heating with acetic anhydride in a sealed tube at 170—180° for 8 hours caused much resinification, but a small amount of oil was isolated, the saponification value of which was 204. Analysis showed that no water had been removed. By saponification with alcoholic potash and distillation in steam, ngaiol can be recovered from the acetate with unchanged physical constants.

The remaining two oxygen atoms are not attacked by acetic anhydride in presence of a drop of sulphuric acid at 0°. In order

as far as possible to avoid any hydrolysis of a sensitive ester group the product was isolated by distillation, after removal of sulphuric acid with calcium carbonate and decomposition of the excess of acetic anhydride by digestion with absolute alcohol. The saponification value of the product was 186.

Ngaiol benzoate cannot be prepared by the Schotten–Baumann method. By the pyridine method it is obtained as an oil which decomposes on distillation (compare daucol, *loc. cit.*). A quantitative experiment with benzoic anhydride according to Gascard (*J. Pharm. Chim.*, 1906, **24**, 97) showed that only one hydroxyl group was esterified. Ngaiol does not form a *p*-nitrobenzoate either by the Schotten–Baumann or the pyridine method.

Ngaiol monomethyl ether is a light yellow, almost inodorous oil. Three grams of potassium (2 mols.) were dissolved in 8 g. of pure tertiary amyl alcohol and 50 c.c. of dry toluene, and 10 g. of ngaiol were added to the hot solution. The mixture was cooled in running water while being gradually treated during 2 hours with excess (12 g.) of methyl iodide. After 12 hours, the mixture was warmed on the water-bath till neutral ($\frac{1}{2}$ hour), treated with water, and the toluene layer dried and distilled: b. p. 178—179°/29 mm. (182° corr.), $d_{20°}^{20°}$ 0·9913, $[\alpha]_D$ −16·82°, $n_D^{20°}$ 1·4701, $[R_L]_D$ 74·89. Calculated for $\frac{=}{2}$, 75·68 (Found: OMe, 11·1. $C_{15}H_{23}O_2{\cdot}OMe$ requires OMe, 11·6%). In the Zeisel determination ngaiol is converted into a resinous substance which dissolves completely in organic solvents. No deposit of carbon was formed, showing that a methylenedioxy-group is not present in the molecule.

Ngaiol methyl ether (3·30 g.) in dry boiling toluene dissolved one atom. of potassium in 6 hours and a second atom. in another 20 hours. The solution of potassium salt reacted slowly with methyl iodide in the cold. After 12 hours, the mixture was heated on the water-bath till neutral, and worked up in the usual way (Found for distilled product: OMe, 11·8%). It is noteworthy that calameone (*loc. cit.*) is regenerated unchanged when methyl iodide is allowed to act on its sodium salt.

The above experiments show that ngaiol contains probably only one hydroxyl group, and therefore that ngaione and ngaiol contain two internal ether groupings.

The work is being continued.

Part of this research was carried out at Otago University, Dunedin, New Zealand, while the author was holder of the John Edmond Research Fellowship. The still used in the extraction of the oil was obtained by aid of a grant from the New Zealand Institute. The author desires to express his thanks to the New Zealand

Institute and to the Chemical Society for research grants, and to Professor Inglis, Professor Collie, and Dr. Brady for their interest in the work.

THE RALPH FORSTER LABORATORIES OF ORGANIC CHEMISTRY,
UNIVERSITY COLLEGE, LONDON. [*Received, June 11th*, 1925.]

CCXCIX.—*An X-Ray Examination of Maleic and Fumaric Acids.*

By KATHLEEN YARDLEY.

THE following investigation was undertaken primarily to determine whether the planosymmetry and centrosymmetry usually ascribed to maleic and fumaric acids respectively have any actual existence in the crystalline state. Maleic acid crystallises in the monoclinic system, and fumaric acid (as will be shown later) in the triclinic.

The crystallographic data for maleic acid ($M = 116$) are given by Groth ("Chemische Krystallographie," Part III, p. 286) as follows: Density $\rho = 1{\cdot}590$ g./c.c.; m. p. 130°; monoclinic prismatic, $a : b : c = 0{\cdot}7386 : 1 : 0{\cdot}7015$, $\beta = 117°7'$.

A preliminary investigation showed that the full (010) spacing was 10·11 Å.U. and substitution in the usual formula, $abc \sin\beta \,.\, \rho = 1{\cdot}65\, nM$, gives $n = 3{\cdot}96$ (4 mols./unit cell).

The spacings calculated on the basis $n = 4$ compare with the observed values as follows:

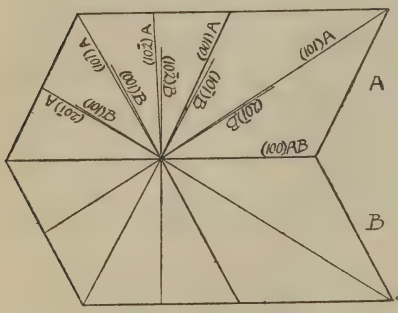
Plane (*hkl*).	Spacings calc.	Spacings obs.	Relative intensity of reflection.	Plane (*hkl*).	Spacings calc.	Spacings obs.	Relative intensity of reflection.
*100	6·67	3·31	Large.	310	2·17	2·16	Very small.
*010	10·14	$5{\cdot}05_5$	Very large.	210	3·18	3·17	Small.
*001	6·33	3·16	Very large indeed.	320	2·03	2·03	Moderate.
041	2·35	2·35	Mod. large.	110	5·57	5·56	Large IInd order only.
021	3·96	3·92	Moderate.	230	2·37	2·36	Very large.
023	1·95	1·92	Very small.	120	4·04	4·04	Mod. small.
301	1·85	1·85	Mod. small.	130	3·02	3·01	Mod. large.
30$\bar{1}$	2·51	2·48	Mod. large.	140	2·37	2·35	Small.
*20$\bar{1}$	3·74	1·85	Moderate.	160	1·63	1·63	Small.
*30$\bar{2}$	2·41	1·19	Very small.	180	1·24	1·25	Small.
101	3·81	3·76	Moderate IInd order only.	11$\bar{3}$	2·28	2·27	Small.
				111	3·57	3·57	Moderate.
10$\bar{1}$	6·22	6·22	Mod. large IInd order only.	11$\bar{1}$	5·30	5·30	Mod. large.
				22$\bar{1}$	2·96	3·02	Small.
*10$\bar{2}$	3·56	1·77	Small.	12$\bar{1}$	3·93	3·93	Mod. large.
410	1·64	1·64	Small.	13$\bar{1}$	2·97	2·95	Small.

The crystals show a perfect cleavage parallel to the (001) plane, and twin on (100) so frequently that a single crystal could not at first be obtained and the spectrometer measurements were made

on a twin. This gave rather complicated results, but it was generally possible to detect which additional reflections were the result of the twinning. For example, since the crystal is monoclinic and twins on (100), the $\{hkO\}$ zone is entirely unaffected and the reflections found are perfectly normal. The $\{h0l\}$ zone, however, shows doubling of its planes throughout. Fig. 1 represents the lattice of the twin (showing four unit cells) projected on the (010) plane.

The reflections from the (101), (001), (10$\bar{2}$), (10$\bar{1}$), (20$\bar{1}$), etc., planes of one individual (A) of the twin are apparently doubled owing to reflections from planes (20$\bar{1}$), (10$\bar{1}$), (10$\bar{2}$), (001), (101), etc., belonging to the other individual (B). The (100) plane shows, of course, a single reflection, since it is common to both individuals; the angular separation is greatest between the (10$\bar{2}$)A plane and the (10$\bar{2}$)B plane. Measurement of the angle (001)A : (001)B gave for the monoclinic angle, $\beta = 117°10'$.

Fig. 1.



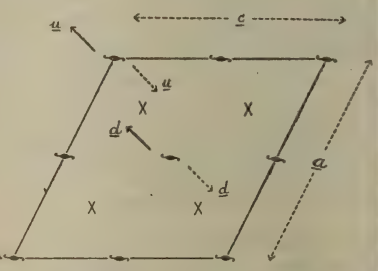


Fig. 2.

The reflections from planes of the $\{Okl\}$A zone may be confused with those from planes of the $\{hk\bar{h}\}$B zone, since the two zone axes are nearly parallel, and if one is vertical the other will be approximately vertical also. To eliminate all possibility of confusion of this kind, the measurements were repeated on a single crystal, grown from acetone after many attempts; several other planes also were measured. It was found, moreover, that, besides the perfect cleavage parallel to (001), there was an imperfect cleavage parallel to (010), and also that the crystals could be bent and twisted in certain directions without fracture. This interesting fact was verified both on single and on twinned crystals and will be described more fully in a separate paper.

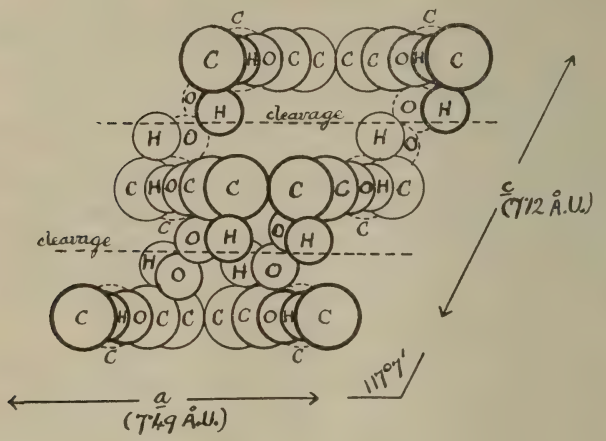
The table of results shows that certain planes (marked *) have an observed spacing of only one-half of the calculated value. In other words, all odd-order reflections were absent from these planes. Apart from the (010) plane, all the marked planes have indices

$\{hOl\}$, where $(h + l)$ is odd. Since full spacings were found for the (301) (30$\bar{1}$) planes, the (101) (10$\bar{1}$) cannot really be halved, although only second-order reflections were found from these planes. The second-order reflection from the (010) plane was very strong, and moreover the planes for which k is odd gave much weaker reflections than those for which k is even. Thus the reflections from (011) and (031) could not be found, but those from (021) and (041) were quite strong; also the (160) and (180) reflections were easily measurable, whereas the (150) and (170) were not. The crystals therefore belong to the space-group C_{2h}^5, for which the (010) plane is halved and also all planes $\{hOl\}$ for which $(h + l)$ is odd (Astbury and Yardley, *Phil. Trans.*, 1924, *A*, **224**, 221). Rotation photographs, kindly taken by Dr. Müller, verified the spectrometer readings and the above conclusions. A diagrammatic representation of the space-group is shown in Fig. 2, in which the unit cell is projected on the glide-plane of symmetry, (010), and the positions of the centres of symmetry are marked by crosses.

Since there are four molecules in the unit cell, the maleic acid molecule must be asymmetric. The planosymmetry usually ascribed to maleic acid from chemical considerations has therefore no existence in the crystalline state. (It is, of course, possible that in solution the molecules do possess a plane of symmetry which is destroyed by slight distortion in the process of crystallisation). The absence of a plane of symmetry is perhaps surprising, as maleic acid on oxidation forms the internally compensated *meso*tartaric acid. It is, however, significant that, although maleic and succinic anhydrides are supposed to be isomorphous, the acids themselves are certainly not. Succinic acid belongs to the space-group C_{2h}^2 with two molecules per unit cell, and the molecule does, presumably, possess a plane of symmetry (Yardley, *Proc. Roy. Soc.*, 1924, *A*, **105**, 451), but its crystals are quite unlike those of maleic acid except in that they belong to the same class. The co-ordinates of equivalent points of the four molecules of maleic acid in the unit cell, relative to the crystallographic axes, are (000), $(\frac{1}{2}v\frac{1}{2})$, $(u\frac{1}{2}w)$, $(u + \frac{1}{2}, v + \frac{1}{2}, w + \frac{1}{2})$. Exact consideration of the relative intensities of reflection from different planes is not likely to be very helpful in deciding the values of the variable parameters, u, v, w, as the positions of the atoms in the molecule are not known. There are, however, some general indications of their value. For instance, since very large second-order but no first-order reflections were found for the (101) (10$\bar{1}$) planes, it seems probable that u and w are approximately equal to $\frac{1}{2}$ and 0 or 0 and $\frac{1}{2}$. Also the exceptionally large reflection from the (001) planes, parallel to which is an excellent cleavage, indicates that most of the atoms lie in these planes and

very few between them. The following structure is suggested as being most probably near to the truth, though not by any means as being correct in every detail. In general, the actual measurements completely define the lattice and space-group, but the

FIG. 3.



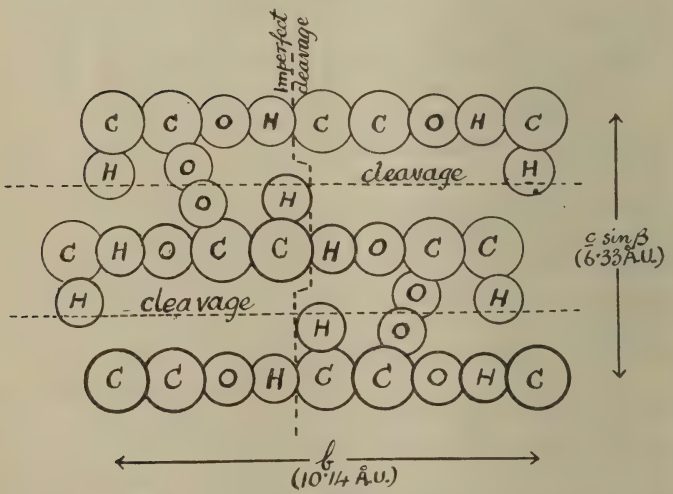


FIG. 4.

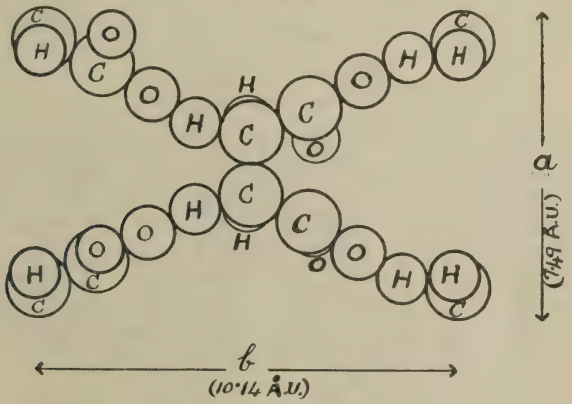

assignment of a structure, however probable or plausible, is alway accompanied by a certain amount of conjecture. The suggeste structure for maleic acid is based on the known space-group C_{2h}^5 an therefore on the simple Bravais lattice Γ_m. In order to explai the very large reflection from the cleavage plane (001) it is necessar

to assume that the double bond lies along the a axis and the two C–C–OH groups lie wholly in the (001) plane, linking between the (001) planes being effected by means of the ketonic oxygen atoms only. Since it is not probable that two ketonic oxygen atoms will attract each other with any great force (indeed, repulsion is more likely), the cleavage parallel to the (001) planes is readily explained. This is illustrated diagrammatically in Figs. 3 and 4.

In Fig. 3 is shown the projection of the unit cell on the (010) plane of symmetry. The measurements show that the molecule at the point $(\frac{1}{2}, v, \frac{1}{2})$ is the reflection of that at the origin. The only satisfactory way of placing the remaining two molecules is for the molecule which is obtained by rotation of that at the origin to lie at

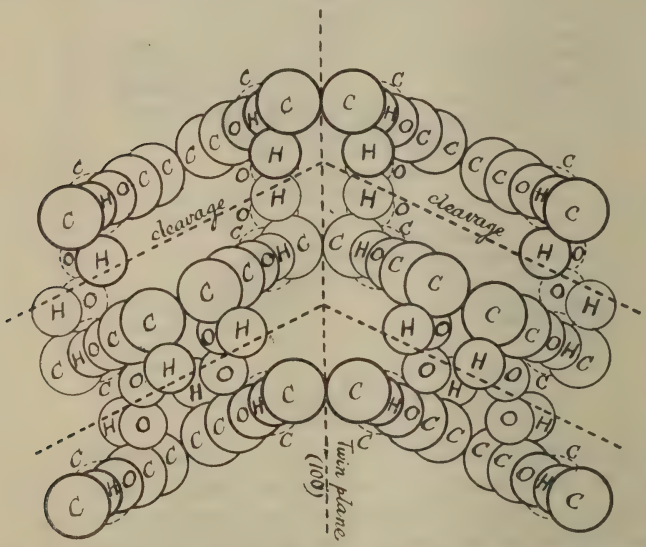

FIG. 5.

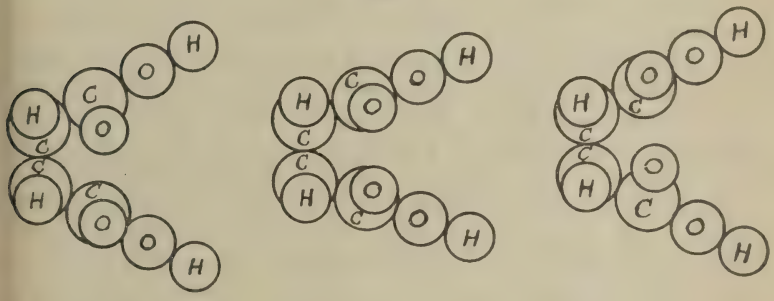
or very near the point $(\frac{1}{2}, \frac{1}{2}, 0)$ and for the molecule which is centrosymmetric with respect to that at the origin to lie at the point $(0, v + \frac{1}{2}, \frac{1}{2})$. The ketonic oxygen atoms lie approximately parallel to the c axis when projected on to the (010) plane. In Fig. 4, the projection is on a plane normal to the a axis. Here both cleavages are clearly seen, and it will also be noticed that the hydrogen of the carboxyl group of one molecule links on to the unsaturated carbon of the next. The exact positions of the hydrogen atoms cannot, of course, be fixed, since their scattering power is too small seriously to affect the X-ray reflections. In Fig. 5, which shows just the atoms lying in the (001) plane and those directly connected to them, the asymmetry of the molecule is at once apparent, and a comparison of the various diagrams shows that such asymmetry is necessary to build up the monoclinic structure. It is essential that such a structure should explain the almost invariable twinning on the (100) plane. Multiple twinning never appeared at all; in fact, examination of the crystals at various stages of their growth tended

to prove that a crystal began to grow at the twin plane and then built itself up to equal amounts on either side of this. The material crystallised at first in long, fine needles, which afterwards increased in thickness. However fine these needles might be, they were always perfect twins, and the smaller the crystal the more nearly exactly was it bisected parallel to its length by the twin plane. If these needles were broken across, a remarkably good re-entrant cleavage was observed, parallel to the (001) plane in each individual of the twin. In the case of a cluster of needle-like twins growing out from a complex nucleus, the apex of the re-entrant angle cleavage always pointed towards the nucleus, showing that the crystal growth

Fig. 6.



had followed certain clearly defined lines in the case of each needle. When crystallisation had taken place fairly rapidly, none of the crystals were single, although by slowing down the rate of evaporation it was sometimes possible to obtain large crystals which had grown unevenly on either side of the twin plane. From these one or two single individuals could be detached. Now if we assume that the crystals start growing as single individuals and then suddenly change direction and form twins, it is not easy to explain either the absence of multiple twinning or the presence of twinning in the very smallest crystals. These facts are readily explained on the hypothesis that growth begins at the twin plane. In that case, since the twin plane is a plane of reflection, molecules lying in it would necessarily possess a plane of symmetry, and would

therefore be slightly different from those in the main body of the crystal. This is not improbable, as a little consideration will show. The molecules in the suggested structure are distorted but very little out of their symmetrical form; in solution, these molecules probably do possess a plane of symmetry (or other two-fold symmetry), since there is no reason from a chemical point of view why one-half of the molecule should differ from the other. When, therefore, crystallisation first begins, it is probable that the molecules will form themselves into a sheet, retaining their original symmetry. On either side of this sheet the crystal would build itself up as shown in Fig. 6.

The molecules on either side of the central twin plane would be pulled out by the next succeeding layer and thus would become asymmetric, but the molecules lying *in* the twin plane, being pulled

FIG. 7.

equally on either side, would not lose their plane of symmetry. The re-entrant cleavage is also easily explained. It is to be expected that at the twin plane the structure would be somewhat strained; in fact, the two individuals can be separated at the twin plane, though there is no cleavage parallel to the (100) plane in any other part of the crystal. An asymmetric molecule and its reflection are non-superposable and so, unless it is assumed that the asymmetry is merely distortion produced during the process of crystallisation, it is impossible to avoid the conclusion that the original solution contained two enantiomorphous kinds of molecules. This is most unlikely.

In Fig. 7, (*b*) represents the undistorted molecule with its plane of symmetry, as it would occur at the twin plane; (*a*) and (*c*) show the molecule distorted in opposite directions, thus accounting for the asymmetric enantiomorphous forms. The approximate atomic diameters in this structure are: C = 1·54 Å.U., O: = 1·15, OH = 2·5, H = 1·15. It is not possible to tell whether the atomic diameter

of the unsaturated carbon atom differs from that of the saturated, especially as in the suggested structure both carbon atoms are, in effect, saturated.

The measurement of crystals of fumaric acid was much more difficult than that of maleic acid. No previous crystallographic data were available, as the crystals grown are utterly unsuited to the usual goniometric examination. They are small and copiously twinned in many directions, and most crystals show either no clear face at all or only one. Nearly all of the fumaric derivatives that have been measured belong to the triclinic system, and it seemed probable that that would prove to be the case for the acid also. Fortunately, by slow evaporation of an aqueous solution, one crystal was obtained that seemed to be twinned in one direction only. Measurements were made on this crystal, the Bragg ionisation spectrometer being used (as before) together with a Coolidge tube of rhodium anticathode. The main planes were first localised by obtaining the "mirror" reflection of "white" X-radiation, and the position of the actual reflection of the homogeneous X-ray beam could then be found quite easily. The crystal was almost shapeless, but it showed one bright, though by no means plane, face. By setting this face as nearly as possible vertical and then rotating the crystal about it very slowly, the main zone axes were found and planes in three principal zones were measured. The unit cell was triclinic. The face which actually grows on some crystals was taken as the (001). The crystal measured was twinned on this plane, which was also a good cleavage plane. Nearly at right angles to it was a second, less definite, cleavage plane which was taken as the (010). A third plane nearly normal to these two was taken as the (100). These planes having been arbitrarily selected as axial planes, the spacings of other planes in the axial zones were measured. By combining all the observations it was possible to determine the size of the minimum crystallographic cell. The unit cell taken is, of course, in the triclinic system, only one of an infinite number of minimum cells all having the same volume. The conditions that any such unit cell must fulfil are (1) that no calculated spacing should be a sub-multiple of the corresponding measured spacing, and (2) that no set of calculated spacings should be multiples of the measured spacings of those planes. If, for example, the measured spacing of each plane with indices $\{hkl\}$, where h is odd, were one-half of the calculated value, it would mean that the unit cell adopted was twice as large as the true unit cell, the a axis of the latter being only one-half the length of the a axis formerly used.

Considerations such as these showed that the arbitrarily selected axial planes did form the boundaries of one such possible minimum

cell. The angles between the axial planes and their spacings were measured; the lengths of the axes and the axial angles calculated therefrom are $a = 7{\cdot}56$, $b = 15{\cdot}00$, $c = 6{\cdot}20$ Å.U., whence $a : b : c = 0{\cdot}504 : 1 : 0{\cdot}413$ and $\alpha = 90°40'$, $\beta = 88°30'$, and $\gamma = 89°48'$.

As these angles are all very nearly right angles, they are almost exact supplements of the measured angles between the axial planes. Also the differences between the lengths of the axes a, b, c, and the observed spacings d_{100}, d_{010}, d_{001} are less than the probable errors of observation and are therefore negligible. From these axial spacings and angles the spacing, d, of any other plane (hkl) can be calculated by means of the formula

$$\frac{N^2}{d^2} = \frac{h^2}{a^2}\sin^2\alpha + \frac{k^2}{b^2}\sin^2\beta + \frac{l^2}{c^2}\sin^2\gamma + 2\left[\frac{kl}{bc}(\cos\beta\cos\gamma - \cos\alpha) + \frac{lh}{ca}(\cos\gamma\cos\alpha - \cos\beta) + \frac{hk}{ab}(\cos\alpha\cos\beta - \cos\gamma)\right]$$

$$= \sum\frac{h_2}{a_2}\sin^2\alpha + 2\sum\frac{kl}{bc}(\cos\beta\cos\gamma - \cos\alpha),$$

where $N^2 = 1 - \cos^2\alpha - \cos^2\beta - \cos^2\gamma + 2\cos\alpha\cos\beta\cos\gamma$

$$= 4\sin\tfrac{1}{2}(\alpha+\beta+\gamma)\sin\tfrac{1}{2}(-\alpha+\beta+\gamma)\sin\tfrac{1}{2}(\alpha-\beta+\gamma)\sin\tfrac{1}{2}(\alpha+\beta-\gamma).$$

Also the angle θ between two planes $(h_1k_1l_1)$ and $(h_2k_2l_2)$ is given by

$$\cos\theta = \frac{d_1d_2}{N^4}\left[\frac{h_1h_2}{a^2}\sin^2\alpha + \frac{k_1k_2}{b^2}\sin^2\beta + \frac{l_1l_2}{c^2}\sin^2\gamma + \frac{h_1k_2 + h_2k_1}{ab}(\cos\alpha\cos\beta - \cos\gamma) + \frac{k_1l_2 + k_2l_1}{bc}(\cos\beta\cos\gamma - \cos\alpha) + \frac{l_1h_2 + l_2h_1}{ca}\cos\gamma\cos\alpha - \cos\beta)\right]$$

$$= \frac{d_1d_2}{N^4}\left[\sum\frac{h_1h_2}{a^2}\sin^2\alpha + \sum\frac{k_1l_2}{bc}(\cos\beta\cos\gamma - \cos\alpha)\right],$$

d_1, d_2 being the spacings of the two planes.

The volume of the unit cell is $abcN$.

Comparison can thus be made between the spacings and angles calculated as above and those actually measured on the spectrometer.

Allowance being made for the obvious difficulties in setting the crystal on the spectrometer table in the correct position, this agreement is quite good.

The density of fumaric acid is 1·625 g./c.c. and $M = 116$. Calling the number of molecules per unit cell n, we have $abcN\rho = nM$. 1·65. Substitution of the known values of a, b, c and N leads to the value $n = 5{\cdot}97$.

This shows that there are six molecules of formula $C_2H_2(CO_2H)_2$ in the unit cell, the *minimum* cell which, repeated through space, will build up the crystal structure. It is well-known, however, that the number of asymmetric units required to build up a triclinic cell is either one or two. A triclinic pedial (C_1) crystal is formed by the repetition through space of a single asymmetric unit, a triclinic pinakoidal (C_i) crystal by the repetition through space of one centrosymmetric unit or of two asymmetric units arranged centrosymmetrically with respect to each other. Now it is impossible from the outward form of the fumaric acid crystals to tell whether they belong to the pedial or to the pinakoidal class, since all the crystals are practically shapeless, nor is it possible by any *X*-ray method to distinguish between the two classes. If the crystals belong to the pedial class, then it follows that six simple molecules of formula $C_2H_2(CO_2H)_2$ must, in the solid state, be associated together to form a single asymmetric unit, which is then repeated through space. If, on the other hand, the crystals are pinakoidal, then the six molecules in the unit cell are arranged in two groups of three, each group being asymmetric in itself, but centrosymmetric with respect to the other. It is important to know whether the simple chemical molecules in such a group are related to one another in a manner different from that in which they are related to all other molecules in the crystal. If this is so, then the group might be called a "crystal molecule," its formula being $[C_2H_2(CO_2H)_2]_6$ in the first case or $[C_2H_2(CO_2H)_2]_3$ in the second. In the unit cell of any symmetrical crystal there exists an association of a given number of ultimate asymmetric parts which are so arranged about the elements of symmetry as to build

up a unit possessing the full symmetry of the class. This unit then repeats itself through space without change of character or orientation. In general, the ultimate asymmetric parts are identical with the chemical molecule (or ions) or are sub-multiples of the chemical molecule. Thus, in the case of naphthalene the molecule is centrosymmetric (that is, it contains two such parts) and two molecules arranged about an axis of screw symmetry build up the unit monoclinic prismatic cell. There is certainly no reason why one should pair a given molecule in such a crystal with any of its four immediate neighbours and call such a pair a double molecule. The case of fumaric acid is, however, quite different. This is one of the few exceptional crystals where the ultimate asymmetric part is a multiple of the simple chemical molecule. Other examples which have been found include α-naphthylamine (Sir W. H. Bragg, Report of the Solway Conference, 1925), where the orthorhombic cell contains eight asymmetric groups of three chemical molecules; monoclinic carbon tetrabromide (Mark, *Ber.*, 1924, **57**, 1820), where the ultimate part is said to be C_2Br_8; and rhombic sulphur (Mark and Wigner, *Z. physikal. Chem.*, 1924, **111**, 398), in which the unit cell contains 128 atoms, the ultimate asymmetric group being either S_4, S_8, or S_{16}. As a rule, when two or more chemical molecules are associated together in the unit cell it is with the object of producing symmetry. When, as in these exceptional cases, there is also an association of a type which does not produce symmetry, we are perhaps justified in assuming that this association is closer than a mere crystallographic connexion and partakes more of the nature of an actual polymerisation in the solid state. In the case of sulphur it is most probable that the different crystalline forms are polymerised to different extents; the polymerisation is known to persist to a certain extent even in the vapour. This point has not been tested in the case of fumaric acid. Very little is known about matter in the solid state, apart from what can be directly deduced from the crystal structure. The fact that fumaric acid sublimes at 200° and melts in a closed tube only at 286—287° may perhaps be taken as evidence of a closer association between the chemical molecules than that usually existing in crystals. The same possibly applies to its insolubility in all ordinary solvents, and to its low heat of combustion (317·6 mol.-gm.-cals.) compared with that of maleic acid (331·3 mol.-gm.-cals.), since it may well be supposed that in the case of fumaric acid heat would be used up in separating the molecules before actual combustion could take place. It is doubtful, however, whether any reliance can at present be placed on conclusions drawn from differences in heats of combustion, heats of solution or crystallisation, etc., since we have very little idea to

what extent these depend on the actual crystal structure and to what extent on the molecular structure (Garner and Randall, J., 1924, **125**, 881). Bruni and Gorni (*Gazzetta*, 1900, **30**, i, 80), when determining the molecular weights of methyl maleate and fumarate cryoscopically in methyl succinate, found a normal value for the maleic ester (149·5 to 164; calc., 144), but the abnormal value of 797 to 914 for the fumaric ester in dilute solution; a raising of the freezing point of more concentrated solutions (above 2%) probably indicated the formation of a solid solution of the fumaric with the succinic ester. The abnormal value obtained for the fumaric ester in dilute solution may possibly be due to molecular association of the same type as that now observed in the case of the acid. Deductions drawn from the behaviour of the esters could not, however, be safely applied to the acids. That there is some difference between maleic and fumaric acids other than this association is obvious, since in solution they both act as if they had the simple formula and yet there are striking chemical differences to be accounted for. Probably there is a difference in the spatial arrangements of the atoms in the simple molecules in solution, but in neither case does the molecule possess symmetry in the crystalline state.

FIG. 8.

The complex twinning mentioned above as characteristic of fumaric acid is worth describing in some detail. Cruciform growths are very frequent (as shown in Fig. 8). The only distinct face on such a twin is the flat surface, from which a small reflection has been obtained showing it to be the {001} plane. The twin planes therefore have indices {*hkO*}. The angles between the arms of the twin are almost exact right angles and the *b* axis runs parallel to the length of the arms. Hence the twin planes must be the {120} and {1$\bar{2}$0}, which make angles of 44°42′ and 44°55′ respectively with the {010} plane. Some crystals are twinned in the above manner and then again each arm is twinned on a plane nearly at right angles to both {001} and {010}, presumably therefore the {100}. Such interpenetrating twins obey at least two twin laws. Other interpenetrating twins have not merely four arms, but six. Some have only four arms, but these are not at right angles. The laws obeyed by such twins have not yet been elucidated.

More recent *X*-ray examination of some of the derivatives of maleic and fumaric acids has shown that in no other case yet investigated does association take place in the solid state. The substances examined were monopotassium chloromaleate, $C_4H_2O_4ClK$,

diammonium chlorofumarate, $C_4HO_4Cl(NH_4)_2$, and ammonium hydrogen fumarate, $C_4H_3O_4NH_4$; the *X*-ray data obtained have been published elsewhere (Yardley, *Phil. Mag.*, 1925, **50**, 864).

In conclusion, I wish to thank Professor Sir William H. Bragg, F.R.S., most heartily for his constant encouragement and advice. My grateful acknowledgments are also due to the Advisory Council of the Department of Scientific and Industrial Research and to the Royal Institution for rendering financial and laboratory assistance. For the preparation of the three compounds last mentioned, I am very much indebted to Mr. W. B. Saville.

CCC.—*Purification of Phosphoric Oxide.**

By HENRY WHITAKER.

FINCH and PETO purified phosphoric oxide from traces of lower oxides by subliming it in a current of oxygen in an iron tube, heated to redness, and collecting the sublimate in a cooled glass tube (J., 1922, **121**, 692). On repeating the experiment, the chief difficulties encountered were the blocking of the glass tube with a solid crust of oxide and its frequent fracture at the glass-to-iron junction. Better results were obtained by employing a special form of receiver.

The receiver shown in Fig. 1 consists of a T-piece of wide glass tubing, the lower end, *b*, of which is fitted by means of a cork to the wide-necked bottle, *c*; transference of the sublimate from the receiver to a bottle for storage is thus avoided.

The receiver shown in Fig. 2 was made by sealing the wide tube, *b*, close to the end of a (broken) Liebig's condenser jacket, which was drawn out at *e* to fit into the end of the iron tube. The glass ram, *a*, served to rake down into the bottle any deposit which collected at *f*, and the tube *b* was kept clear by occasional raking with a glass rod, applied through *d*, which was normally closed with a cork. In the glass-to-iron junctions at *e*, a packing consisting of a collar of thin asbestos paper was found preferable to cementing with phosphoric acid. The chief drawback of either form of receiver, however, was fracture, which invariably occurred sooner or later in the course of the experiment. An iron T-piece was next tried, which proved more satisfactory.

* The work now described was completed in 1922. The peculiar difficulties attending the distillation of phosphoric oxide are disclosed by the work of Smits and Rutgers (J., 1924, **125**, 2573).

The bent glass tube, with rake, employed by Finch and Peto for admitting small quantities of phosphoric oxide at a time into the iron tube was found to be inconvenient, and a simple form of feeding apparatus was substituted, which proved entirely successful. It consists of a wide glass tube, drawn out and sealed to the end of a thinner glass tube and provided with an ordinary cork, through which passes a glass rod flattened at the end into a circular disk. The glass rod should slide easily through the cork and the circular disk should loosely fit the narrow tube. The dropping tube is charged by raising the cork, keeping the glass rod in position with

Fig 1.

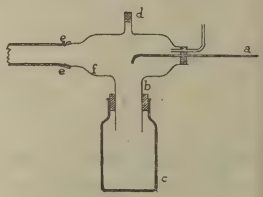

Fig 2.

Fig 3.

the disk closing the narrow tube; the cork is then slid back into position. The crude phosphoric oxide contained in the dropping tube can be admitted as required, by slightly raising the glass rod and tapping the tube. This form of apparatus can be repeatedly recharged with fresh phosphoric oxide without interrupting the experiment.

Blockages tended to occur in the vertical limb of the central iron T-piece; these were eliminated by using a vertical tube of wider diameter than the horizontal portion. The final form of the apparatus is shown in Fig. 3.

The current of oxygen (dried by passage through sulphuric acid, stick caustic potash, and crude phosphoric oxide) enters the iron

tube at *e*. It was found unnecessary to have an exit tube for the escaping oxygen. By properly adjusting the "fit" of the bottle *c* (receiver for the sublimed phosphoric oxide) to the cork *b*, fitted over the iron tube, *a*, the oxygen escaped *viâ b*. During the progress of an experiment, the plug, *d*, is unscrewed occasionally and the iron T-piece raked with an iron rake.

In one experiment, from approximately 200 g. of impure phosphoric oxide, 70 g. of pure pentoxide were obtained in 2 hours. This product, tested with silver nitrate in the manner suggested by Finch and Peto, was found to be free from lower oxides.

The use of mercuric chloride as a reagent for detecting the presence of lower oxides of phosphorus (suggested by Sir Richard Threlfall in a private communication to Professor A. Smithells) was found to be more convenient than silver nitrate, as neutralisation of the phosphoric acid with sodium hydroxide is unnecessary. A small quantity of the phosphoric oxide to be tested, dissolved in water, is boiled with mercuric chloride solution; if traces of phosphorous acid are present, a white turbidity or precipitate of mercurous chloride appears. All the samples of phosphoric oxide prepared by the method described above, when thus tested, were found to be free from lower oxides.

THE UNIVERSITY, LEEDS. [*Received, August 20th*, 1925.]

CCCI.—*Determination of Metals Dissolved in Mercury. Rapid Method of Purifying Mercury.*

By ALEXANDER SMITH RUSSELL and DEREK CURTIS EVANS.

THE work to be described is dependent on two observations, both of which, we think, are new: (1) that all metals more electropositive than mercury except cobalt go rapidly into solution as sulphates without the accompaniment of mercury when amalgams of them are shaken with potassium permanganate or certain other oxidising agents in dilute sulphuric acid, and (2) that the point at which the last trace of the metal in the mercury has gone into solution is shown by the breaking of the surface of the mercury into bubbles. For the determination of single metals in mercury by the method to be described it is necessary that the reducing power of the metal be 100%, that is to say, that the metal go into solution only in so far as it reduces the permanganate or other oxidising solution. For purifying mercury, on the other hand, rapidity of action between the metals to be removed and the

oxidising solution is more necessary than efficiency of reducing power.

We find * that the order in which metals when dissolved in mercury are removed from it by oxidising solutions is not the same as that of the electrode potentials of the metals in the free state. This order in mercury is (proceeding from electropositive to noble metals and including only those with which we have experimented) : zinc, manganese, cadmium, thallium, tin, lead, copper, chromium and iron, bismuth, cobalt, mercury, and nickel. It was found by obtaining the metals two at a time in mercury and finding out which went first into solution when ferric sulphate, or potassium permanganate or uranyl sulphate in sulphuric acid was reduced. The order seems quite definite; it appears to be the same whatever oxidising solution be reduced, whether the solution be hot or cold, whether sulphuric or hydrochloric acid be employed, and whatever other metals be present in the amalgam. The order in mercury differs from the order of the electrode potentials of metals in the free state only in the absolute positions of chromium, manganese, iron, cobalt, and nickel (atomic numbers 24 to 28). This is ascribed to passivity (Russell, *loc. cit.*). The relative order of these elements in both series is the same.

Experimental.

The reducing efficiency of a metal in mercury was investigated as follows : an amalgam containing from 0·2 to 0·4 g. of the metal in 200 g. of mercury was prepared either by direct solution, or by electrolysing solutions of sulphate in sulphuric acid the concentrations of which before and after electrolysis had been determined; the amalgam was shaken in a 300 c.c. stoppered bottle with 80 c.c. of $2N$-sulphuric acid and a volume of accurately $N/10$-potassium permanganate until the pink colour was just discharged; further volumes of permanganate were run into the bottle and the colour discharged until a point was reached such that on further shaking the surface of the mercury became a mass of small bubbles. This point could be accurately judged with experience to about 0·2 or 0·3 c.c. and was taken as the point at which the whole of the metal had left the mercury. The mass of the metal theoretically necessary to oxidise the volume of reduced permanganate was then compared with the known weight contained originally in the mercury.

* This experimental work with discussion will be published elsewhere In *Nature*, 1925, **115**, 455, one of us (A. S. R.) gave this order slightly differently. By a slip *chromium* read *manganese*. The position of manganese had not then been investigated.

The results obtained for seven metals and potassium permanganate are in the table below.

Gram taken.	Gram found.	% efficiency.	Gram taken.	Gram found.	% efficiency.
	Zinc.			Lead.	
0·210	0·193	91·9	0·100	0·101	101
0·210	0·192	91·4	0·202	0·200	99
0·219	0·200	91·3	0·205	0·206	100·5
0·929	0·865	93·1	0·206	0·206	100
			0·406	0·410	101
	Cadmium.			Copper.	
0·222	0·222	100	0·1115	0·1115	100
0·230	0·228	99·1	0·1673	0·1680	100·4
0·263	0·261	99·2		Iron.	
0·281	0·279	99·3	0·1791	0·1722	96·1
	Tin.		0·3658	0·3515	96·1
0·400	0·400	100		Bismuth.	
0·401	0·402	100·2	0·302	0·302	100
0·403	0·400	99·2	0·367	0·365	99·5
0·403	0·401	99·5			

It is seen that the results obtained by this rapid method (an experiment could be easily completed in 5 minutes) are fairly consistent and that each metal tried, with the exception of zinc and iron, is 100% efficient as oxidiser of potassium permanganate. These results contrast remarkably with the reducing efficiencies, and also the rate of oxidation, of some of these metals in the free state as investigated by Thorpe (J., 1882, **41**, 287) and Sugden (J., 1921, **119**, 233).

The results obtained in a similar manner when the metals reduced a $N/10$-solution of ferric sulphate in $2N$-sulphuric acid were approximately 100% for cadmium, tin, lead, copper, and bismuth, as with permanganate. Zinc, however, was now also 100% efficient, the actual values obtained being 100, 100·9, and 100·1. The reducing efficiency of iron was, however, again less than 100%, the values obtained varying from 94 to 97. Ferric sulphate was found to oxidise the metal of the amalgam much more rapidly than permanganate, and shaking had to be carefully done to avoid over-running the end-point and bringing some of the mercury itself into solution.

When uranyl sulphate was reduced, none of the metals showed reducing efficiencies of 100%. Of the seven metals mentioned above, only zinc, cadmium, tin, and lead could be investigated, because these alone were found to reduce uranium quantitatively from the sexavalent to the quadrivalent form. The mean values of their efficiencies decreased in decreasing order of potential, the mean values found being 91, 88, 82, and 74 for zinc, cadmium, tin, and lead, respectively.

It is obvious that the reducing efficiency of a metal may be investigated in this way only when it is completely removed from the mercury without being accompanied by mercury. It was found that mercury invariably accompanied cobalt and nickel when amalgams of these elements were shaken with oxidising solutions. The number of atoms of cobalt oxidised by the permanganate was found to be greater than that of mercury, and the number of atoms of nickel less. Cobalt appears, therefore, to act like a more electropositive and nickel like a more electronegative metal than mercury. It was found possible by sacrificing some mercury to remove the whole of the cobalt, but not the whole of the nickel from the mercury by shaking with oxidising solutions. These are the only metals which lie in potential between zinc and mercury in the free state which cannot be determined quantitatively by the method described in this paper.

The whole of these results receive a ready explanation with the help of present knowledge of the phenomenon of over-voltage. When a metal dissolved in, and more reactive than, mercury is shaken with sulphuric acid, it goes to some extent into solution and the equivalent amount of ionic hydrogen is discharged at the surface of the mercury. This has been proved to occur whether or not the metal is more electropositive than hydrogen in the potential series (S. W. J. Smith, *Phil. Mag.*, 1909, **17**, 834). Two extreme courses are open to this atomic hydrogen : it may wholly combine with the oxidising solution present (in which case the reducing efficiency of the metal is 100%), or it may wholly combine to form molecular hydrogen at the surface of the metal. The former course, it is expected, would be favoured by the presence of ions which are quickly reduced, and by a metal the power of which for catalysing the formation of molecular from atomic hydrogen is small; the latter course would be favoured by the presence of ions that are reduced slowly, and by a metal which catalyses the formation of molecular hydrogen. Of the three solutions tried, ferric sulphate was found by a series of comparative tests to be reduced most quickly, and uranyl sulphate most slowly, by amalgams of each of the metals investigated. Of these metals, mercury has the highest, and iron the lowest, hydrogen over-voltage, and, if this phenomenon be interpreted as the inability of the metal to catalyse the reaction $2H \longrightarrow H_2$, it follows that, of the metals under discussion, mercury does this most slowly and iron most quickly.

The experiments described above may now be explained. When potassium permanganate is reduced in acid solution, only the very reactive zinc can generate more hydrogen (or more reactive hydrogen) than can be retained at the surface of the metal until it

reacts with the permanganate. When ferric sulphate is reduced, the increased rate of reaction between it and the atomic hydrogen is sufficient to prevent any formation of molecular hydrogen; zinc is consequently, like the other metals, 100% efficient as a reducer. When uranyl sulphate is reduced, the slower rate of reaction between it and atomic hydrogen explains the smaller reducing efficiency of zinc. Comparative tests which we have made on the rate of reduction of uranyl sulphate in acid solution by amalgams of different metals, show that as the metal becomes more and more electronegative the rate at which it reduces uranyl sulphate relative to that at which it reduces permanganate decreases rapidly. Zinc, for example, reduces permanganate about 20% more rapidly than the less reactive lead under similar conditions; it reduces uranyl sulphate, however, about ten times more rapidly. These observations explain the low efficiencies of metals and their decrease with decrease in electrode potential when they reduce uranyl sulphate.

Since iron falls in the potential series of metals in mercury between copper and bismuth, it is to be expected from the results above that it would show a 100% reducing efficiency both with potassium permanganate and with ferric sulphate. The lower values found cannot be explained by supposing that the iron, which appears to be in the passive state in mercury, has become active, because there is no other evidence that iron when reducing permanganate or ferric sulphate becomes active, and further, zinc, which is 100% efficient as a reducer of ferric sulphate, is more electropositive than active iron. The explanation of the low values is that iron is the only metal in the amalgams investigated which so catalyses the reaction $2H \longrightarrow H_2$ that not all of the atomic hydrogen is used in reducing the oxidising solution. This is confirmed by the results of experiments on the reducing efficiency of zinc on permanganate in amalgams containing one other metal.

We find that cadmium, tin, and lead do not lower the reducing efficiency of zinc, that iron lowers it a little, and that tungsten, molybdenum, and platinum, which have very small hydrogen over-voltages, reduce it considerably. These experiments will be detailed in a separate communication. The following experiments lead more simply to the same result: (1) When a c.c. of $N/10$-permanganate are shaken in sulphuric acid solution with iron amalgam the permanganate is first reduced and the resulting ferric sulphate is then quantitatively reduced by more iron to the ferrous condition. When this solution is titrated with the same permanganate, it requires theoretically $a/2$ c.c., if iron has a reducing efficiency of 100%. Experimentally it requires usually from 0·2 to 0·5 c.c. in excess of this amount, showing that some of the iron

present in the amalgam has gone into solution without performing any reduction of either the permanganate or the ferric solutions present. (2) When a c.c. of $N/10$-ferric sulphate are shaken in sulphuric acid solution with iron amalgam a solution of ferrous sulphate results. This solution should theoretically require $3a/2$ c.c. of $N/10$-permanganate when titrated. Experimentally it requires from 0·2 to 0·5 c.c. in excess of this amount for the reason explained above. (3) When the same volume of the solution in (2) is shaken with a tin- instead of an iron-amalgam, ferrous sulphate and stannous sulphate but no stannic sulphate are found to form. This solution should theoretically require $2a$ c.c. of $N/10$-permanganate, since stannous sulphate and ferrous sulphate are formed in equivalent amounts. Experimentally this value is found, which shows that tin is 100% efficient in these circumstances.

From this survey it follows that, of the metals considered, iron alone cannot be directly determined in mercury by measuring the volume of potassium permanganate or ferric sulphate reduced by the metal. Owing to the rapidity of the reaction between the metal and the ferric sulphate and consequent danger of over-running the end-point, it is better to use potassium permanganate in presence of $2N$-sulphuric acid as oxidiser except when zinc is being determined. Iron may be determined easily and quantitatively by the following modification of the method. The iron amalgam is shaken with the permanganate until the end-point is obviously passed. The reduced solution is transferred to a bottle and shaken for one minute with 1% zinc amalgam. Mercury salts are thereby reduced to the metal, which dissolves in the amalgam, and iron salts are wholly reduced to the ferrous state. The liquid is then decanted from the amalgam, which is washed by decantation with two volumes of 50 c.c. of water containing dilute sulphuric acid and the whole titrated with $N/10$-permanganate.

The method described above should be a rapid and useful alternative to several more accurate but tedious processes. Three readily suggest themselves and we have carried out a few experiments on each: (1) the determination of the solubilities of metals in mercury, (2) the determination of tin and lead in solder, (3) the determination of metals electrolytically using a cathode of mercury.

Determination of Solubilities of Tin and Iron in Mercury at 15°.— To 800 g. of mercury were added 15 g. of pure tin. The solid phase was obviously present. The mixture was kept for an hour at 15° and then pressed through chamois leather three times to remove the whole of the solid phase. The amalgam was shaken with acidified permanganate in the usual way until the end-point was reached; the whole of the tin was then in solution in the

stannic form, since tin amalgam was found not to reduce stannic sulphate in measurable amount. The mass of tin in the known weight of the amalgam was then calculated from the volume and strength of the permanganate. The percentage of tin in solution in mercury at 15° was found in this way in two experiments to be 0·61 and 0·60.

A similar experiment was carried out with iron. This metal was obtained in solution by electrolysing a normal solution of ferrous sulphate containing sulphuric acid with a current of 3 amperes with a mercury cathode until the solid phase was obviously present. The solid phase was removed at 15° as with tin. Owing to the very small solubility of iron in mercury, as well as to its not being 100% efficient, the permanganate was used merely to remove the iron quantitatively from the mercury. The solution containing the iron was then treated as mentioned above and titrated with permanganate. In three experiments the solubility of iron in mercury at 15° was found to be 0·00138, 0·00140, and 0·00140%. Richards and Garrod Thomas (*Z. physikal. Chem.*, 1910, **56**, 758) found by other methods the value 0·00134 at 20°.

Determination of Tin and Lead in Solder.—The conditions necessary for success in these determinations are (*a*) that the alloy dissolves without difficulty in warm mercury, (*b*) that it has two constituents only, each of which is 100% efficient in reducing the oxidising solution used, and (*c*) that the equivalents of the metals be as widely different as possible. Solder fulfils these conditions well. A table was compiled showing the quantities of decinormal permanganate theoretically required by a gram of solder (containing lead and tin only) of varying tin composition when it is oxidised to stannic and lead sulphates. It showed that a difference in percentage composition of tin or lead of 0·1 corresponded to 0·24 c.c. of $N/10$-potassium permanganate. Since the end-point in our method can be judged with practice to about 0·2 to 0·3 c.c. of permanganate, the error of a single determination need not exceed 0·1. In practice, however, this accuracy was not always attained. In the table below, the percentage compositions of three solders obtained by the new method are compared with those determined gravimetrically.

	Percentages determined by new method.					Average values.	% determined gravimetrically.
Sn	46·4	46·3	46·5	46·3	46·4	46·4	46·4
Pb	53·6	53·7	53·5	53·7	53·6	53·6	53·6
Sn	36·4	36·3	36·1			36·3	36·1
Pb	63·6	63·7	63·9			63·7	63·9
Sn	50·7	49·8	50·0			50·2	50·5
Pb	49·3	50·2	50·0			49·8	49·5

It is seen that in the three cases the agreement is fair. A determination by the new method which includes the time taken to weigh the solder may be made in 15 minutes. We usually weighed out about 0·2 g. and this required about 60 c.c. of $N/10$-permanganate. As is to be expected from its position in the potential series, tin in the solder oxidises the permanganate before lead. This is inferred because the discoloured solution is at first clear. Later the white precipitate of lead sulphate makes its appearance. The precipitate does not obscure the end-point.

Modification of E. F. Smith's Method of Determining Metals with a Mercury Cathode.—The following metals have been found by Smith and others to be rapidly and quantitatively precipitated from solution with the use of a rotating anode and a mercury cathode : bismuth, cadmium, chromium, cobalt, copper, gold, iron, lead, manganese, mercury, nickel, silver, tin, and zinc (E. F. Smith, "Electroanalysis," 6th edition, 1919). These metals are determined by Smith's method as the difference in the weight of pure mercury before electrolysis and that of the amalgam after. With our method neither the pure mercury nor the amalgam need be weighed, so that the errors involved, especially in the second of these weighings, are avoided. On the other hand, the error of determination is greater with our method (about 0·5%) than with Smith's method when properly carried out (0·1 to 0·2%). Moreover, our method is confined to the determination of bismuth, cadmium, copper, iron, lead, manganese, tin, and zinc. The other metals named above, except chromium and cobalt, cannot be determined because they are more electronegative than mercury. Chromium cannot be determined by our method because instead of forming chromium sulphate, as is to be expected, in presence of an oxidising agent, it leaves the mercury in a finely divided state and becomes oxidised to chromous oxide. The case of cobalt has already been considered.

Rapid Method of Purifying Mercury.

A rapid method of purifying mercury from other metals may be founded on the quantitative determinations described above and is indeed obvious. It cannot be used for removing nickel or metals more electronegative than mercury, and cobalt presents some difficulty. The remaining metals more electropositive than mercury, even when in the passive state, may be removed quickly, completely, and without any loss of mercury.

If the amalgam is a concentrated one, it should be pressed twice through chamois leather to withdraw the whole of the metals in the solid phase. This lowers the concentrations of cadmium,

indium, thallium, lead, zinc, and tin to approximately 3, 2, 2, 1, 1, and 0·5%, respectively, and leaves those of copper and iron less than 0·003% (Richards and Wilson, *Z. physikal. Chem.*, 1910, **56**, 729; Richards and Garrod Thomas, *ibid.*, p. 758). The amalgam may then be placed in a stout reagent bottle and shaken vigorously with a mixture of equal volumes of 9*N*-sulphuric acid and saturated aqueous solution of potassium permanganate till it becomes discoloured. More of the oxidising solution is then added and the shaking continued till bubbles of mercury appear on the surface. The amalgam is then washed from impurities by a stream of water, and the removal of the last traces of the impure metal completed by shaking with *N*/10-permanganate acidified with 2*N*-sulphuric acid till the end-point, at which the mercury when shaken becomes a mass of small bubbles, is reached. The mercury should then be again washed by a stream of running water, shaken with 2*N*-sulphuric acid to destroy the bubbles, and pressed through chamois leather.

If *N*/10-potassium permanganate in sulphuric acid solution be used instead of the more concentrated solution the rate at which the metallic impurities are removed is slower. For small concentrations of impurities, however, this rate is not unduly slow (the removal of 0·2 g. of zinc, for example, would require about 2 minutes' shaking), and whenever the reduced solution is intended to be subsequently analysed this rate is recommended because it ensures that the end-point is not over-stepped. When the amalgam is shaken with a concentrated solution of ferric sulphate in sulphuric acid or with a mixture of this solution with permanganate, the rate at which the impurities are removed is very greatly increased. This is due to the observed fact that ferric sulphate is reduced much more rapidly than permanganate, and the greater the concentration of the ferric sulphate the more rapid is the reduction. Ferric sulphate thus catalyses the reduction of potassium permanganate and other oxidising solutions by amalgams because the former after reduction to ferrous sulphate reacts almost instantaneously with the latter and the ferric sulphate regenerated is then reduced by more of the metal of the amalgam. Using a normal solution of ferric sulphate in 2*N*-sulphuric acid, we were able, by vigorous shaking, to remove 1 g. of lead from 200 g. of amalgam in 10 seconds, and 7 g. of zinc in ½ minute. With a concentrated solution of permanganate in 6*N*-sulphuric acid and 20 c.c. of *N*/10-ferric sulphate we removed completely, by shaking in a large reagent bottle, 14 g. of a mixture of zinc, cadmium, tin, lead, solder, and bismuth from 480 g. of pure mercury, to which it had been added, without the loss of any mercury except a little removed

mechanically in washing. This fact is of interest because in the literature on the purification of mercury it is stated that when an amalgam is passed through, or shaken with, the oxidising solutions in general use, either the mercury is not completely freed from the more electropositive metals or, if it is, a considerable proportion of mercury accompanies the other metals into solution (Harries, *Z. angew. Chem.*, 1921, **34**, 359; Harries and Evers, *ibid.*, p. 541; Hulett and Minchin, *Physical Rev.*, 1905, **21**, 396).

Summary.

1. The order in which metals are removed from mercury by oxidising solutions has been determined, and is given but not discussed.

2. The reducing efficiency of amalgams of zinc, cadmium, tin, lead, copper, iron, and bismuth has been determined in solutions of ferric sulphate, potassium permanganate, and uranyl sulphate containing dilute sulphuric acid. The results are interpreted in terms of the hydrogen over-voltages of these metals.

3. The results are applied to rapid, approximate methods of determining (*a*) the solubilities of metals in mercury, (*b*) tin and lead in solder, (*c*) metals deposited by electrolysis with a rotating anode and a mercury cathode.

4. A rapid method of purifying mercury from more electropositive metals by shaking the amalgam with an oxidising agent is described. It removes such metals completely without necessarily the loss of mercury. The rate at which this purification is done may be regulated.

We wish to thank the Government Grant Committee of the Royal Society for providing us with the materials employed in this work.

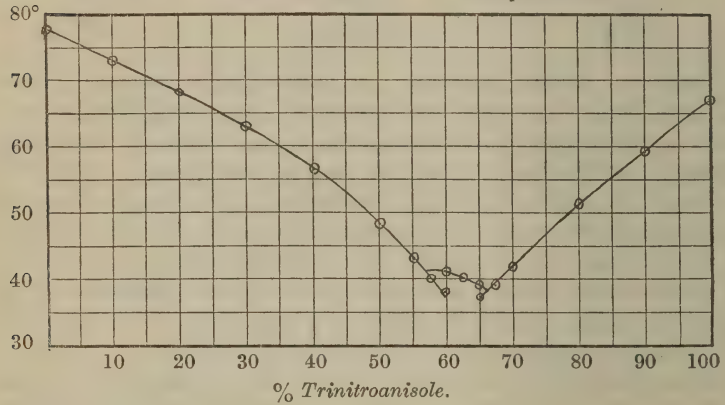
CCCII.—*The Alcoholysis of Trinitroanisole and Trinitrophenetole.*

By OSCAR L. BRADY and HAROLD V. HORTON.

IN connexion with other investigations it had been found that when 2 : 4 : 6-trinitro-*m*-tolyl methyl ether was crystallised from alcohol, partial conversion into the corresponding ethyl ether occurred and that when 3 : 5-dinitro-*o*-tolyl methyl ether was heated with

alcohol in the presence of alkali a similar change took place. The behaviour of 2 : 4 : 6-trinitroanisole and trinitrophenetole has now been investigated. Meisenheimer (*Annalen*, 1902, **323**, 205) has shown that the same compound is obtained by the action of sodium ethoxide on trinitroanisole and of sodium methoxide on trinitrophenetole and that this compound on decomposition with acids gives a mixture of trinitroanisole and trinitrophenetole; he proposed the following mechanism :

Similarly, Loving, Jackson, and Boos (*Amer. Chem. J.*, 1898, **20**, 444) found that when the compound obtained by the action of sodium methoxide on trinitroanisole was crystallised from ethyl alcohol, substitution of ethyl for methyl took place. Purdie and Marshall (J., 1888, **53**, 391) observed that a change of groups occurred between esters of carboxylic acids and alcohol in the presence of a small amount of sodium. The conversion can, in some cases, be carried out without the addition of sodium (Shimomura and Cohen, J., 1922, **121**, 883, 2051; see also Cohn, *Monatsh.*, 1900, **21**, 200; Lapworth and Havin, J., 1902, **81**, 1501).



When 2 : 4 : 6-trinitroanisole (m. p. 68°) is crystallised from ethyl alcohol, a mixture, m. p. 58°, of trinitroanisole and trinitrophenetole separates, whilst trinitrophenetole crystallised from methyl alcohol gives a mixture, m. p. 52°. These observations probably account for the different values given for the melting point of trinitroanisole, namely, 48° to 64°. We have found that trinitroanisole, crystallised from dry methyl alcohol, melts in a capillary tube at 68° and freezes in bulk at 67·0°. For the purpose of analysis the binary fusion diagram of trinitroanisole and trinitrophenetole has been constructed (Fig. 1).

The two substances apparently form an unstable addition compound consisting of 3 mols. of trinitroanisole and 2 mols. of trinitrophenetole, corresponding with 58·7% of trinitroanisole. This compound does not separate readily and it is possible to prolong the left and right branches of the curve for some distance into the metastable region; in taking the time–cooling curve of a mixture containing 60% of trinitroanisole, trinitrophenetole separates at 38·0°, the temperature remains constant for some time and then rises to 41·0°, when the additive compound separates.

When a mixture of trinitroanisole (1 mol.) and absolute alcohol (10 mols.) was evaporated in an air-oven, and the residue dried at 100°, irregular results were obtained, the product having a freezing point of from 38·4° to 42·3°; it was found that picric acid had been formed owing to absorption of water by the alcohol during working. An apparatus was therefore designed in which the alcohol was distilled from calcium oxide directly on to the trinitroanisole in the vessel in which the freezing point was ultimately to be determined, the whole apparatus being filled with dry air; the mixture was then heated in an oil-bath, finally to 150°, a current of dry air being passed

FIG. 1.

2 : 4 : 6-*Trinitroanisole*–2 : 4 : 6-*Trinitrophenetole*.

over it to remove alcohol vapour. Since two layers formed as the alcohol evaporated, the mixture was stirred continuously. By this means it was found that in mixtures of alcohol and trinitroanisole in the molecular proportions of 11 to 1 and 16 to 1 conversion occurred to the extent of 16% and 22% respectively; with larger amounts of alcohol, the results were irregular, but even with 68 mols. not more than 35% of the trinitroanisole was converted into trinitrophenetole.

EXPERIMENTAL.

Preparation of Materials.—2 : 4 : 6-Trinitroanisole was prepared by two methods. 2 : 4-Dinitroanisole, prepared by the action of sodium methoxide in methyl alcohol on 2 : 4-dinitrochlorobenzene, was nitrated by Holleman's method (*Rec. trav. chim.*, 1903, 22, 263), the nitrating mixture being heated for 3 hours at 100° and the product crystallised from methyl alcohol. Picryl chloride was treated in boiling methyl alcohol with sodium methoxide (1 equiv.) in the same

solvent, a fresh addition not being made until the colour produced by the last had almost faded. When all the sodium methoxide had been added, the mixture was diluted somewhat with water; the trinitroanisole that separated on cooling was crystallised twice from dry methyl alcohol and thus obtained pure (m. p. 68°).

Attempts to nitrate 2 : 4-dinitrophenetole to trinitrophenetole under various conditions were unsuccessful, hydrolysis occurring and picric acid being the only product isolated. Trinitrophenetole was therefore prepared from picryl chloride by the action of sodium ethoxide in a similar way to trinitroanisole (Austen, *Ber.*, 1875, **8**, 666). After experiments with thionyl chloride had proved unsuccessful, picryl chloride was prepared by a modification of Pisani's method (*Annalen*, 1854, **92**, 326). Picric acid (50 g.; larger quantities cannot safely be employed) was mixed with phosphorus pentachloride (100 g.) and heated under reflux on the water-bath. After the violent reaction had subsided, the product was poured into water and rapidly collected. After air-drying, the crude material was purified in lots of 20 g. by heating at 100° for some time with a mixture of one part of nitric acid (*d* 1·4) and four parts of sulphuric acid (*d* 1·8), cooling, pouring into water, and crystallising from a mixture of benzene and alcohol (1 : 3). The yield of pure product was about 50% of that calculated.

The freezing points of mixtures of trinitroanisole and trinitrophenetole were determined from time–cooling curves; the results are in Table I.

TABLE I.

% Trinitroanisole	0	10	20	30	40	50	55	56	57·5
F. p.	77·6°	72·6°	67·9°	62·9°	56·4°	48·1°	43·0°	42·0°	40·1°
% Trinitroanisole	60	62·5	65	67·5	70	80	90	100	
F. p.	41·0° (38·0°)	40·3°	39·4° (37·3°)	39·2°	41·7°	51·0°	59·3°	67·0°	

The figures in brackets correspond to the first arrest, where the trinitroanisole or trinitrophenetole first separated and crystallisation of the compound followed.

In conclusion, one of us (H. V. H.) wishes to thank the Department of Scientific and Industrial Research for a grant which has enabled him to take part in this work.

THE RALPH FORSTER LABORATORIES OF ORGANIC CHEMISTRY,
UNIVERSITY COLLEGE, LONDON. [*Received, July 21st*, 1925.]

CCCIII.—*The Supposed Formation of* 1:2:4-*Oxadiimine Rings from Nitroso-compounds and Methyleneарylamines.*

By GEORGE NORMAN BURKHARDT, ARTHUR LAPWORTH, and EDWIN BREW ROBINSON.

INGOLD prepared a number of compounds by the action of nitrosobenzenes on methyleneanilines (J., 1924, **125**, 93 *et seq.*). He ascribed to the products a ring structure, $ArN<^{CH_2}_{-O-}>NAr'$, and asserted that the facts were totally contrary to "the hypothesis by means of which so many obscure facts in chemistry are nowadays 'explained'" (*loc. cit.*, p. 93).

He subsequently discovered that his products were not ring compounds at all, but *N*-hydroxyamidines. In a paper with Farrow (J., 1924, **125**, 2543), he maintained, nevertheless, that cycloids are formed in the first instance and that these cycloids isomerise to hydroxyamidines at the moment of their formation (*loc. cit.*, p. 2545):

$$\left.\begin{matrix}CH_2{:}NAr\\ O{:}NAr'\end{matrix}\right\} \rightarrow ArN<^{CH_2}_{-O-}>NAr' \leftarrow \left\{\begin{matrix}CH_2{:}NAr'\\ O{:}NAr\end{matrix}\right.$$

$$\downarrow$$

$$ArN(OH)\cdot CH{:}NAr'$$

The proof given was that "the substances obtained in the two ways shown by the equation above are, in each case, identical with one of the pair of isomerides prepared by Comstock and Clapp's reaction."

Only one such case, however, was described, namely, that where $Ar = C_6H_4Br(p)$ and $Ar' = C_6H_4Cl(p)$ (Ingold, *loc. cit.*, p. 101), an unsatisfactory pair in view of the close chemical relationship and likely isomorphism of their derivatives.

Farrow and Ingold also referred to the case where $Ar = C_6H_5$ and $Ar' = C_6H_4\cdot CH_3(p)$; but here the product was made in only one of the ways indicated in the above scheme, namely, from $CH_2{:}N\cdot C_6H_4\cdot CH_3(p)$ and $O{:}N\cdot C_6H_5$. It is most significant that the product was identified with $N(C_6H_4\cdot CH_3){:}CH\cdot N(C_6H_5)\cdot OH$, which on alkaline hydrolysis gave *azoxybenzene* with no trace of azoxytoluene (*loc. cit.*, p. 2551—2552) and *p*-toluidine. Here, be it noted, the aromatic radical in the original *nitroso*-compound reappears in attachment to *oxidised nitrogen* and the other, originally as methylene*amine*, as pure amine with *unoxidised nitrogen*.

Returning to the crucial case where $Ar = C_6H_4Br$ and

$Ar' = C_6H_4Cl$: a product A, made from chloronitrosobenzene and methylenebromoaniline, was identified with another, B, made from bromonitrosobenzene and methylene-*p*-chloroaniline (Ingold, *loc. cit.*), and both with a third product, C, which was made in quite a different way and certainly had the structure

$$C_6H_4Cl\cdot N(OH)\cdot CH{:}N\cdot C_6H_4Br.$$

The last-mentioned gave pure *p*-bromoaniline when hydrolysed by alkali (Farrow and Ingold, *loc. cit.*, 2551, 2552).

The present authors had good theoretical reasons for thinking it unlikely that such a ring would be formed at all in the addition process, and still more unlikely that such a ring, once formed, would break down exclusively in one direction. They therefore took up the re-examination of the product obtained by Ingold's method from *p*-chloromethyleneaniline and *p*-bromonitrosobenzene. Observing that, even after recrystallisation from benzene, the product was not very well defined, and remembering that it might be isomorphous with its isomeride (from which it differs only in the interchange of place of chlorine and bromine), they decided to hydrolyse it with aqueous-alcoholic sodium hydroxide in the general way described by Farrow and Ingold (*loc. cit.*, pp. 2547, 2548) and to examine the substituted aniline so formed. The resulting base solidified at once; even before recrystallisation it melted 67—69°, and after one crystallisation from light petroleum at 68·5—69°. (A sample of pure *p*-chloroaniline obtained from British Drug Houses Limited melted after similar treatment at 69·5—70°; and a sample of pure *p*-bromoaniline after similar treatment at 62—62·5°.)

We are indebted to Dr. E. Chapman, who has had much experience in the determination of halogen by Robertson's method, for an analysis of the base. 0·1068 Gram of the compound gave halogen equivalent to 8·23 c.c. of $N/10$-$AgNO_3$. Formula C_6H_6NCl requires 8·37 c.c. and C_6H_6NBr requires 6·21 c.c.

It is thus clear that the base was mainly *p*-chloroaniline; the authors thought they detected a very small quantity of bromine in a careful qualitative test, but this would not be very surprising, as some reduction of the bromoazo-compounds during the original hydrolysis seemed quite possible.

It is evident that a compound which yields mainly *p*-chloroaniline cannot possibly be identical with one which, as Farrow and Ingold stated, yields *p*-bromoaniline with no trace of *p*-chloroaniline. That such a mistake could ever have been made is proof that the evidence on which Ingold relied was not trustworthy and it cannot be admitted that there is any good reason to suppose that his cycloids are formed at any stage.

If Farrow and Ingold are disposed to maintain their original view, then the onus of proof rests with them. An obvious and acceptable line of proof would be for them to prepare their compounds by both the methods in the scheme on p. 2234 and to show that these then give the same products in the same proportion when hydrolysed.

In conclusion, the facts, so far as they have yet been fully established, are entirely consistent with polarity theories, all previous statements to the contrary notwithstanding (*inter alia*, Ingold, J., 1924, **125**, 93; Ingold and Weaver, *ibid.*, pp. 1457—1459).

THE UNIVERSITY, MANCHESTER. [*Received, June 18th*, 1925.]

CCCIV.—*The Properties and Constitution of Coal Ulmins. Studies in the Composition of Coal.*

By WILFRID FRANCIS and RICHARD VERNON WHEELER.

WE have demonstrated (this vol., p. 112) that bituminous coal consists essentially of a matrix of insoluble ulmins in which morphologically organised plant tissues and natural plant-substances devoid of morphological organisation, that have escaped ulmification, are dispersed; * thereby confirming conclusions reached from other considerations (Tideswell and Wheeler, J., 1922, **121**, 2345; 1925, **127**, 110). In some bituminous coals the proportion of plant entities, chiefly cuticles and spore exines, is as high as 20% by weight, but in all bituminous coals the ulmins form the predominant material. Knowledge of their properties and constitution is therefore essential to an understanding of the composition of coal. We have sought to obtain this knowledge by both synthetic and analytical means. The present paper deals with the results of our analytical studies.

The chief effect of mild oxidation on bituminous coal is to change the matrix of ulmins from a form insoluble in dilute alkalis to a soluble form, thereby allowing of their separation from the organised plant material associated with them and rendering possible their examination by the usual methods of organic analysis. Suitable

* The matrix is not structureless, as was originally supposed, but close examination discloses, even in material selected as being a vitrain, a more or less pronounced structure, usually of woody tissue, such as a theoretically perfect vitrain should not possess. Such structures cannot, however, be separated from the coal mass intact, as can the cuticles and spore-exines, and they are ulmified.

mild oxidation can be effected by such reagents as hydrogen peroxide, or by exposure to air at 150°.

No fundamental change in the structure of the ulmin molecule is made by such a mild oxidation, but the external groupings are modified, those most readily detached being eliminated as simple oxygenated compounds and their place being taken by carboxylic groupings. The internal or nuclear arrangement of the molecule of the soluble " regenerated " ulmin (*loc. cit.*, p. 123) is thus identical with that of the insoluble matrix of unoxidised bituminous coal, and from a knowledge of the constitution of the former the essential structure of the main mass of bituminous coal can be deduced.

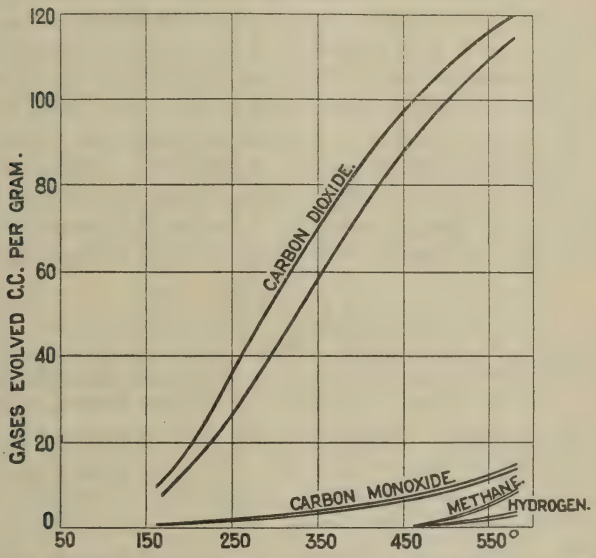
The change from insoluble to soluble ulmins is a gradual one. A moderate degree of oxidation will produce sufficient change in the external groupings of the ulmin molecule to render the matrix of bituminous coal soluble with difficulty in alkalis. As oxidation proceeds, more groupings are eliminated and the ulmins become more acidic in character and more readily soluble in alkaline or neutral solvents. A limiting condition is, however, eventually reached when all suitable external groupings have been eliminated. (In this connexion, compare Pearson, *J. Soc. Chem. Ind.*, 1923, **42**, 68T.) This stage is reached on oxidation by air at low temperatures. Further, carefully regulated, oxidation by hydrogen peroxide or nitric acid can cause a breakdown of the nuclear structure of the ulmin molecule and it is by the identification of any simpler compounds resulting from such a breakdown that the character of the nucleus of the complicated ulmin molecule can be revealed.

The Properties of Regenerated Ulmins.—Because the changes produced in bituminous coal by mild oxidation are gradual, the soluble ulmins produced are not homogeneous. They can be separated into a number of fractions by means of different solvents; but all the fractions are compounds of the same type and differ but slightly one from another in their analysis. We have not considered it necessary to effect a separation of them for the major portion of the work described in this paper.

The carboxyl groups produced by oxidation give to the soluble ulmins a definite acidic character allowing of salt formation. Amongst the insoluble salts that we have prepared are those of barium, iron, silver and copper. From the last-named an average value of 170 for the equivalent of the ulmins has been obtained, a figure which should be compared with that given by Sven Odén, namely, 350, for soil ulmins (*Proc. Faraday Soc.*, 1921). No convenient method is at present available for determining the molecular weight (if the colloidal character of the substances admits of such

a determination), but from the value of the equivalent an expression can be given of the contents of such determinable groupings as hydroxyl and carboxyl, and of nitrogen. The presence of hydroxyl groups has been proved by acetylation and benzoylation and by Grignard's reaction. By hydrolysis of the acetyl derivatives the percentage of hydroxyl groups in the " regenerated " ulmins as an average has been found to be 2·5, or one hydroxyl group for each molecular unit of 680. Such a unit would contain four carboxyl groups, a supposition confirmed by a quantitative estimation of the methane evolved from the dry ulmin on treatment under suitable conditions, with Grignard's reagent.

It is significant that as the oxidation of coal proceeds, with the gradual formation of soluble ulmins, the nitrogen-content increases up to the point at which the whole of the coal matrix becomes soluble. Moreover, all the slightly modified types of regenerated ulmins that can be separated by means of organic solvents contain nitrogen in the same proportion. This element must therefore be an essential constituent of the nucleus of the ulmin molecule.* The percentage of nitrogen found, 2·20—2·25, would indicate the presence of one nitrogen atom in the molecular unit suggested.



The presence of nitrogen as an essential constituent of the molecule renders it necessary to take account of this element in any theory regarding the origin of the coal-ulmins and lends particular interest to the reaction between amino-acids and sugars discovered by Maillard (*Ann. Chim. Phys.*, 1916, **5**, 258; 1917, **7**, 113) which results in the formation of ulmins. In the coal-forming process, from plant debris, the sugars may be derived from the celluloses of the cell-walls by enzyme or bacterial action and the amino-acids from the polypeptides in the protein matter of the cell contents. These reactions, whereby it is conceivable that the matrix of coal can be synthesised, are being studied by Mr. T. A. Buckley.

Some information as to the character of the external groupings of the molecule of the regenerated ulmin is given by the results of regulated destructive distillation. On heating the ulmins in the manner described in the experimental portion of this paper, gas began to be evolved in small quantity at 160—170°. This gas consisted of the oxides of carbon in ratio CO_2/CO of 12 : 1. This ratio increased up to 300° and then rapidly decreased. Measurable quantities of hydrogen and saturated hydrocarbons were not evolved until about 450°. Water accompanied the oxides of carbon at the lower temperatures of distillation, but no other

* A similar conclusion is to be drawn from the experiments of Monkhouse and Cobb (*Trans. Inst. Gas. Eng.*, 1922) on the action of steam on coke.

liquid made its appearance until 550°, when a slight trace of oil could be detected. These results correspond in general character with those obtained with the peat ulmin, dopplerite (Tideswell and Wheeler, J., 1922, **121**, 2345). The striking similarity of the curves relating the evolution of gases with temperature (Fig. 1), obtained with ulmins prepared from a vitrain and a durain respectively, confirms the deductions previously made (*loc. cit.*) that the matrix of a durain is essentially the same as that of a vitrain (or a clarain), differing from it only as regards the character of the less important external groupings of the molecules.

FIG. 1.

Destructive distillation of regenerated ulmins. For each gas the upper curve relates to a vitrain ulmin and the lower to a durain ulmin.

The Constitution of the Regenerated Ulmins.—By breaking down the nucleus of the molecule, by the cautious use of hydrogen peroxide or dilute nitric acid, simpler compounds can be obtained, the identification of which gives information as to the groupings within the nucleus. A number of such compounds have been identified.

The extreme action of hydrogen peroxide on the regenerated ulmins results in the formation of water and the oxides of carbon, the nitrogen appearing quantitatively as ammonia. Intermediate action yields aliphatic dibasic acids, of which oxalic and succinic have been isolated in pure crystalline form, together with a number of acids having all the properties of benzene polycarboxylic acids.

The isolation and identification of all these acids can, however, more readily be effected by the use of dilute nitric acid, which yields water-soluble products, amounting to about 25% of the regenerated ulmin, consisting of aliphatic dibasic acids, aromatic acids and nitrophenols. The products so far isolated and identified are oxalic, succinic, picric and pyromellitic acid (benzene-1 : 2 : 4 : 5-tetracarboxylic acid), whilst there is evidence of the presence of trimellitic acid. (Fischer and Schrader, *Brennstoff-Chem.*, 1921, **2**, 213, obtained traces of aromatic carboxylic acids by the pressure oxidation of a bituminous coal at 200—250°.)

The identification of picric and pyromellitic acids proves beyond question the presence of benzenoid rings in the nucleus of the regenerated ulmin molecules, and hence in the matrix of bituminous coal, for no part of our treatment of the coal has been such as to cause ring formation where none previously existed. Since such aliphatic acids as oxalic and succinic have also been obtained, whilst the nitrogen is clearly present in stable ring formation, it can be concluded that the nuclei of the ulmin molecules—which form the bulk of all bituminous coals—consist of compact systems of benzenoid groupings connected together by heterocyclic ring structures, such as pyrrole and furan or their derivatives.

Experimental.

Preparation of Regenerated Ulmins from Bituminous Coal.—A vitrain was usually employed so as to avoid the complications introduced by the presence of plant debris and to obtain the maximum yield of ulmins. The vitrain was finely ground and added to three times its weight of 100 vol. hydrogen peroxide. After a few minutes the mixture began to rise in temperature and the reaction tended to become violent. To moderate it, cold distilled water was added. The mixture was then heated at about 90° during several hours. The soluble ulmins thus formed were extracted with dilute sodium hydroxide solution and the residue was re-treated with hydrogen peroxide, the processes being repeated until no residue remained.

As thus prepared, soluble ulmins from the vitrain of East Kirkby coal contained C 68·8 and H 3·9%. Successive treatments of this material with hydrogen peroxide caused a reduction in the carbon and hydrogen contents until a limiting composition C 62·5 and H 2·8% was reached, similar figures being obtained with all the coals examined (whether vitrains, clarains, or durains). In obtaining this limiting composition, however, some destruction of the ulmins occurred and, since for subsequent examination a large yield rather than a homogeneous material was required, the usual

procedure was to check the oxidation as soon as solubility was attained.

Solubility of the Regenerated Ulmins.—The non-homogeneous ulmins so obtained were fractionated by means of solvents and each fraction was examined separately. The solvents used, at their respective boiling points, were : Chloroform, ethyl alcohol, acetone, methyl ethyl ketone, pyridine, pentane, light petroleum, benzene, ether, and carbon disulphide. Only the first five of these had any marked solvent action. In Table I the percentage amounts extracted by each solvent, in the order named, from a number of samples of regenerated ulmins are recorded.

TABLE I.

Solubility of Regenerated Ulmins.

	Source of Regenerated Ulmin.					
	East Kirkby vitrain.			East Kirkby vitrain α-compounds.*		
Solvent.	Sample A.	Sample B.	East Kirkby durain.	Sample A.	Sample B.	Hamstead vitrain.
Chloroform	0·4	0·4	0·3	0·4	—	—
Alcohol	7·2	2·2†	7·5	6·4	40·2	28·0
Acetone	3·8	12·2†	4·5	5·4	9·0	5·0
Me Et ketone ...	—	4·3	—	—	—	—
Pyridine	33·0	42·0	38·5	36·0	23·0	19·5

* The term α-compounds refers to that portion of the coal that was insoluble in pyridine.

† Order of extraction reversed.

All the ulmins, except sample B from the East Kirkby vitrain α-compounds and the sample from the Hamstead vitrain, were obtained as soon as the treatment with hydrogen peroxide rendered the coals soluble in alkalis. The two exceptions were subjected to more prolonged oxidation. Analyses of many of these fractions are given in Table II.

TABLE II.

Analyses of Fractionated Ulmins. Per cent. on ash-free dry material.

Fraction. Ulmins prepared from :		Carbon.	Hydrogen.	Oxygen and nitrogen (by difference).
East Kirkby vitrain,	alcohol-sol.	64·4	5·1	30·5
,, ,,	acetone-sol.	66·6	4·9	28·5
,, ,,	pyridine-sol.	68·3	4·5	27·2
,, ,,	α-compounds alcohol-sol.	65·5	4·8	29·7
,, ,,	α-compounds acetone-sol.	65·6	4·6	29·8
Hamstead vitrain,	alcohol-sol.	63·8	4·1	32·1
,, ,,	pyridine-sol.	65·5	3·7	30·8

It will be seen that the compounds were all of the same type, the different degrees of solubility being caused presumably by slight modifications in the external groupings of the molecules. The amount extracted by each solvent depended upon the order of extraction and each fraction was to some extent soluble in the other solvents. In general it was found that the further oxidation with hydrogen peroxide had been carried the more soluble in such neutral solvents as alcohol and acetone were the products.

The Preparation of Salts and Determination of the Equivalent.—Well-defined salts of barium, calcium, silver and copper were formed by the addition of a soluble salt of the metal to an ammoniacal solution of the ulmin. The copper salt was used to determine the equivalent. For its preparation, excess of a boiling ammoniacal solution of copper hydroxide was added to the boiling ulmin solution, the mixture well stirred and allowed to cool. The precipitate, which formed readily, was washed several times by decantation, filtered off and washed free from copper hydroxide with dilute ammonia and finally with distilled water. The equivalent was calculated from the analysis of the dried salt and found to be : East Kirkby vitrain ulmin, 171 ; East Kirkby vitrain ulmin, fraction insoluble in pyridine, 164 ; East Kirkby vitrain α-compound ulmin, 165.

Examination for Hydroxyl and Carboxyl Groups.—The presence of these groups in the regenerated ulmins was proved by the formation of an acetyl derivative, using acetic anhydride and sodium acetate, and by the formation of a benzoyl derivative, using benzoyl chloride in pyridine solution. The acetyl derivative was used to estimate the content of hydroxyl by determining the amount of acetic acid liberated on hydrolysis and steam distillation with benzenesulphonic acid. The ulmin from Hamstead vitrain was found to contain hydroxyl equivalent to 2·6% ; and that from the East Kirkby vitrain 2·4%.

Estimation of the total hydroxyl, including that in carboxyl groupings, was made by the use of Grignard's reaction, 13·4% being found ; whence the number of carboxyl groups is four times that of free hydroxyl groups. As was to be anticipated, methoxyl groups were not present.

Nitrogen Content.—During the production of regenerated ulmins by atmospheric oxidation there was a gradual increase in the nitrogen content of all the coals examined until a proportion of 2·25% was reached. This figure was confirmed on analysis of the ulmins produced by the action of hydrogen peroxide. From whichever coal they were formed, and whichever solvent fraction was taken, the nitrogen content was about 2·25%. From this it

appears that most of the nitrogen of the ulmins (and of coal) resides in the nuclear groupings, which mild oxidation does not attack. Moreover, since there must be at least one nitrogen atom per molecule, it follows that the average molecular weight of the regenerated ulmin is not less than about 680. Suitable tests showed that the nitrogen was present in limited amount (not more than about 0·2%) as $-NH_2$ and $-N{\cdot}CH_3$, but the greater proportion was inert, suggesting that its chief mode of occurrence is in a closed ring compound. On the complete breakdown of such a ring, by the extreme action of hydrogen peroxide, the nitrogen is evolved quantitatively as ammonia.

Destructive Distillation.—One gram of the regenerated ulmins prepared from the East Kirkby vitrain and durain respectively was destructively distilled in a horizontal glass tube attached to a Sprengel mercury pump. The temperature was raised by stages of 50°, each temperature being maintained constant during 24 hours or until all gas had ceased to be evolved. The results of examination of the gaseous products are recorded in Tables III and IV.

Explosion analysis in each instance showed the paraffin hydrocarbon present to be methane only.

In Fig. 1 the volumes of the principal gases evolved per gram of material are plotted against temperatures of decomposition. These curves should be compared with that obtained by Tideswell and Wheeler (*loc. cit.*) on the destructive distillation of the peat ulmin, dopplerite.

Oxidation of Regenerated Ulmins.—The action of hydrogen peroxide on the regenerated ulmins was in some instances continued with the intention of breaking down the nucleus of the large ulmin-molecule, so as to obtain compounds of smaller molecular weight from which the internal structure of the ulmins could be deduced. The intense action of hydrogen peroxide was difficult to regulate, resulting most often in the production of water, ammonia and the oxides of carbon, many compounds, the isolation of which would have been of value, having only a transient existence. Nevertheless, good yields of oxalic and succinic acids were obtained and separated by fractional crystallisation. Other crystalline products, apparently polybasic acids, await identification. In addition, small quantities of acids have been obtained having all the properties of benzene polycarboxylic acids.

A more satisfactory reagent with which to effect the breakdown of the regenerated ulmin molecule, since its action could more readily be controlled, was found to be 30% nitric acid. The reaction was carried out in a flask with reflux condenser, at first without external heat and later by boiling during 12 hours. The soluble products

were then distilled in steam, the distillate containing acetic acid. The residue was heated on a water-bath to remove the last traces of nitric acid, the product thus obtained being a pale yellow, spongy mass, completely soluble in ether and amounting to about 25% of the original ulmin. By benzene extraction, picric acid, 3% on the original ulmin, was obtained, its identification being effected by the method of mixed melting points and by the preparation of a naphthalene derivative, m. p. 149°.

By means of their lead, silver and barium salts the remainder of the soluble products of the action of nitric acid on regenerated ulmins were separated. Oxalic acid was obtained in pure crystalline form, whilst other products, nearly pure but difficult to crystallise, were benzene tri- and tetra-carboxylic acid. Symmetrical benzene-tetracarboxylic acid (m. p. 264°, with decomposition) has been isolated in a pure form by slow crystallisation from acetic acid, and its methyl ester, m. p. 138°, formed. The tricarboxylic acid appears to be trimellitic acid, but it has not yet been obtained in sufficiently pure crystalline form to identify.

The presence of picric acid and these benzene polycarboxylic acids in the products, whilst proving the existence of aromatic nuclei in coal, does not necessarily confirm the theory of Fischer and Schrader (*Brenn. Chem.*, 1922, **3**, 161) as to the origin of coal exclusively from lignin; for Marcusson's explanation (*Ber.*, 1921, **54**, 542) of the formation of ulmins from sugars through furfural as an intermediary equally allows of there being benzene nuclei in the products, the condensation of the furfural derivative to a *peri*difuran compound resulting in a substance containing both furan and six-membered rings.

The work of isolating further compounds resulting from the breakdown of regenerated ulmins from bituminous coal is being continued. Our thanks are due to the Safety in Mines Research Board for permission to publish these results.

CCCV.—*The Coagulation of a Colloidal Solution by Hydrogen Ions.*

By Alan B. Weir.

Investigations have been recently carried out in America into one of the chief problems met with in the study of the precipitation of suspensions, emulsions, and colloidal solutions by electrolytes;

namely, whether the active agent is the ion carrying a charge of sign opposite to that of the colloid particles, or whether there is a peptising or stabilising effect due to the other electrolyte ion, the charge of which is of the same sign as that carried by the colloid.

Tartar and Gailey (*J. Amer. Chem. Soc.*, 1922, **44**, 2212) studied the precipitation of gamboge and mastic suspensions, in the first case by acids. These are negative suspensions, and the active agent should therefore be the hydrogen ion. The minimum concentration of acid for complete precipitation of the suspensions was found in the case of five acids : hydrochloric, sulphuric, oxalic, acetic, and phosphoric. The amounts of acid required differed considerably from acid to acid, but the hydrogen-ion concentration of the supernatant liquid, *i.e.*, of the medium from which coagulation had just taken place was, " within the limits of experimental error," the same in each case. The conclusion drawn from these and further experiments described in the same paper was that the " so-called stabilising effect " of the anion (on negative suspensions) could not be detected, and, further, that the irregularities often attributed to this effect were due, even in the case of coagulation by neutral salts, to the important factor of hydrogen-ion concentration.

Bradfield (*J. Amer. Chem. Soc.*, 1923, **45**, 1243), using a clay suspension, confirmed these results for several acids, which precipitated at an almost uniform p_H of 3·8, but found that citric acid was consistently abnormal, requiring a p_H of 3·2.

The author has therefore investigated the applicability of this rule to a true colloidal solution of negative sign, noting whether the abnormality of citric acid recurred.

Experimental.

The sol chosen was one of Prussian blue, as preliminary work on various arsenious sulphide sols showed that they could not be completely precipitated either with citric or acetic acid.

The sol was prepared by slowly adding 0·4 g. of potassium ferrocyanide, dissolved in 20 c.c. of water, to 0·4 g. of ferric chloride in 20 c.c. of water, filtering off the dye, washing, peptising with a solution of oxalic acid (16 g. in 300 c.c. of water), and dialysing till free from oxalic acid. The sol was then diluted to 700 c.c.

Procedure.—The precipitation of the sol by four acids, hydrochloric, sulphuric, acetic, and citric, was examined. The minimum concentration of each acid required for complete coagulation of the sol was found in the usual manner. Graded amounts of the stock acid solutions were placed in test-tubes and accurately diluted to 10 c.c., then 10 c.c. of the sol were added, the whole was mixed

by pouring, and kept for 48 hours (for this sol flocculates slowly). The amounts of the acids required (per 20 c.c. of mixture) were thus found with an accuracy of 0·1 c.c.

In the case of the four critical concentrations, the supernatant liquid, after the dye had been precipitated, was poured off, and its hydrogen-ion concentration ascertained by means of a Clark hydrogen electrode. For standards, saturated and $N/10$-calomel electrodes were used.

In order to see whether any pronounced adsorption of the acid on the colloid had taken place, identical acid mixtures were similarly examined in absence of any colloid, *i.e.*, with 10 c.c. of water substituted in each case for the 10 c.c. of sol used previously.

Acid.	Conc. in milli-equivs. per litre.	p_H of medium after precipitation.	p_H of acids alone.
Hydrochloric	17·1	1·88	1·80
Sulphuric	26·0	1·80	1·73
Acetic	1800	2·27	2·17
Citric	642	1·91	1·83

The results show: 1. An agreement in p_H values, in the case of three of the acids, which is as good as has yet been attained by this method. Such discrepancy as exists the author believes to be due to the difficulty of deciding whether "complete precipitation" has taken place or not, which might be overcome by the use of some form of colorimeter.

2. That citric acid appears to behave normally, contrary to what was found by Bradfield.

3. That some adsorption, either of hydrogen ions or acid molecules, on the precipitating colloid has taken place (compare third and fourth columns).

4. That acetic acid precipitates at a p_H distinctly lower than that of the other acids. This may be due either to a specific adsorption of the anion, or to the action of the undissociated acid molecules present at such a relatively high concentration.

Effect of the Oxalic Anion.—In the usual preparation of Prussian blue sols the dye is peptised by a solution of oxalic acid. A strong specific adsorption of the oxalic ion is inferred. Consequently, precipitation of such sols by means of oxalic acid solutions would not be expected. The sol already studied was not affected at all by concentrations of oxalic acid up to 100 milli-equivs. per litre. With the object of investigating the effect of the oxalic ion, a Prussian blue sol was prepared without the aid of oxalic acid, and its precipitation carried out. The dye was prepared exactly as before, thoroughly washed, and a sol obtained by repeatedly grinding the solid with water and filtering. The sol was dilute,

but perfectly stable after standing for 3 weeks. Analysis showed it to contain 0·072 g. of solid per litre. The stock solutions were *N*-oxalic and 0·11*N*-hydrochloric acid, and the technique was the same as that described above. Precipitation by oxalic acid occurred at a high, but quite definite concentration, whereas only a very small amount of hydrochloric acid was required. The p_H of the precipitating medium was observed as before.

Acid.	Conc. in milli-equivs. per litre.	p_H of medium after precipitation.
Hydrochloric	1·1	2·63
Oxalic	303 to 404	0·91 to 0·79

In the case of oxalic acid, precipitation was partial at the lower, but complete at the higher, concentration. The critical concentration lies between these two values. At a concentration of 202 milli-equivs. of oxalic acid per litre the sol showed no signs of precipitation after several days.

In view of the peptising effect of this acid, already referred to, the possibility of its use as a precipitant is interesting. Once precipitated by this acid, the dye could not be peptised by shaking with the precipitating mixture, whereas precipitates produced by other acids were readily peptised by adding a solution of oxalic acid and shaking.

In the high concentration and p_H values which oxalic acid demands for flocculation of the dilute sol, a strong protective adsorption of the anion is indicated.

My thanks are due to Mr. A. E. Clarence Smith for his advice and assistance.

UNIVERSITY COLLEGE, SOUTHAMPTON. [*Received, July 25th,* 1925.]

CCCVI.—*The Constitution of the Thionic Acids.*

By ISRAEL VOGEL.

ALTHOUGH the problem of the constitution of the thionic acids has occupied the attention of many investigators (compare Fordos and Gelis, *Compt. rend.*, 1842, **15**, 920; Blomstrand, "Chemie der Jetztzeit," p. 157; Mendeléev, *Ber.*, 1870, **3**, 870; Michaelis, *Annalen*, 1873, **170**, 37; Spring, *Ber.*, 1874, **7**, 1161; Debus, J., 1888, **53**, 280; Hertlein, *Z. physikal. Chem.*, 1896, **19**, 286; Riesenfeld and Feld, *Z. anorg. Chem.*, 1921, **119**, 225; Martin and Metz, *ibid.*, 1923, **127**, 82; Benrath, *Z. angew. Chem.*, 1922, **35**, 33; Raschig, "Schwefel und Stickstoffstudien," 1924, p. 305; Vogel, *Chem. News*, 1924, **128**, 325, 343, 361; Vogel, Thesis, 1925, University of London; the last-named contains a complete review of

the literature), it cannot be said that a final or even a satisfactory solution has yet been attained.

In the course of an investigation of sulphur sesquioxide (Vogel and Partington, this vol., p. 1514) it became evident that none of the formulæ hitherto proposed could give a rational explanation of the experimental facts recorded therein. For example, the gradual increase with time of the relative quantities of tetra- and penta-thionates in the products obtained by the interaction of sulphur sesquioxide with water, with sodium ethoxide, and with the blue solution obtained by the dissolution of sulphur in 65% oleum, respectively, and also the almost exclusive formation of trithionate in the reaction between concentrated potassium acetate solution and a solution of sulphur sesquioxide in oleum, were some of the facts for which an explanation had to be found. In addition to these, the liberation of *two* atoms of sulphur from pentathionates by bromine and by mercuric cyanide (Debus, *loc. cit.*), and by mercuric chloride (Sander, *Z. angew. Chem.*, 1916, **29**, 11; compare Riesenfeld and Feld, *loc. cit.*), the separation of *one* atom of sulphur from pentathionates on treatment with cold sodium carbonate solution (Raschig, *op. cit.*, p. 273), the conversion of tetrathionates into pentathionates by acidified sodium thiosulphate solution and the formation of dithionates by the action of acid potassium permanganate solution on trithionates (Raschig, *op. cit.*), the strong acidity of the thionic acids and the non-formation of complex-ions with mercury or silver salts (Hertlein, *loc. cit.*), the difference in refractivity corresponding to bivalent sulphur between two consecutive thionates, *e.g.*, between $K_2S_4O_6$ and $K_2S_5O_6$, are some of the chief experimental facts the interpretation of which is not possible on any one set of formulæ.

The following formulæ, which are in agreement with experiment, are proposed for the thionic acids:

$\begin{matrix}SO_2\cdot OH\\SO_2\cdot OH\end{matrix}$	$S<\begin{matrix}SO_2\cdot OH\\SO_2\cdot OH\end{matrix}$	$S{:}S<\begin{matrix}SO_2\cdot OH\\SO_2\cdot OH\end{matrix}$	$S{:}S{:}S<\begin{matrix}SO_2\cdot OH\\SO_2\cdot OH\end{matrix}$
Dithionic acid.	Trithionic acid.	Tetrathionic acid.	Pentathionic acid.

It might be of interest, in view of the controversy as to the relative stabilities of the thionic acids (compare Riesenfeld and Feld, *loc. cit.*; Foerster and Hörnig, *Z. anorg. Chem.*, 1922, **125**, 86), to point out that according to the above formulæ the relative stabilities should decrease in the order di-, tri-, tetra-, and penta-thionic acid. This is in accord with the thermochemical measurements of Martin and Metz (*ibid.*, 1923, **127**, 83).

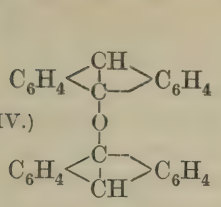
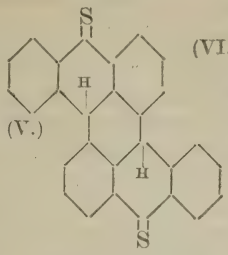
CCCVII.—meso-*Thioanthracene Derivatives. Part II. Dianthranyl Disulphide and Dianthranyl Tetrasulphide.*

By William Herbert Cooke, Isidor Morris Heilbron, and George Hugh Walker.

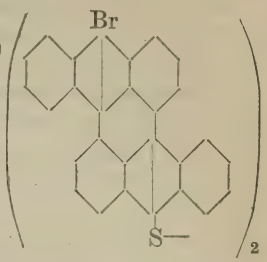


The action of the equivalent amount of sodium hydrosulphide (2 mols.) upon 9 : 10-dibromoanthracene in amyl-alcoholic solution has been shown (Heilbron and Heaton, J., 1923, **123**, 173) to give rise to a complex series of *meso*-thioanthracene derivatives, but the conditions attending the production of any particular compound were obscure, as successive precisely similar experiments did not invariably lead to the same substances. In continuing this investigation, the effect of employing a large excess of sodium hydrosulphide (4 mols.) was first studied, as it was hoped thus to be able to isolate the disodium salt of the hypothetical 9 : 10-dithiolanthracene (I), which, as previously stated, is to be regarded as the initial product. Actually, however, the reaction proceeded in a wholly different direction, the product containing 30—40% of dianthranyl disulphide (III) (Friedländer and Simon, *Ber.*, 1922, **55**, 3969).



The presence of this compound in such large quantities harmonises well with the view that 9 : 10-dithiolanthracene truly represents the first stage in the reactions. Its formation is doubtless the result of reduction of the dithiolanthracene to 9-anthranyl mercaptan (II) during the course of the reaction, followed by oxidation of the latter substance to the disulphide during the working-up process (see experimental part). In addition to dianthranyl disulphide a compound containing neither sulphur nor halogen was isolated and to this the structure (IV) has been assigned on the grounds that on reduction it yields both anthranol and anthracene. It is probably formed from 9-anthranyl mercaptan by hydrolysis and is the oxygen analogue of the dianthranyl sulphide (*loc. cit.*).

The effect of employing less than one equivalent of sodium hydrosulphide was the production of a large quantity of dithioheptacyclene (V) (80—90% yield); which is invariably produced



in 10% yield when equivalent quantities of sodium hydrosulphide and 9 : 10-dibromoanthracene are employed (*loc. cit.*).

(IV.)

(V.)

(VI.)

The effect of sodium sulphide, sodium disulphide, and sodium polysulphides upon dibromoanthracene has also been examined.

Sodium sulphide. When the equivalent quantity of this salt was used, the dibromoanthracene ceased to separate from the amyl-alcoholic solution after 3 days' continuous boiling; the products were unchanged material and small quantities of dianthranyl disulphide and anthracene. Even when a considerable excess of sodium sulphide was present, very little change was noted on simply boiling the reactants under reflux, but on heating in an autoclave for 2 hours at 150°, the dibromoanthracene was completely converted into dithioheptacyclene.

Sodium disulphide. On refluxing a solution of the reactants in amyl or butyl alcohol the dibromoanthracene rapidly disappeared; after 8 hours, the solution was deep red and addition of small quantities of water precipitated practically pure dianthranyl disulphide (average yield: 60%). When ethyl alcohol was used as solvent, dibromoanthracene was recovered even after 3 days' boiling. On the other hand, by heating the reactants with amyl alcohol in an autoclave for 4 hours at 200° a yellow, amorphous compound (insoluble in all media) was formed to which the constitution (VI) has been tentatively assigned. Its formation may be attributed to a fusion of the anthracene molecules with loss of hydrogen bromide in an analogous manner to that leading to dithioheptacyclene.

Sodium polysulphides. On treatment of 9 : 10-dibromoanthracene in boiling amyl-alcoholic solution with this mixture of salts, in which the tetrasulphide is probably the main constituent, a good yield was obtained of the substance to which Heilbron and Heaton (*loc. cit.*) had assigned the dithiodianthrone disulphide structure (VII) on the grounds that it was soluble in boiling alcoholic potash,

(VII.)  (VIII.)

supposedly existing in the solution as the potassium salt of the tautomeric dithiodianthranol derivative (VIII). Owing to the ease with which this substance can now be obtained, it has been possible to make a more detailed examination of its properties. The action of boiling alcoholic potash has been confirmed in so far as the substance dissolves completely on boiling, forming a blood-red solution. In no case, however, could the original compound be recovered, for on acidification by means either of dilute acetic acid or of carbon dioxide in ice-cold solution, hydrogen sulphide was evolved and dianthranyl disulphide produced. It is impossible to reconcile the ready formation of the disulphide in this way with the structure (VIII), and it would appear that the true constitution of this compound is that of an organic tetrasulphide the structure of which could be expressed by one or other of the following formulæ :

$C_{14}H_9{\cdot}S{\cdot}\underset{\|}{S}{\cdot}\underset{\|}{S}{\cdot}C_{14}H_9$ (IX.) $\quad$ $C_{14}H_9{\cdot}S{\cdot}\underset{\|}{S}{\cdot}S{\cdot}C_{14}H_9$ (X.) $\quad$ $C_{14}H_9{\cdot}S{\cdot}S{\cdot}S{\cdot}S{\cdot}C_{14}H_9$ (XI.)

Holmberg (*Annalen*, 1907, **359**, 81), in a critical review of the structure of organic tetrasulphides, comes to the conclusion that the straight-chain type is the most probable, and in the case of the compound under review, (XI) is wholly in keeping both with its method of formation and with its ease of decomposition. Again, an attempt to form a methiodide by boiling the dianthranyl tetrasulphide with methyl iodide failed, and this is in agreement with the results obtained by Smythe and Foster (J., 1910, **97**, 1197) in their work on benzyl tetrasulphide.

Experimental.

Treatment of 9 : 10-*Dibromoanthracene with Excess of Sodium Hydrosulphide.—Dianthranyl disulphide* (III). A solution of sodium amyloxide (sodium 9 g., amyl alcohol 1000 c.c.) was saturated with dry hydrogen sulphide with precautions against clogging. 9 : 10-Dibromoanthracene (30 g.) was then added and the mixture heated to boiling, the stream of hydrogen sulphide being maintained throughout the whole reaction. The solution became light red and then dark brown; after 12 hours, no 9 : 10-dibromoanthracene separated on cooling. No dithioheptacyclene was thrown out of solution, as was invariably the case when the equivalent quantity of sodium hydrosulphide was employed (Heilbron and Heaton, *loc. cit.*). The cold amyl-alcoholic solution was shaken with water to remove inorganic salts, and the brown precipitate thereby produced was removed, dried, and repeatedly crystallised from benzene, dianthranyl disulphide being obtained in orange prisms, m. p. 223°. On treatment with zinc dust and glacial acetic acid,

it was readily reduced to 9-anthranyl mercaptan, m. p. 90° (Friedländer and Simon, *loc. cit.*) (Found : C, 80·1; H, 4·3; S, 15·0. Calc., C, 80·4; H, 4·3; S, 15·3%). In later experiments, it was found that the yield of dianthranyl disulphide could be considerably increased (40% calculated on the dibromoanthracene) by cutting off the current of hydrogen sulphide during the heating process. Experiments were carried out substituting 9 : 10-dichloroanthracene for the bromo-derivative, potassium for sodium, and butyl alcohol for amyl alcohol, but with none of these variations was the yield of disulphide so satisfactory.

Dianthranyl oxide (IV). The amyl-alcoholic mother-liquors from the above experiment were dried over anhydrous sodium sulphate and concentrated; the yellow substance that slowly separated from the cold solution proved extremely troublesome to crystallise, but was ultimately obtained in long, straw-coloured needles from alcohol, m. p. 213° (Found : C, 90·6; H, 5·0. $C_{28}H_{18}O$ requires C, 90·8; H, 4·9%). Dianthranyl oxide was not affected by alkalis alone, but on reduction with zinc dust and hot sodium hydroxide solution it yielded anthracene (identified as the picrate) and anthranol, m. p. 120° (not sharp) (compare Meyer, *Annalen*, 1910, **379**, 37). Like so many of these derivatives, dianthranyl oxide was not invariably obtained in all the experiments carried out and it has been impossible to ascertain the exact conditions of formation.

Treatment of 9 : 10-*Dibromoanthracene with less than one Equivalent of Sodium Hydrosulphide.*—When less than 1 equivalent of sodium (2 g. Na : 20 g. dibromoanthracene) was used under the conditions described in the first experiment, dithioheptacyclene began to separate after 6 hours; the reaction was completed after 9 hours' boiling. The product was purified as described in Part I (yield 80—90%).

Action of Sodium Sulphide.—9 : 10-Dibromoanthracene (15 g.) was added to a solution (300 c.c.) of sodium sulphide (16 g.) prepared by mixing solutions of equivalent quantities of sodium hydrosulphide and sodium amyloxide in amyl alcohol. Very little change occurred on heating at 140°, and even after 2 days' boiling the bulk of the dibromoanthracene separated on cooling. The mixture was therefore heated in an autoclave at 150° for 2 hours. On cooling, dithioheptacyclene separated in almost quantitative yield (Found : C, 80·8; H, 3·9; S, 15·2. Calc., C, 80·8; H, 3·8; S, 15·4%). Using only the equivalent quantity of sodium sulphide had very little effect, a small quantity of dianthranyl disulphide, together with anthracene and unchanged dibromoanthracene, being obtained after 3 days' boiling.

Treatment of 9 : 10-*Dibromoanthracene with Sodium Disulphide.—Dianthranyl disulphide.* A solution of sodium amyloxide (300 c.c.) containing 6 g. of sodium was converted into sodium sulphide as described above, and the theoretical quantity of powdered sulphur (4 g.) added. The mixture was gently boiled for 3 hours together with dibromoanthracene (15 g.), the colour becoming light red and finally dark brown. The solution was filtered from a small residue of unchanged 9 : 10-dibromoanthracene, the filtrate distilled to remove as much amyl alcohol as possible, and then steam-distilled. The residual light red alkaline solution contained a deep brown semi-solid mass which quickly solidified. After six crystallisations from benzene in presence of animal charcoal, orange crystals (m. p. 223°) of dianthranyl disulphide were obtained (weight of crude product : 10 g.).

By employing butyl alcohol (b. p. 116°) in place of amyl alcohol and heating for 8 hours, the whole of the dibromoanthracene was utilised and a dark red solution resulted from which the dianthranyl disulphide was completely precipitated by treatment with small quantities of water. By adopting this method, resin formation was prevented and an average yield of 60% of dianthranyl disulphide, calculated on the weight of the dibromoanthracene used, resulted (Found : C, 80·3, 80·1; H, 4·5, 4·6; S, 15·0. Calc., C, 80·4; H, 4·3; S, 15·3%).

ms-*Dibromodiheptacyclene disulphide* (VI) was obtained by heating a mixture of 9 : 10-dibromoanthracene (15 g.), crystallised sodium disulphide (5 g.), and amyl alcohol (1000 c.c.) in the autoclave for 4 hours at 200°. The yellow, amorphous product was boiled with water to remove inorganic matter and again, after drying, with xylene to remove unchanged dibromoanthracene. It was insoluble in all organic solvents and resisted reduction and the action of boiling alcoholic potash (Found : C, 72·5; H, 3·5; S, 6·7; Br, 17·4. $C_{56}H_{28}Br_2S_2$ requires C, 72·7; H, 3·0; S, 6·9; Br, 17·4%).

Dianthranyl Tetrasulphide (XI).—A sodium polysulphide mixture was prepared by slowly heating hydrated sodium sulphide ($Na_2S,9H_2O$; 60 g.) with finely powdered rock sulphur (24 g. for 2 hours at a maximum temperature of 150°. The fused orange melt was cooled and while still syrupy was added to 9 : 10-dibromoanthracene (40 g.) dissolved in amyl alcohol (700 c.c.); after being heated under reflux for 2 days, the solution was deep red. On standing over-night or longer, dianthranyl tetrasulphide separated. After boiling with water to dissolve inorganic matter, it was crystallised from benzene, separating in yellow spangles, m. p. 190° (Heilbron and Heaton, *loc. cit.*, give m. p. 194°) (yield : 33%). If the amyl alcohol is impure or if the crude polysulphide is allowed to

solidify before addition to the amyl-alcoholic solution, a quantity of free sulphur is deposited with the dianthranyl tetrasulphide, rendering purification extremely difficult. The identity of this compound with Heaton and Heilbron's dithiodianthrone disulphide (VIII) was proved by mixed melting-point determinations and by analysis (Found: C, 69·9, 69·9; H, 4·2, 4·0; S, 26·2. Calc., C, 69·7; H, 3·7; S, 26·5%).

Dianthranyl tetrasulphide was boiled with alcoholic sodium hydroxide for 3 hours, and the hot, deep red solution filtered and set aside; dianthranyl disulphide was slowly deposited. A repeat experiment was carried out, but in this case the filtrate, which was immersed in powdered ice, was acidified with dilute acetic acid; hydrogen sulphide was evolved and a buff-coloured precipitate of dianthranyl disulphide separated. That the tetrasulphide is decomposed by the alkali to give in the first place 9-anthranyl mercaptan was proved by the actual isolation of this compound from the reaction mixture in which the heating was suspended immediately the dianthranyl tetrasulphide had gone into solution. The hot solution was rapidly saturated with carbon dioxide and the residue washed with hot water to remove sodium carbonate. After drying, it separated from light petroleum in yellow crystals, m. p. 90°, which were freely soluble in dilute aqueous sodium hydroxide and readily oxidised by potassium ferricyanide solution to the disulphide.

THE UNIVERSITY, LIVERPOOL. [*Received, July 18th*, 1925.]

CCCVIII.—*The Reaction between Sodium Hypobromite and Carbamide.*

By MAXWELL BRUCE DONALD.

THE reaction between carbamide and sodium hypobromite may be represented as:

$$CON_2H_4 + 3NaOBr \longrightarrow CO_2 + N_2 + 3NaBr + 2H_2O,$$

but in actual practice it is found that it never goes to completion. The course of the reaction can be followed by estimating (1) the amount of nitrogen evolved, (2) the amount of hypobromite decomposed, or (3) the amount of carbonate formed. All these methods give substantially the same results and indicate that, with the usual methods of performing the experiment, the reaction goes only to about 90% of completion.

The incompleteness of the reaction has been attributed to various

causes, such as (1) the solubility of nitrogen in the hypobromite solution, (2) the formation of a compound of carbamide and bromous acid (Hüfner, *J. pr. Chem.*, 1871, **3**, 1), (3) the impurity of the nitrogen (Rayleigh and Ramsay, *Phil. Trans.*, 1895, **186**, *A*, 187; Rayleigh, *Proc. Roy. Soc.*, 1898, **64**, 95; Krogh, *Z. physiol. Chem.*, 1913, **84**, 379; Hurtley, *Biochem. J.*, 1921, **15**, 11), (4) the formation of oxides of nitrogen in the solution (Fauconnier, *Bull. Soc. chim.*, 1880, **33**, 102; Luther, *Z. physiol. Chem.*, 1889, **13**, 500; Krogh, *loc. cit.*). None of these explanations, however, is adequate (see, for example, Lescœur, *J. Pharm. Chim.*, 1919, **20**, 305; Werner, J., 1922, **121**, 2318; Margosches and Rose, *Biochem. Z.*, 1923, **137**, 542).

The alternative suggestion (Fenton, J., 1878, **33**, 300; P., 1895, 138; see also Lescœur, *loc. cit.*; Margosches and Rose, *loc. cit.*) that the reaction does not go to completion because of the formation of sodium cyanate is supported by the evidence brought forward in the present communication. The work of Margosches and Rose, on which the view was based that the formation of sodium cyanate cannot be the chief cause of the nitrogen deficit, is inconclusive, since no account was taken of the composition of the hypobromite used.

Experimental.

The gasometric method was found to be unsatisfactory for two reasons. The usual solution (40% brominated 10*N*-sodium hydroxide)* was made by adding bromine to a sodium hydroxide solution cooled to below 0° and analysed for hypobromite by sodium arsenite and for total hypobromite and bromate by sodium thiosulphate. The original solution was then kept for 20 hours and analysed again. Although there was no change in the thiosulphate titration, the hypobromite had been half converted into bromate over-night. The old hypobromite solution evolved about 3% more nitrogen from a carbamide solution than the freshly prepared hypobromite. This, as will be seen from subsequent results, is probably due to the decreased ratio of hypobromite to hydroxide.

The other objection to this method is that the reaction between carbamide and hypobromite gives off a considerable amount of heat; in fact, Smith (*Chem. News*, 1895, **71**, 259) used such heat as a basis for determining the amount of carbamide in urine. Wagner (*Z. anal. Chem.*, 1874, **13**, 383) suggests keeping the reaction vessel under water; but the volume of gas only becomes constant 15

* A hypobromite solution made by adding 25 c.c. of bromine (1 equiv.) to 100 g. of sodium hydroxide (2·5 equivs.) dissolved in water, and making up to 250 c.c. is described as a 40% brominated 10*N*-sodium hydroxide solution.

minutes after the reaction, even when it is kept in a well-stirred thermostat. The factor generally given in text-books for 40% brominated 10*N*-sodium hydroxide is 0·92. Careful measurements with thermostat control, using freshly prepared cool hypobromite and applying all corrections to the volume of gas evolved, gave 0·90, whereas the titration method shows that the factor should be 0·87.

More trustworthy results were obtained by estimating the hypobromite decomposed. The procedure was to add the carbamide solution slowly to the hypobromite, allow the reaction to proceed with occasional shaking for 5 minutes, dilute the reaction mixture to 500 c.c., and add about 20 c.c. of 3*N*-hydrochloric acid and a solution containing about 5 g. of potassium iodide. The solution was kept for 2 minutes and then titrated with thiosulphate, with starch as an indicator. There was a certain tendency to " reblue " on standing. The difference between the amounts of thiosulphate required for this titration and for the hypobromite alone gives the equivalent amount of hypobromite which has been used up in the reaction. The carbamide was recrystallised three times from alcohol and dried at 100°.

A number of experiments were undertaken to determine the chief factors which influenced this reaction at room temperature. Excess of hypobromite had no effect, confirming previous observations on a similar reaction with ammonia (*Analyst*, 1924, **49**, 375). The actual concentration of the hypobromite had no effect at moderate concentrations. Thus a 40% brominated 4*N*-sodium hydroxide solution was diluted in steps down to 0·25*N* without any effect on the reaction. In stronger solutions of hypobromite, there are secondary effects due to time changes in the hypobromite–hydroxide ratio to be allowed for. The chief factor at room temperature was the extent to which the sodium hydroxide had been brominated.

Some of the experimental results obtained with carbamide and various hypobromite solutions are in Table I. The expression " c.c. thio. required " indicates the difference in thiosulphate required for a blank and that required after the carbamide has been added to the hypobromite.

Similar results are obtained with hypobromite solutions prepared from sodium hydroxide as strong as 2*N*. Both titration and gasometric methods show that the nitrogen deficit becomes greater as the percentage bromination increases until the hydroxide is 75% brominated. At this point a sudden change occurs, the amount of gas evolved still decreases, but a slow oxidation sets in. After 30 minutes, an amount of hypobromite is used up which is about equivalent to the

TABLE I.

Sodium thiosulphate 0·1963*N*. Sodium hydroxide 0·496*N*. 5 C.c. of carbamide solution contain 0·075 g., which is equivalent to 38·3 c.c. of thiosulphate.

No. of sol.	% Brominated.	C.c. of thio. required after 5 mins.	15 mins.	30 mins.	Carbamide decomposed %.

10	97·5	—	4·2	4·0	

quantity of carbamide taken (*i.e.*, 38·3 c.c. of thio.). When the sodium hydroxide is completely brominated, there is no gas evolution and no hypobromite is used up.

Sodium cyanate was prepared by the method of Leuchs and Geserick (*Ber.*, 1908, **41**, 4171) from urethane and sodium in boiling benzene and was twice recrystallised from pure alcohol. With it and with the same hypobromite solutions as before, the following results were obtained.

TABLE II.

5 C.c. of sodium cyanate taken contain 0·075 g., equiv. to 17·7 c.c. of 0·196*N*-thio.

No. of solution.	% Bromination.	C.c. of thio. after 5 mins.	15 mins.
5	75	—	—
6	80	0·4	0·3
7	85	0·4	0·3
8	90	1·0	0·7
9	95	17·9	18·0

There is no action of hypobromite on sodium cyanate below the composition 75% brominated. Above this value the hypobromite reacts slowly with the sodium cyanate, but with 100% brominated solutions there is a vigorous gas evolution from the mixture.

The figures for sodium cyanate (Nos. 7 and 8) do not show complete oxidation, as would be expected from the figures in Table I. Another series of experiments was therefore made with the same hypobromite solutions, using a mixture of carbamide and sodium cyanate.

These figures point to the fact that the deficit of nitrogen is due to the formation of sodium cyanate and that with hypobromite solutions brominated to more than 75% and less than 95% a secondary oxidation of the sodium cyanate is induced only if carbamide is present. They also show that the rate of this secondary oxidation

TABLE III.

5 C.c. of the solution contain 0·0375 g. each of carbamide and sodium cyanate, which are equivalent to 19·15 and 17·7 c.c. of 0·196*N*-thiosulphate respectively.

7	85	15·8	28·5
8	90	28·2	28·4

is greater with increase in the amount of bromination of the sodium hydroxide. Carbamide is not acted upon by 100% sodium hypobromite, as there is no excess of sodium hydroxide to decompose the compound which it probably forms with the bromine.

The potential of a platinum electrode dipping into the various solutions shows that there is no marked change in the oxidising power except in the neighbourhood of completely brominated solutions.

Summary.

The chief factor influencing the deficit of nitrogen in the reaction between carbamide and sodium hypobromite at room temperature is the extent to which the sodium hydroxide has been brominated. The effect of this variable has been studied for all brominations from 0 to 100%. The reaction does not go to completion owing to the formation of sodium cyanate. The amount of sodium cyanate formed becomes greater as the ratio of hypobromite to hydroxide increases until it corresponds to 75% bromination, when it is oxidised in a secondary reaction. Sodium cyanate solutions are not appreciably oxidised by 75 to 90% hypobromite solutions except in the presence of carbamide. With pure hypobromite (*i.e.*, without any excess of sodium hydroxide present) sodium cyanate solutions are vigorously decomposed. The experiments of Margosches and Rose proving that sodium cyanate is not formed in the reaction are inconclusive, since they do not take into account the effect of the composition of the hypobromite. The use of 10*N*-sodium hydroxide solutions for the estimation of carbamide gasometrically leads to inaccurate results.

The author wishes to thank Professor J. C. Philip, F.R.S., for his kind advice and interest in this research.

SOUTH KENSINGTON. [*Received, May 16th,* 1925.]

CCCIX.—*Nitrosation of Phenols. Part II. Nitrosation of* 3-*Bromo-*, 2-*Bromo-*, 3-*Iodo-*, *and* 2-*Iodo-phenol. Evidence for the Nitroso-formula of* 4-*Nitrosophenol.*

By Herbert Henry Hodgson and Francis Harry Moore.

The investigation now to be described, dealing mainly with the nitrosation of 3-bromo- and 3-iodo-phenol, supplements work on 3-chlorophenol (J., 1923, **123**, 2499).

Unlike 3-chloro-4-nitrosophenol, 3-bromo-4-nitrosophenol is so sensitive to transformation that the quinoneoxime form is produced in every solvent except ether. 3-Iodo-4-nitrosophenol has been obtained only in the quinoneoxime modifications. Geometrical isomerides of both compounds have been isolated which exhibit differences in colour (see also Kehrmann and Wolff, *Ber.*, 1900, **33**, 1539; Kehrmann and Denk, *ibid.*, p. 3297). Oxidation to the corresponding halogenated nitrophenols has established the 4-positions of the nitroso-groups, and molecular-weight determinations the unimolecular character of the isomerides.

2-Chloro- and 2-bromo-4-nitrosophenol were readily obtained by the general process for nitrosating *m*-halogenated phenols (*loc. cit.*); but from 2-iodophenol a tar was produced, and the nitroso-compound was obtained only by working at great dilution and in the presence of acetic instead of sulphuric acid. These three nitroso-compounds could not be converted into the quinoneoxime forms, the immobility of the phenolic hydrogen in proximity to a halogen atom being thus made manifest.

A very fine specimen of nitrosophenol free from resinous matter has been prepared from phenol by the general nitrosation method; it melts at 133°, *i.e.*, 7° higher than the m. p. (126°) usually recorded. A specimen prepared 2 years ago is still in good condition.

The data in the following table are claimed to support the view that 4-nitrosophenol is a genuine nitroso-compound and not a quinoneoxime.

Substance.	M. p. of nitroso-compound.	M. p. of quinoneoximes.
Phenol	133° (126° recorded)	126° (prepared from benzoquinone)

* Nietzki and Schneider, *Ber.*, 1894, **27**, 1426.

Experimental.

Nitrosation of 3-Bromo-, 2-Bromo-, and 3-Iodo-phenol.—The method for preparing 3-chloro-4-nitrosophenol (J., 1923, **123**, 2502) was found generally applicable; the nitroso-compounds, however, formed gradually and separated, partly as pale yellow crystals (0·5—1 g.) and partly as tars, from which, after draining and washing with cold benzene, about 2 g. more of the products were obtained.

3-Bromo-4-nitrosophenol dissolves readily in alcohol or ether and is moderately easily soluble in hot benzene or light petroleum, but almost insoluble in the cold solvent. It was obtained in yellow needles, m. p. 139° (decomp.), by addition of light petroleum to an ethereal solution (Found: Br, 39·5; N, 7·0. $C_6H_4O_2NBr$ requires Br, 39·6; N, 6·9%).

*3-Bromo-*p*-benzoquinone-4-oxime* was obtained in red needles when the preceding compound was crystallised from benzene, dilute hydrochloric acid, and dilute alcohol; the three products melted and decomposed at 187°, 188°, and 186°. On recrystallisation from dilute hydrochloric acid, the quinoneoxime was obtained in orange needles, m. p. 188° (decomp.) (Found: Br, 39·6; N, 7·1; *M*, cryoscopic in phenol, 189. $C_6H_4O_2NBr$ requires Br, 39·6; N, 6·9%; *M*, 202). All the solvents tried except cold ether effected the conversion.

Action of Alkalis on 3-Bromo-4-nitrosophenol.—The nitroso-compound dissolves in aqueous sodium hydroxide (10%) to a red solution which froths after a few seconds. If the solution is acidified immediately, a pale yellow almost colourless substance of m. p. 189—190° (needles from benzene) is precipitated (Found: Br, 39·55; N, 7·2), but if it is kept for some time a dark-coloured substance of indefinite m. p. is produced on acidification. Sodium carbonate effects the same transformation unaccompanied by frothing, or decomposition on short standing.

Interconversion of the Geometrical Isomerides.—Dissolution of the orange form of the quinoneoxime in alkalis (unaccompanied by frothing), followed by acidification in the cold, produces the colourless form, and crystallisation of the latter from dilute hydrochloric acid converts it into the orange isomeride.

Liebermann's Nitroso-reaction.—All three products gave identical results owing to the ready conversion of two of them into the acid-stable form. To 0·05 g. of each isomeride, 0·1 g. of phenol and 1 c.c. of concentrated sulphuric acid were added. The solutions were deep green and became brownish-red on dilution and then violet on addition of sodium hydroxide.

Oxidation of 3-Bromo-4-nitrosophenol and its Tautomerides to 3-Bromo-4-nitrophenol.—Oxidation proceeds much more readily than in the case of 3-chloro-4-nitrosophenol. A solution of 0·5 g. of any one of the three isomerides in water (100 c.c.) containing potassium ferricyanide (5 g.) and sodium hydroxide (5 g.) was kept for 48 hours at room temperature and then acidified with dilute sulphuric acid (25%). The solution was filtered, shaken with ether, the solvent removed from the extract, the residue treated with a minimum of aqueous sodium hydroxide (10%), and the alkaline solution acidified in the cold with concentrated hydrochloric acid; the brown precipitate thus obtained crystallised from benzene in almost colourless needles, m. p. 131° (Auwers and Deines, *loc. cit.*, give m. p. 130—131°) (Found : Br, 36·75; N, 6·5. Calc. for $C_6H_4O_3NBr$, Br, 36·7; N, 6·4%).

2-*Bromo-4-nitrosophenol.*—This nitroso-compound is not transformed into a quinoneoxime by hot dilute mineral acids. It crystallises from benzene in light brown needles and from dilute alcohol in red needles, m. p. 150° (Found : Br, 39·4; N, 7·0. $C_6H_4O_2NBr$ requires Br, 39·6; N, 6·9%). The colour produced in the Liebermann nitroso-reaction is deep green and changes to wine-red on dilution; it reverts to deep green in aqueous sodium hydroxide. Oxidation with ferricyanide as described above converts the nitroso-compound into 2-bromo-4-nitrophenol, m. p. 112° (Found : Br, 36·6; N, 6·5. Calc., Br, 36·7; N, 6·4%).

3-*Iodo*-p-*benzoquinone*-4-*oxime.*—The nitrosation product of 3-iodophenol has no m. p.; it darkens at 170—180°, begins to decompose at 185°, and a deep reddish-brown vapour is evolved at 200°. The compound is readily soluble in alcohol or ether, moderately easily soluble in hot benzene but very sparingly soluble in the cold solvent, and insoluble in light petroleum. The yellow needles obtained from its solution in benzene or hot dilute hydrochloric acid decompose at 185—195°; if the latter solution is boiled for a few minutes, iodine is liberated and no crystallisation ensues. Light petroleum added to an ethereal solution of the quinoneoxime produces small, deep yellow prisms. This isomeride, which is tentatively assumed to be the *syn*-form (compare J., 1923, **123**, 2499), has a normal molecular weight in phenol solution (Found : N, 5·8; I, 50·9; *M*, cryoscopic in phenol, 254. $C_6H_4O_2NI$ requires N, 5·6; I, 51·0%; *M*, 249).

The *syn*-modification dissolves in 10% aqueous sodium hydroxide without frothing. From the red solution, on acidification, a very pale straw-coloured substance is precipitated. This, the *anti*-form, decomposes at about 185° and is highly dissociated in phenol solution (Found : N, 5·7; I, 50·9%; *M*, cryoscopic in phenol, 160).

The Liebermann reaction produced a yellowish-brown colour, which changed to reddish-brown when the solution was diluted or made alkaline. Decomposition appears to have taken place.

Oxidation with alkaline ferricyanide as described above gave *3-iodo-4-nitrophenol*, which crystallised from alcohol in long, slender, almost colourless needles, m. p. 123° (Found: N, 5·5. $C_6H_4O_3NI$ requires N, 5·3%), and was identified by comparison with a specimen prepared by nitrating 3-iodophenol.

Preparation of 2-Iodophenol.—2-Iodonitrobenzene was obtained in 91% yield from *o*-nitroaniline by the usual procedure; only a slight excess of potassium iodide, however, was employed. It melted at 50—51° (Nölting and Wrzesinski, *Ber.*, 1875, **8**, 820, give m. p. 43°). Its reduction with tin and hydrochloric acid produced a mixture of 2-iodo- and 2-chloro-aniline, and the yield of the former obtained by means of ferrous sulphate and ammonia was poor (compare Körner and Wender, *Gazzetta*, 1887, **17**, 486). 2-Iodonitrobenzene (28 g.), iron filings (28 g.), glacial acetic acid (70 c.c.), and water (70 c.c.) were mixed together and the mild reaction was completed by heating on the water-bath. The product was made alkaline with sodium bicarbonate and distilled with steam. The 2-iodoaniline thus obtained (22 g. or 89·5%; m. p. 57°. Körner and Wender, *loc. cit.*, give m. p. 56·5°) was converted, by rapidly cooling a hot solution in concentrated sulphuric acid (20 c.c.) and water (50 c.c.), into small crystals of the sulphate, which was diazotised and the excess of nitrous acid destroyed by carbamide; the diazo-solution was added drop by drop to a boiling solution of sulphuric acid (50 c.c.) and water (50 c.c.) through which a current of steam was passing. The 2-iodophenol thus obtained (yield 20 g. or 91%) melted at 40° after crystallisation from ether (Schall, *Ber.*, 1883, **16**, 1897; 1887, **20**, 3363, gives m. p. 39—40°).

Nitrosation of 2-Iodophenol.—The general method was useless in this case, tarry matter only being formed. The main product of the action of amyl nitrite and glacial acetic acid on 2-iodophenol in benzene solution was 2-iodo-6-nitrophenol, which was isolated by means of its volatility in steam. This compound, which was also prepared by nitrating 2-iodophenol, crystallised from light petroleum in bright yellow, feathery needles, m. p. 109°, and formed a red sodium salt.

A solution of 2-iodophenol (4 g.) and sodium nitrite (7 g.) in water (850 c.c.) was cooled to 10° and treated gradually with a mixture of glacial acetic acid (4·5 c.c.) and water (5 c.c.). After 24 hours, the solution was filtered, and shaken with ether. The extract was treated with 10% sodium hydroxide, and the deep-

coloured aqueous layer very cautiously acidified in the cold. The yellow precipitate (1 g.) of 2-*iodo*-4-*nitrosophenol* crystallised from benzene or dilute hydrochloric acid in yellow needles, which decomposed at 152°. No conversion into a quinoneoxime could be effected (Found: N, 5·7; I, 50·85; *M*, cryoscopic in phenol, 255. $C_6H_4O_2NI$ requires N, 5·6; I, 51·0%; *M*, 249). The colour produced in the Liebermann reaction was deep green; it changed to crimson on dilution and to blue when the solution was made alkaline. 2-Iodo-4-nitrophenol, m. p. 86—87°, was obtained by oxidising 2-iodo-4-nitrosophenol with ferricyanide and by nitrating 2-iodophenol (Found: N, 5·4. Calc., N, 5·3%).

The authors desire to thank the British Dyestuffs Corporation for gifts of the chemicals used in this investigation.

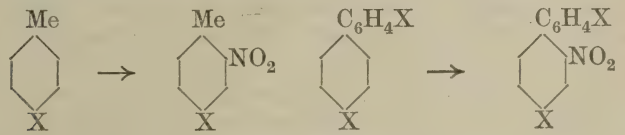
CCCX.—*Nitration of Phthal- and Succin-*p*-tolil.*



By OSCAR L. BRADY, WILLIAM G. E. QUICK, and WALTER F. WELLING.

THE nitration of aniline in the presence of a large quantity of concentrated sulphuric acid has long been known to give *m*-nitroaniline (Hübner and Frericks, *Annalen*, 1881, **208**, 299; Noelting and Collin, *Ber.*, 1884, **17**, 261; Bruns, *Ber.*, 1895, **28**, 1954; Tingle and Blanck, *Amer. Chem. J.*, 1906, **36**, 605), and of *p*-toluidine to give 2-nitro-*p*-toluidine. Acylated amines, however, on nitration usually give compounds in which the nitro-group has entered in the *o*- or *p*-position to the acylamino-group, but in some cases, if a large quantity of concentrated sulphuric acid is present, meta-substitution occurs; for example, under these conditions Noelting and Collin (*loc. cit.*) obtained after hydrolysis a small quantity of *m*-nitroaniline from acetanilide and a considerable quantity of 2-nitro-*p*-toluidine from aceto-*p*-toluidide; with plain nitric acid, however, the group entered in the ortho- or para-position to the acylamino-group. Phthal-*p*-tolil on nitration with a mixture of sulphuric and nitric acids gives mainly 2-nitro-*p*-toluidine (D.R.-P. 141893).

Sulphuric acid was employed in all these nitrations, but Miolati and Lotti (*Gazzetta*, 1897, **27**, i, 298) obtained 2-nitro-*p*-toluidine by nitrating succin-*p*-tolil with fuming nitric acid. (Compare also Cain and Micklethwait, *J. Chem. Soc.*, 1914, **105**, 1442, for the nitration of diphthalyltolidide.) This problem has now been investigated on more quantitative lines, the succinyl-, phthalyl-,

3-nitrophthalyl-, and tetrachlorophthalyl-compounds being nitrated with fuming nitric acid alone. Under these conditions, the aniline derivatives gave almost exclusively *p*-nitroaniline, but the derivatives of *p*-toluidine all gave 2-nitro-*p*-toluidine as the main product. It appears, therefore, that the dibasic acyl group does not sufficiently influence the amino-group to enable meta-substitution to occur, but so reduces its directive influence in the case of *p*-toluidine as to enable the comparatively feebly directive methyl group to take control. Nitrophthal-, tetrachlorophthal-, and succin-*p*-tolil gave approximately 84%, and phthal-*p*-tolil 76%, of 2-nitro-*p*-toluidine; the nature of the dibasic acid accordingly does not greatly influence the proportion of the isomerides formed.

This investigation arose from the study of the isomerism of the dinitrobenzidines (compare Brady and McHugh, J., 1923, **123**, 2047, where the literature of these compounds is summarised) and the behaviour of phthal-*p*-tolil in giving 2-nitro-*p*-toluidine with fuming nitric acid is consistent with the possibility that one of the nitro-groups in Bandrowski's dinitrobenzidine, obtained by the nitration of phthalylbenzidine, is in the meta-position to the amino-group, since one phthalylaminophenyl group can be regarded as replacing methyl in phthal-*p*-tolil.

$$X = \cdot N\!<\!\begin{matrix}CO\\CO\end{matrix}\!>\!C_6H_4.$$

Experimental.

The System 2-*Nitro*-p-*toluidine*–3-*Nitro*-p-*toluidine*.—The fusion diagram was constructed in the usual way from cooling curves of mixtures of the pure compounds. The results are in Table I. In the neighbourhood of the eutectic, crystallisation was very slow and the freezing point was easily missed if the rate of cooling exceeded 0·3° per minute; indeed with two mixtures no definite arrest was obtained until the eutectic temperature was reached, the freezing point being indicated only by the change of slope of the cooling curve; these values are given in brackets.

Nitration of Phthal-p-*tolil*.—Two parts of *p*-toluidine were heated with one of phthalic anhydride for 2 hours on the water-bath. The product was extracted repeatedly with hot alcohol, and the sparingly soluble residue crystallised from benzene. The phthalyl compound so obtained was added in small portions to 10 times its

TABLE I.

% 3-Nitro-*p*-toluidine.	F. p.	% 3-Nitro-*p*-toluidine.	F. p.	Eutectic.
0	74·8°	33·1	(60·9°)	56·1°
10·5	69·0	38·7	(65·6)	56·2
18·0	64·1	49·7	74·0	
23·5	60·3	55·0	78·4	
29·0	56·3	100	116·7	

weight of nitric acid (*d* 1·5) cooled in ice, the mixture kept on ice for 10 minutes and then poured on to crushed ice. When the ice had melted, the solid was collected, washed free from nitric acid, and hydrolysed by boiling with 2*N*-sodium hydroxide for 2 hours. After cooling, the mixture of nitrotoluidines which separated was collected, washed with water, and dried thoroughly in a vacuum over concentrated sulphuric acid. The freezing point was 59·9°, corresponding to 76% or 67% of 2-nitro-*p*-toluidine; the former value was shown to be correct by obtaining the right rise in freezing point by the addition of a known amount of pure 2-nitro-*p*-toluidine. The eutectic of the nitration mixture separated at 55·1° as against 56·2° for the synthetic mixture, indicating the presence of a small quantity of one or more other compounds, possibly 2 : 3-, 2 : 5-, 2 : 6-, and 3 : 5-dinitro-*p*-toluidines, all of which might be formed in the nitration; the amount, however, must be small and cannot greatly influence the relative proportions of the 2- and 3-nitro-*p*-toluidines here given. The separation of the main constituents of the hydrolysis product was achieved by acetylating with acetic anhydride with the addition of a drop of concentrated sulphuric acid, pouring into water, and crystallising the product three times from 50% alcohol, when pure 2-nitroaceto-*p*-toluidide was obtained. The mother-liquors from the crystallisation were hydrolysed by boiling with 2*N*-sodium hydroxide, and the amine was crystallised three times from 50% alcohol, when a small quantity of pure 3-nitro-*p*-toluidine was obtained. The crude phthalyl compound on crystallisation from benzene yielded pure phthal-2-nitro-*p*-tolil (D.R.-P. 141893).

Nitration of Succin-p-*tolil.*—Succin-*p*-tolil, prepared in an analogous way to the phthalyl derivative by means of succinic anhydride and heating to 150°, was nitrated in a manner similar to the above. The yield of mixed amines was poor; the product froze at 65·2°, corresponding to 84% of 2-nitro-*p*-toluidine.

Phthal-2-nitro-p-*toluidic and Succin-2-nitro*-p-*toluidic Acids.*—When phthal-2-nitro-*p*-tolil was warmed with 2*N*-sodium hydroxide, it dissolved completely; hydrochloric acid then precipitated the toluidic acid. This was purified by dissolving in cold dilute ammonia,

filtering off any amine, reprecipitating with hydrochloric acid, and crystallising from dilute alcohol, when *phthal*-2-*nitro*-p-*toluidic acid* was obtained as a cream-coloured, crystalline powder melting and decomposing indefinitely at about 160° (Found : N, 9·4. $C_{15}H_{12}O_5N_2$ requires N, 9·3%). The succintoluidic acid underwent further hydrolysis with ease, and in its preparation in an analogous manner to the above the alkali must not be warmed above 50° and solution must be obtained as rapidly as possible by vigorous shaking. After purifying by solution in ammonia and reprecipitation, it was dried and crystallised from benzene to which a few drops of alcohol had been added. *Succin*-2-*nitro*-p-*toluidic acid* crystallises in almost colourless, feathery needles, m. p. 163° (Found : N, 11·3. $C_{11}H_{12}O_5N_2$ requires N, 11·1%).

Nitration of 3-*Nitrophthal*-p-*tolil*.—A mixture of *p*-toluidine (30 g.) and nitrophthalic anhydride (25 g.) was heated for an hour at 130° with stirring. After cooling, the mass was dissolved in acetone, reprecipitated by the cautious addition of water, and the product crystallised from alcohol, when 3-*nitrophthal*-p-*tolil* was obtained as a yellow powder, m. p. 149° (Found : N, 9·8. $C_{15}H_{10}O_4N_2$ requires N, 9·9%). This was nitrated and hydrolysed as above, and the amines were extracted from the alkaline solution with ether. After drying in a vacuum, they froze at 64·7° (a repetition of the whole of the operations gave 64·5°), corresponding to 83·5% of 2-nitro-*p*-toluidine. The eutectic froze at 54·8°. The yield of amine from the nitrated product was small owing apparently to partial decomposition by the alkali, but other agents such as concentrated hydrochloric acid or 50% sulphuric acid did not bring about hydrolysis.

Nitration of Tetrachlorophthal-p-*tolil*.—Tetrachlorophthal-*p*-tolil prepared in a similar way to the nitrophthalyl compound consists of a pale yellow, crystalline powder, m. p. 145° (Found : Cl, 37·4. $C_{15}H_7O_2NCl_4$ requires Cl, 37·8%). Nitration and hydrolysis were carried out as with the nitrophthalyl compound, the yield of amines being small. The freezing point of the product was 65·1°, corresponding to 84·5% of 2-nitro-*p*-toluidine.

Nitration of Succinanil and Phthalanil.—These compounds were nitrated under identical conditions with the above. From the hydrolysed product pure *p*-nitroaniline was obtained by one crystallisation; the mother-liquor from this crystallisation was investigated, but no *m*-nitroaniline could be obtained by fractional crystallisation of the amine or of its acetyl derivative.

CCCXI.—*Substitution in Vicinal Trisubstituted Benzene Derivatives. Part III.*

By Leon Rubenstein.

The mixture of 5- and 6-nitro-3-methoxy-2-ethoxybenzaldehydes produced by nitrating 3-methoxy-2-ethoxybenzaldehyde (Davies and Rubenstein, J., 1923, **123**, 2839) has now been separated into its constituents by the method employed by Perkin, Robinson, and Stoyle to separate the isomerides formed in the nitration of *o*-veratraldehyde (J., 1924, **125**, 2355); it contains 60% of the 5-nitro- and 40% of the 6-nitro-compound.

The same method was applied in an attempt to separate the mixture of 5- and 6-nitro-2 : 3-diethoxybenzaldehydes obtained in the nitration of 2 : 3-diethoxybenzaldehyde (Davies and Rubenstein, *loc. cit.*); these were condensed with *p*-toluidine and with *m*-nitroaniline, but in neither case could a complete separation of the Schiff bases be effected by fractional crystallisation.

Evidence was obtained, however, that both in the nitration of 3-methoxy-2-ethoxybenzaldehyde and of 2 : 3-diethoxybenzaldehyde the 4-nitro-aldehyde is formed in small quantity.

Experimental.

Nitration of 3-Methoxy-2-ethoxybenzaldehyde and Separation of the Products.—The following modified method of nitration (compare *loc. cit.*) renders the subsequent separation easier: 3-Methoxy-2-ethoxybenzaldehyde (12 g.) cooled to 0° is added drop by drop with vigorous stirring to nitric acid (30 c.c.; *d* 1·42), the temperature being maintained at 0°. The crystals of 5-nitro-3-methoxy-2-ethoxybenzaldehyde (7·4 g.) that separate after several hours are removed. The filtrate, on dilution with water, deposits a yellowish-white mixture of 5- and 6-nitro-3-methoxy-2-ethoxybenzaldehydes, which is collected and dried. This mixture (7·4 g.) is heated with *p*-toluidine (3·6 g.) on the steam-bath during 30 minutes, and alcohol is added until a boiling solution is obtained. 5-Nitro-3-methoxy-2-ethoxybenzylidene-*p*-toluidine separates on cooling, and the 6-nitro-isomeride from the filtrate after concentration. These substances can be almost completely separated by careful fractional crystallisation from alcohol.

5-*Nitro*-3-*methoxy*-2-*ethoxybenzylidene*-p-*toluidine* crystallises in pale yellow, slender needles, m. p. 148° (Found: N, 9·1. $C_{17}H_{18}O_4N_2$ requires N, 8·9%). It is readily hydrolysed by hot dilute hydrochloric acid, giving 5-nitro-3-methoxy-2-ethoxybenzaldehyde, m. p. 137°. 6-*Nitro*-3-*methoxy*-2-*ethoxybenzylidene*-p-*toluidine* crystallises in golden prisms, m. p. 88° (Found: N, 9·0%).

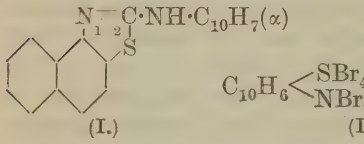
6-*Nitro*-3-*methoxy*-2-*ethoxybenzaldehyde*, readily obtained by hydrolysing the pure *p*-toluidine derivative with hot dilute hydrochloric acid, crystallises from aqueous alcohol in colourless, slender prisms, m. p. 57° (Found : N, 6·4. $C_{10}H_{11}O_6N$ requires N, 6·2%); the p-*nitrophenylhydrazone* consists of stout, brown needles, m. p. 188—189°. Treatment with acetone and alkali gives an indigotin derivative.

6-*Nitro*-3-*methoxy*-2-*ethoxybenzoic Acid.*—A mixture of the aldehyde (1 g.), water (10 c.c.), and potassium bicarbonate (0·6 g.) is boiled during the addition of hot 10% potassium permanganate solution (10 c.c.). The filtered, cooled solution is separated from a little unchanged aldehyde and acidified with hydrochloric acid. The 6-*nitro*-3-*methoxy*-2-*ethoxybenzoic acid* thus precipitated melts at 119—120° after crystallisation from hot water, in which it is fairly soluble (yield 50%) (Equiv., 240. $C_{10}H_{11}O_6N$ requires equiv., 241).

Nitration of 2 : 3-*Diethoxybenzaldehyde*.—This was carried out similarly to the nitration of 3-methoxy-2-ethoxybenzaldehyde. The material obtained (5·7 g.) was treated with *p*-toluidine (2·5 g.), and the product with alcohol, as described above ; 5-*nitro*-2 : 3-*diethoxybenzylidene*-p-*toluidine* (2·4 g.) crystallised in long, slender, cream needles, m. p. 105—106° (Found : N, 8·6. $C_{18}H_{20}O_4N_2$ requires N, 8·5%); further fractionation yielded a small quantity of a substance, m. p. 100° (Found : N, 8·7%).

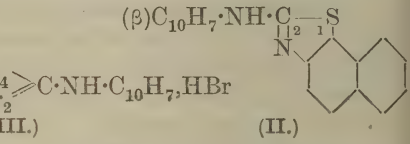
5-*Nitro*-2 : 3-*diethoxybenzaldehyde*, which is readily obtained by hydrolysing the pure *p*-toluidine derivative, m. p. 105—106°, with hot dilute hydrochloric acid and recrystallising the product from aqueous alcohol, consists of white needles, m. p. 71°. It does not yield an indigotin derivative with acetone and alkali and gives no depression of m. p. when mixed with a sample of 5-nitro-2 : 3-diethoxybenzaldehyde obtained by nitrating 2-hydroxy-3-ethoxybenzaldehyde and methylating the product.

6-*Nitro*-2 : 3-*diethoxybenzaldehyde*, similarly obtained from the compound, m. p. 100°, crystallises from dilute alcohol in almost colourless needles, m. p. 75—76° (Found : N, 6·0. $C_{11}H_{13}O_5N$ requires N, 5·8%). It turns green on exposure to the air, as do its solutions in all solvents. With acetone and alkali an indigotin derivative is obtained. The p-*nitrophenylhydrazone* consists of bright yellow, stout needles, m. p. 268—270°.



The author is indebted to the Research Fund Committee of the Chemical Society which has defrayed some of the expenses of this investigation.

THE DYSON PERRINS LABORATORY,
OXFORD. [*Received, August 14th*, 1925.]



CCCXII.—*Aminobenzthiazoles. Part II. Naphthylaminonaphthathiazole Derivatives.*

By Robert Fergus Hunter.

The curious observations on the conversion of symmetrical diarylthiocarbamides into arylaminobenzthiazole bromides recorded in Part I (this vol., p. 2023) made it of interest to extend the investigation to the halogen derivatives of the naphthalene homologues of 1-anilinobenzthiazole (I and II), and the bromination of the *s*-dinaphthylthiocarbamides in chloroform was therefore studied.

(I.) (III.)

(II.)

Under conditions analogous to those employed in the previous cases (*loc. cit.*), *s*-di-α-naphthylthiocarbamide readily passed into the *tetrabromo*-addition compound of 2-α-naphthylamino-β-naphthathiazole (I), a substance having properties analogous to those of the tetrabromides described in Part I. On exposure to air it rapidly lost bromine, yielding a yellowish-orange *tribromide*; this, however, was not so stable as the tribromides of the benzenoid series, since it gradually lost bromine on exposure to the atmosphere. On treatment with sulphurous acid, the tetrabromide was rapidly reduced, the added bromine being eliminated as hydrogen bromide, and the free *base* (I) formed. The tetrabromide was converted by boiling hydroxylic solvents and alkalis into a *dibromo*-substitution derivative of the usual type (*loc. cit.*). The tetrabromide differs from those of the benzenoid series in that it is capable of uniting with hydrogen bromide and more bromine, yielding a *heptabromide*, which no doubt has the constitution (III), analogous to that of the *m*-toluthiazole heptabromide (*loc. cit.*).

On one occasion, when bromine was added to a warm suspension of di-α-naphthylthiocarbamide in chloroform, a bright red, unstable tribromo-addition compound was isolated, which was probably the hydrobromide of a dibromo-addition compound.

Since the bromination of *s*-di-α-naphthylthiocarbamide yielded as many as three bromo-addition compounds and was complicated by the tendency of the nascent thiazole to add on hydrogen bromide as well as bromine, the bromination of the naphthathiazole base itself was examined; as might have been anticipated, in

presence of excess of halogen it yielded a well-defined *hexabromide* the most probable constitution of which is

$$C_{10}H_6<\begin{matrix}SBr_4\\NBr_2\end{matrix}>C\cdot NHC_{10}H_7.$$

This compound has the usual properties of losing bromine on exposure to air, being reduced by sulphurous acid, and passing into the substitution product in presence of hydroxylic solvents and alkalis.

On bromination under similar conditions to those used in the case of the α-compound, *s*-di-β-naphthylthiocarbamide readily yielded a dark purplish-red *hexabromide* of (II), which doubtless is similar to the α-hexabromide in constitution. The β-hexabromide was isolated in two forms having identical chemical properties but different melting points. It differs from the higher bromo-addition compounds of the arylaminobenzthiazole series in being remarkably stable to air, in this respect resembling dehydrothio-toluidine dibromide (this vol., p. 1318); unlike this, however, it is decomposed by dilute alkalis and hydroxylic solvents. On treatment with sulphurous acid, the six bromine atoms are eliminated in the usual way with the liberation of (II). The direct elimination of bromine by treatment with hydroxylic solvents and alkalis had previously been observed in the case of 1 : 1-bisbenzthiazole tetrabromide (this vol., p. 1319), but this is a highly unstable substance which completely loses the whole of its added bromine on exposure to the air for some hours.

A *tribromo*-addition compound of 2-β-naphthylamino-α-naphthathiazole was also isolated, which resembled the hexabromide in its remarkable stability to air; on treatment with hydroxylic solvents and alkalis, however, the added bromine was eliminated (initially) as sodium hypobromite, with liberation of the thiazole base (II). The tribromide was reduced in the usual way by sulphurous acid, being no doubt the hydrobromide of the dibromo-addition compound of the thiazole.

The bromination of 2-β-naphthylamino-α-naphthathiazole in chloroform yielded, as might have been anticipated, the hexabromo-addition compound.

The bromine addition compounds of β-naphthylamino-α-naphthathiazole therefore differ from those of α-naphthylamino-β-naphthathiazole and of the arylaminobenzthiazoles (1) in their stability in air, which is of the order of that of dehydrothiotoluidine dibromide, (2) in losing their added halogen as hypobromite, with regeneration of the α-thiazole base, on treatment with hydroxylic solvents and alkalis, and (3) in being incapable of conversion into a stable, yellowish-orange tribromide by atmospheric oxidation.

Experimental.

s-Di-α-naphthylthiocarbamide was prepared from α-naphthylamine by the usual method (Hofmann, *Annalen*, 1846, **57**, 256). The crude product, after treatment with dilute acid, water, etc., was digested with boiling acetic acid and with boiling alcohol; the microcrystalline powder thus obtained had m. p. 196°; a further quantity slowly separated in prisms from the acetic acid filtrate.

2-α-*Naphthylamino*-β-*naphthathiazole Tetrabromide.* — Di-α-naphthylthiocarbamide (2 g.) was suspended in 20 c.c. of chloroform, and 2 c.c. of bromine were slowly added with continuous shaking; heat and hydrogen bromide were evolved towards the end of the bromination. The solution was refluxed for 2 minutes on a steam-bath and cooled in a freezing mixture; the *tetrabromide* then separated in minute, brilliant vermilion crystals, which were dried in a vacuum over potassium hydroxide. The tetrabromide lightened in colour at 190°, became yellow at 200°, and colourless at 260° (Found: Br, 50·2. $C_{21}H_{14}N_2Br_4S$ requires Br, 49·6%).

On exposure to air the tetrabromide lost bromine, yielding a yellowish-orange, crystalline mass of the *tribromide*, which after boiling with chloroform and drying in a vacuum was obtained in small, yellow prisms; these became pale at 200° and colourless at 280° [Found: Br, 42·6. $(C_{21}H_{14}N_2Br_3S)_2$ requires Br, 42·4%]. On treatment with sulphurous acid, the tribromide yielded the thiazole base in the usual way.

2-α-*Naphthylamino*-β-*naphthathiazole Heptabromide.*—By using 1 g. of *s*-di-α-naphthylthiocarbamide, 6 c.c. of chloroform, and 1 c.c. of bromine diluted with a little chloroform, and proceeding as in the previous bromination, bright red granules of a *heptabromide* (III) were obtained which lost bromine and became yellow at 160° (Found: Br, 62·6. $C_{21}H_{15}N_2Br_7S$ requires Br, 62·9%). This displayed the usual behaviour of the bromo-addition compounds on exposure to air, on treatment with sulphurous acid and on boiling with alcohol and subsequent treatment with sodium hydroxide.

Dibromo-2-α-*naphthylamino*-β-*naphthathiazole.* — Either of the above bromides (1 g.) was digested with 20 c.c. of boiling alcohol for a short time, the crystalline hydrobromide so obtained was treated with warm 2*N*-sodium hydroxide for a few minutes, the product washed, dried, and crystallised from benzene–ethyl acetate (1 : 1); from this the *dibromo*-substitution product separated in small prisms which sintered at 180°, became yellow at 240°, and melted at 270—272° (Found: Br, 35·9. $C_{21}H_{12}N_2Br_2S$ requires Br, 35·6%).

Red Tribromide of 2-α-*Naphthylamino*-β-*naphthathiazole*.—A suspension of 1 g. of the dinaphthylthiocarbamide in 6 c.c. of warm chloroform was treated with 1 c.c. of bromine diluted with a little chloroform; the yellow, crystalline precipitate that formed at the half stage turned red when the addition of the bromine was completed. The mixture was boiled for a minute, cooled, and the vermilion, microcrystalline precipitate dried in a vacuum over potassium hydroxide. The *tribromide* became orange at 180°, yellow at 190°, pale ochre-yellow at 215°, and showed signs of softening at 260°, but was still unmelted above 280° (Found: Br, 41·8. $C_{21}H_{14}N_2Br_2S,HBr$ requires Br, 42·4%). This tribromide lost bromine on exposure to air and was reduced by sulphurous acid in the usual way.

2-α-*Naphthylamino*-β-*naphthathiazole*.—Any one of the bromo-addition products obtained from the dinaphthylthiocarbamide by bromination in chloroform was suspended in sulphurous acid, and sulphur dioxide passed through the mixture until all solid matter was colourless. The reduction product was collected, digested with 2*N*-sodium hydroxide on a steam-bath for a few minutes, and the product washed, dried, and crystallised from ethyl acetate–toluene (1 : 1). The *naphthathiazole*, which separated in hard prisms, m. p. 217°, was recrystallised from benzene–ethyl acetate and obtained in colourless prisms, m. p. 221° (Found: S, 9·6. $C_{21}H_{14}N_2S$ requires S, 9·8%).

Bromination. From a solution of the naphthathiazole (0·3 g.) and bromine (0·5 c.c.) in chloroform, bright red prisms of the *hexabromide* separated slowly; they were dried in the usual way (Found: Br, 60·3. $C_{21}H_{14}N_2Br_6S$ requires Br, 59·6%). The hexabromide showed colour change without melting at 238° and behaved as usual on exposure to air and on treatment with sulphurous acid and with alcohol and sodium hydroxide.

s-Di-β-naphthylthiocarbamide was prepared from β-naphthylamine in the usual way. In the first experiments the thiocarbamide was recrystallised from glacial acetic acid, from which it separated in small prisms, m. p. 194°; in later experiments the product was treated as in the previous case and obtained as a micro-crystalline, white powder, m. p. 198°.

2-β-*Naphthylamino*-α-*naphthathiazole Hexabromide*.—(A) *s*-Di-β-naphthylthiocarbamide (m. p. 194°) (1 g.) containing a trace of acetic acid was suspended in 6 c.c. of chloroform and treated with 1 c.c. of bromine diluted with a small quantity of the same solvent as in the previous cases; the clear dark brown solution obtained became hot and evolved hydrogen bromide. The solution was refluxed for 2 minutes and cooled in a freezing mixture; the *hexa-*

bromide which then separated in fine, dark red crystals was dried in a vacuum over potassium hydroxide. It became light yellow at 190°, soft at 210°, and decomposed without melting at 216° (Found : Br, 60·3. $C_{21}H_{14}N_2Br_6S$ requires Br, 59·6%).

(B) The above bromination was repeated and the solution shaken to induce sudden crystallisation. The product consisted of small, purplish-red plates, which were dried in a vacuum as before. This hexabromide showed lightening in colour at 140°, further colour change at 194°, and melted to a clear red liquid at 196° (Found : Br, 59·8%).

Both forms of the hexabromide were reduced by sulphurous acid in the usual way, and exhibited the remarkable stability in air already referred to.

2-β-*Naphthylamino*-α-*naphthathiazole*.—The hexabromide was suspended in sulphurous acid and treated with a current of sulphur dioxide as in the previous case. The product was warmed with 2*N*-sodium hydroxide, washed, dried, and crystallised from toluene–ethyl acetate (1 : 1), from which it separated in large, silky plates, m. p. 221°. After recrystallisation from ethyl acetate–benzene, it was obtained in plates, m. p. 223° (Found : S, 8·9. $C_{21}H_{14}N_2S$ requires S, 9·8%).

Red Tribromide of 2-β-*Naphthylamino*-α-*naphthathiazole*.—One g. of *s*-di-β-naphthylthiocarbamide (microcrystalline powder, m. p. 198°) was suspended in 6 c.c. of chloroform and brominated in the usual way. The solution deposited the *tribromide* as a vermilion, microcrystalline powder which, after drying in a vacuum over potassium hydroxide, showed a colour change at about 170° and melted at 245° (Found : Br, 42·8. $C_{21}H_{14}N_2Br_2S,HBr$ requires Br, 42·4%).

Bromination of 2-β-*Naphthylamino*-α-*naphthathiazole*. — The naphthathiazole (0·5 g.) was treated with excess of bromine (1 c.c.) as in the previous case : on scratching, the hexabromide separated in small, dark purple-red prisms, m. p. 198°, after drying (Found : Br, 60·2. Calc., Br, 59·6%).

In conclusion, the author desires to express his gratitude to Prof. J. F. Thorpe, F.R.S., for the kind interest he has taken in the progress of these experiments.

CCCXIII.—*An Investigation of the Action of Halogens on 2 : 4-Dimethylbenzoyl Chloride.*

By William Henry Perkin, jun., and John Frederic Smerdon Stone.

In a communication published a short time since (J., 1922, **121**, 2203), Davies and Perkin showed that ω-derivatives of the toluic acids such as

$$C_6H_4<\begin{matrix}CH_2X\\CO_2H\end{matrix} \qquad C_6H_4<\begin{matrix}CHX_2\\CO_2H\end{matrix} \qquad C_6H_4<\begin{matrix}CX_3\\CO_2H\end{matrix}$$

may be conveniently prepared from the corresponding toluoyl chlorides, $CH_3{\cdot}C_6H_4{\cdot}COCl$, or bromides by treatment with chlorine or bromine at temperatures varying from 160—220°, according to the degree of substitution desired, and subsequent decomposition of the substituted acid chlorides or bromides by formic acid, methyl alcohol, amines, etc. This simple process has made it possible to prepare conveniently many mono- and di-substitution derivatives of benzoic acid, such, for example, as the aldehydo-acids $CHO{\cdot}C_6H_4{\cdot}CO_2H$, which had previously been difficult of access.
